

McGRAW-HILL
SPECIALTY BOARD REVIEW

Graber and Wilbur's Family Medicine

Examination and Board Review

5TH EDITION

- Covers every topic on the Family Medicine Boards
- Great for USMLE® Step 3 review
- Features hundreds of clinical cases covering all specialty areas
- Includes Quick Quizzes, Clinical Pearls, and Learning Objectives

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

*To the people who make Family Medicine happen. **Jogjakarta:** Dr. Mora Claramita, Dr. Adi Heru Husodo, Dr. Wahyudi Istiono, and Dr. Fitriana Murriya. **Moscow:** Professor Dr. Gregorii Efimovich Roitberg, Dr. Olga Sharkun, Dr. Irina Slastnikova, Dr. Janna Dorosh, and Professor Timothy O'Connor. **Haiphong:** Dr. Hùng Nguyễn Văn, Dr. Linh Nguyễn, and Dr. Nguyễn Thuý Hiếu.*

—MAG

To my parents, Bill and Bonnie Ray, for always loving, supporting, and encouraging me to follow my dreams to become a family physician. To all of my Family Medicine and education mentors including: Drs. George Bergus, Rick Dobyns, Jason Wilbur, Bob Tallitsch, Jeff Pettit, and Marcy Rosenbaum. Your guidance and support along this journey have shaped me into the family physician educator I have become!

—BER

To my many mentors in Family Medicine, including Drs. John Ely, Mark Graber, Paul James, Gerald Jogerst, and Barcey Levy; and to Dr. Kate Thoma and all the Family Medicine program directors and faculty members who work tirelessly (and mostly thanklessly) to develop the next generation of excellent family doctors. Keep teaching; keep leading!

—JKW

Preface

Welcome to the fifth edition of *Graber & Wilbur's Family Medicine Examination & Board Review* book. We hope that you are as excited to be here as we are. The whole book has been meticulously updated to not only serve you well as a study guide, but also to provide you with cutting edge, up-to-date, information pertinent to your practice. For those of you who love your e-readers and tablets, there is a portable, electronic version of the book. You can also now find us on "AccessMedicine."

What is new? We have added a succinct guide to the recommended health maintenances for children and adults, perfect for a quick review. We estimate that 30% of the material has been changed since our last edition: think of hepatitis C diagnosis and treatment, new cholesterol and blood pressure guidelines, new heart failure guidelines (and drugs), the ever-changing anticoagulation guidelines, etc.

What has not changed? Our essential style remains the same. The book is divided into 29 chapters based on body system and elements of patient care, followed by the "Final Examination" (Chapter 30). The thousands of questions in the book are woven into cases, which we hope you will find interesting, practical, and relevant. To test your acquisition of knowledge, each case ends with the learning objectives. To break the monotony of slogging through a study guide, you will find "Quick Quizzes" and "Helpful Tips" peppered throughout each chapter.

A dozen years ago when we wrote the first edition, we made the decision to use the second-person voice in order to engage the reader better and to give the book a conversational appeal. We have tried to keep the book from being boring. Yes, we are aware that this is a study aid. But why must studying be an exercise in tedium and endurance? It should be enjoyable, applicable to real life and provide a surprise every now and again. You will find (sometimes feeble) attempts at humor throughout the book. We have noticed that an occasional reader does not appreciate our sense of humor. As Abraham Lincoln famously never said, "You can please some of the people all of the time, and then again, some people just won't think you're funny."

We have been impressed with the level of engagement of our readers. Over the years, we have received scores of e-mails from readers who have thanked us, corrected us, and sometimes chided us. No matter the intent of the message, the tone is almost universally positive—readers are invested in the book and want to offer helpful suggestions. Likewise, the comments posted online (not usually the place one goes for affirmation) have been mostly approving, constructive, and enthusiastic.

The first edition was published amid a less-than-friendly environment, with declining interest in print media and several well-known board review books already on the market. Because our book carried a different tone, readers slowly gravitated to it, and its market share grew by word-of-mouth. Engaged and supportive readers play a huge role!

In preparation for work on the fifth edition, we saved all of your e-mails and scoured the Internet for reader comments and reviews. We read and considered all that we could find—which amounted to several hundred readers' ideas. So, you, the reader, have helped shape this book. Keep those e-mails coming!

With all of the board review books out there, why should you choose our text? **There are two crucial differences between this book and other board review books on the market.** First, we have written this book not only to help you pass the boards but also to broaden your knowledge of family medicine. The majority of questions contain a detailed explanation not only of why an answer is right but also why the other answers are wrong. In the rapidly changing world of medical knowledge, we have endeavored to provide you with the most relevant and up-to-date evidence. When the current evidence is controversial and we are not certain what the American Board of Family Medicine (ABFM) will do with it, we acknowledge the uncertainty and try to help you navigate the current evidence.

We have tried to make this book as broad and as comprehensive as possible. In addition to its use as a board review book for family medicine, it can be employed as a general review for primary care physicians, physician assistants, and nurse practitioners. Students and residents studying for Step 3 of the licensing examination should find the book helpful as well. However, no board review book can possibly cover the entire scope of family medicine. Use these questions as a guide: what areas are your strengths and what do you need to study further? Each answer of the "Final Examination" is referenced in the book so you can go back and review any topic that you might have missed.

In this book, the use of eponymous medical terms such as Crohn disease and Wilson disease reflects the current American Medical Association recommendations for these and similar terms where the possessive form is dropped. In addition, there is a general trend toward using fewer eponyms, such as Wegener, which has been dropped completely. We have made note of both new and old terms when we have deemed the old term more recognizable.

We enjoyed writing this book and we hope that you enjoy using it. If you have suggestions or complaints (okay, maybe all of our jokes aren't politically correct or even funny), do not hesitate to write us at mark-graber@uiowa.edu, jason-wilbur@uiowa.edu, or brigit-ray@uiowa.edu. We take your comments seriously as we endeavor to make studying for the board examination more effective and more fun.

We acknowledge and thank all our chapter authors who have brought their expertise to bear on this project. We also want to thank the good people at McGraw-Hill who have edited the book to keep errors to a minimum and created a handsome and readable layout.

Mark would like to thank you, the reader, for buying this book. Thanks also to his family: Hetty, Rachel, and Abe (as always). But not to the dogs, Nietzsche and "Vash the Stampede." They need to learn to stay either in or out of the house. No more of this back and forth. Music that has kept Mark awake: "Hellborg, Lane, and Sipe" (check out "Time is the Enemy" and "Personae" [yes, it is spelled with an "e"]), Stephane Wrembel (Barbes-Brooklyn is Mark's favorite but you can't go wrong), and the Kinks. Finally, thanks to his bicycle for keeping Mark sane ... although some would argue this point.

Jason thanks his loving and supportive family. After some initial threats, Deb has granted her patience and understanding

to the project, and Jason simply owes her dinner every night ... for a year. Jason thanks his boys, Ken and Ted, who offer a great distraction from work (like learning to drive—yikes!) and find it entertaining that their dad is some form of an author. Finally, as with every edition, Jason must acknowledge that the book would never get finished without large amounts of coffee; so, he thanks everyone involved in the worldwide production of coffee, from the pickers on the Central American fincas to the local baristas. He's really hoping that we all do something about climate change to at least save the coffee-growing regions of the world.

Brigit thanks her husband, Austin, for being so patient when she has been cranky and sleep deprived. She is so proud of her husband's hard work and dedication in the completion of his research, residency, and fellowship. He has been an inspiration and her greatest sidekick, friend, and love, and she can't wait to start this new chapter in their life together; by FINALLY living in the same location! She would like to acknowledge the "Academy" (no really, she's not joking) as she has spent many hours on her couch with the movies and the AAFP editing this book and completing her CME questions. Lastly, she would like to thank the open roads, blue skies, and sunshine for always providing her with much needed "run therapy" and happiness.

A Few Words on Studying and Taking the Board Examination

Throughout the book, you will find that we give advice on what we think is likely to be on the examination. That's what you're paying for, right? However, the fourth edition marked the first time that we offered advice on studying for and taking the examination. We thought it worthwhile to keep this section for the fifth edition. **We recommend you read this section prior to diving into the rest of the book.**

While we acknowledge that some people are simply better test takers than others, there is good evidence to show that anyone can improve his or her scores. In fact, examination scores are directly proportional to time spent studying for the examination (although this association grows weaker for those who have high scores already). The point is, you don't have to be a genius who got a 36 on the ACT in order to rock the ABFM Certification/Recertification Examination. But you may need to put in the work.

Your first step in studying for the examination—after purchasing this book, of course—should be to develop a study plan. Plotting out time and dedicating that time to uninterrupted study is important. How much time do you have before the examination? How many hours per week can you devote to studying? When are you most productive in your studying—morning or night? What are the chances of a worldwide failure of coffee crops? Will a new *Star Wars* movie open before the examination? Thinking through these questions, get a calendar, mark the examination date, and plot out days and times that you will devote to studying. If you have taken the examination before and it didn't turn out so well, you may need to change your daily work schedule for 2 to 3 months before the examination to accommodate studying 10 to 15 hours per week. We endorse neither “cramming” for the examination nor “adding on” studying to an already full schedule. To get the most out of studying, you need to approach it like a daily devotion.

In order to maximize your return on your studying and to focus on deficiencies, try taking a pre-test. The best pre-test is the ABFM In-Training Examination (ITE) — keep reading for more on this. You can use your results on the pre-test to see what areas are your weakest. Studying weak areas is less fun but will net higher yield results than studying areas of relative strength. If your practice is narrow in scope (e.g., a hospitalist),

you probably already have a sense of areas of strength and weakness. Make sure you address your weak areas with relatively more time on them.

Next, know what is on the examination. The percentage of examination content devoted to various systems is posted on the ABFM website, and we recommend you review it. The top systems tested are usually cardiovascular, respiratory, and musculoskeletal systems. If you are weak in any of these areas, be certain to focus your studying on them.

Now, what material should you use when studying? Some of our readers have been overly kind, suggesting in their reviews that this book is the only study tool needed for the board examination. While we would like to believe it, we cannot endorse this point of view.

To get a flavor for the questions on the examination, the best strategy is to go to the source. The ABFM posts its ITE for the last 3 years on its website (www.theabfm.org). A login is required, which board-certified family physicians should all have. **The ITEs are perhaps the best source for assessing your knowledge—we strongly recommend you use them.** Although we do not recommend relying on the ITEs as your only study aid (obviously; we're trying to sell books here!), you can use these as a way to measure your progress as you study. The critiques are available as well, so you can learn what the ABFM thinks you should know. The ABFM also has extensive information on what you should expect when you sit for the certifying/recertifying examination, including a tutorial that simulates the examination. If you are an anxious test-taker, be certain to check out the tutorial. While the ABFM has several useful tools, be aware that the Self-Assessment Modules are **not** representative of the types of questions you will find on the certifying/recertifying examination; however, the more recent Continuous Knowledge Self-Assessment activity, where the diplomate answers 25 questions per quarter, is a closer representation.

Another great source for questions is the American Academy of Family Physicians (AAFP) website. If you are a member of AAFP, you can access questions for free. They are categorized by body system and can be done in chunks of ten at a time worth 0.25 CME credits. This question bank offers another opportunity to test your knowledge and determine where you need to focus your studying.

Also, the AAFP markets a comprehensive board review self-study course, which will set you back over \$1,000 if you are a member and more if you are not. Indeed, it covers everything you need to know for the examination. But so does this book! So, the choice is yours, but we doubt that you will need both our book and the AAFP board examination self-study package.

What about texts and primary sources? Well, while we would admire your perseverance in slogging through whole texts preparing for the examination, we do not recommend attempting to read cover-to-cover texts like Robert Rakel's *Textbook of Family Medicine* or reference material like *UpToDate*. Don't get us wrong. We like these sources and recommend them to you as references as you are studying, but you should not rely on them as your sole study material. Likewise, using primary sources, like medical journals, is impractical as a study foundation but useful to expand your knowledge when you don't understand something.

As far as board review courses: to each his or her own. If you are considering attending a course, the AAFP offers comprehensive courses multiple times per year in locations all across the country. For-profit entities provide additional options. If you learn best in a live lecture setting, these courses may be a good option for you, but you need not attend a course to get all that information (c'mon—you've got this book!).

There are some important basic things you need to know about the examination. As of the writing of this book, the examination is composed of 4 sections, each consisting of 80 multiple choice questions and 100 minutes in length. Sections 1, 3 and 4 have questions from a wide variety of family medicine topics. Section 2 consists of 40 questions from a chosen module and 40 questions pertaining to the general breadth of family medicine. It is best to choose modules with which you are more familiar. For example, if you practice primarily in an emergency department, you may want to choose Emergent/Urgent Care or Hospital Medicine rather than Maternity Care (unless you're looking for the additional challenge). We highly recommend to check out the ABFM website (<https://www.theabfm.org/continue-certification/cognitive-expertise/one-day-fmc-exam>) for exam information as this may change.

The examination consists entirely of four-item multiple-choice questions. You are not penalized for guessing. An unanswered question will always be wrong; whereas, a guessed question has a 25% chance of being right. If you have no idea, go ahead and guess. As a corollary to that rule, never exit the examination without first completing all the items. You cannot return to answer unmarked items.

Read every stem and option carefully. Although we doubt that the ABFM writes "trick questions," they do use catch words/phrases, such as "except," "most likely," "first step," and "least likely." If you are not attending to the catch phrase, you are likely to answer the question wrong.

In the past, the ABFM recommended relying on evidence in place up to 2 years before the examination rather than the most recent medical evidence. Now, the ABFM recommends examinees rely on the most up-to-date evidence available. So, when you are looking at a question and thinking, "Well, the answer last year might have been 'A' but now the evidence points to 'B'." Choose "B."

Successful test-takers do not use grand strategies to outsmart the question writers; instead they tend to employ a few simple rules when answering multiple-choice questions. These simple rules that follow amount to guidelines that cannot be blindly applied to the entire test, but are often true. No secret to many of you, perhaps, but here they are:

- Go with your first thoughtful choice unless you have a solid reason to change it (e.g., you misread the question).
- Look for catch words in the answers, such as "always" and "never." These will often be incorrect.
- Avoid answers with unfamiliar terms (e.g., obscure disease names or rarely performed procedures). These are often incorrect.
- The most detailed answer is often the correct answer.
- If two answers are similar, they are probably both wrong.
- Stick with family medicine principles (e.g., answers with "more history" or "shared decision making" are more likely to be correct).
- If you don't know, guess and move on. Do not waste time deliberating on a single question.

Finally, we part offering advice that we know busy doctors seldom follow: get plenty of rest. Seriously! Be prepared for the examination day by getting a good night's sleep. Don't stop taking care of your health prior to the examination, and that includes rest. Eat a good breakfast, bring a snack for your breaks, and plan to take yourself out for a nice lunch (but skip the martini—you've got an examination to finish). Just like a mountain climber, wear layers. Some of those test-taking centers are freezing; some are boiling. Stay positive, take a deep breath and keep moving through it. You will pass this thing! Good luck.

Emergency Medicine

1

Olivia E. Bailey, Sarah L. Miller, and Mark A. Graber

▶ CASE 1.1

You get a call from a panicked mother because her 4-year-old drank a bottle of children's Tylenol. She found the empty bottle in her child's bed after a nap, and her child had been in bed for 90 minutes. She thinks there were about 3 ounces of liquid left in the bottle. She is about 35 minutes from the hospital. She states her child weighs 15 kg.

Question 1.1.1 Your advice to her is:

- A) Induce vomiting to reduce acetaminophen absorption
- B) Have the child eat to slow absorption and proceed directly to the hospital
- C) Proceed to the hospital
- D) Breathe deeply and calm down; the amount of acetaminophen this child could have ingested is harmless

Answer 1.1.1 The correct answer is "C." Proceed to the hospital. "A" is incorrect for a couple of reasons. After 90 minutes, it is not likely that there is significant medication left in the stomach and induced vomiting can lead to aspiration (this is true of liquids and pills). "B" is incorrect because you do not want to delay definitive treatment. "D" is incorrect as this patient may have ingested up to 3 oz (90 mL) of 160 mg/5 mL solution (total dose of 2880 mg or 192 mg/kg).

HELPFUL TIP:

Acetaminophen is the most common agent involved in pediatric ED visits for over-the-counter medication exposures. Reasons for these high exposure rates include the medication's reputation as "safe," its ubiquity in medicine cabinets, errors in dosing, as well as co-administration of medications that also contain acetaminophen.

The patient arrives in your emergency department (ED). She is alert with stable vital signs. The mother states she now

believes the ingestion occurred about 50 minutes ago as her child told her she found the bottle in the bathroom when she woke up from her nap. You contemplate gastrointestinal (GI) decontamination.

Question 1.1.2 Which of the following statements is true about gastric lavage?

- A) Except in extraordinary circumstances it should only be done in the first hour after an overdose
- B) Patients who have had gastric lavage have higher incidence of pulmonary aspiration than patients who have not
- C) Patients who undergo gastric lavage have a higher incidence of esophageal perforation
- D) It can push pill fragments beyond the pylorus
- E) All of the above are true

Answer 1.1.2 The correct answer is "E." All of the options are true. Generally, the efficacy of gastric lavage is limited. Outcome data do not support the use of gastric lavage after the first hour. In a particularly severe overdose or in an overdose that is likely to delay gastric emptying (e.g., tricyclic antidepressants), you might want to consider lavage, but such circumstances are unusual. Gastric lavage increases the risk of aspiration, esophageal perforation, and can push pill fragments beyond the pylorus.

Question 1.1.3 After careful consideration, you decided not to lavage. She is now 90 minutes after the ingestion. Her physical exam is normal other than some dried sticky liquid on her face, shirt, and hands that smells like cherry flavoring. The next best step to take in this patient is to:

- A) Check blood acetaminophen levels and refer for hemodialysis if markedly elevated
- B) Administer 5 g/kg of charcoal with sorbitol
- C) Start treatment with N-acetylcysteine (NAC)
- D) Prophylactically treat this patient for seizures using phenytoin
- E) Observe and measure acetaminophen level at 4 hours after ingestion

Answer 1.1.3 The correct answer is “E.” Giving charcoal is likely helpful only *within the first hour after ingestion*, and even this remains controversial. “A” is incorrect because hemodialysis is not indicated for acetaminophen (APAP) overdose and measuring levels at 90 minutes will not allow appropriate risk stratification for this child. “C” and “D” are incorrect because seizure prophylaxis is not indicated in this patient, and although NAC could be initiated for a known dose of >150 mg/kg, this child clearly had spilled medication on her skin and clothing. In order to determine the risk of APAP-induced hepatotoxicity and treatment via the Rumack–Matthew nomogram, a 4-hour APAP level is necessary.

HELPFUL TIP:

Although frequently given, single dose activated charcoal has limited or no effect on outcomes of poisonings. It reduces absorption by about 30% if given within 1 hour of ingestion and likely has no benefit after 1 hour. It can also cause vomiting with aspiration. For this reason, it has fallen out of favor (we don’t remember the last time we used it in our ED). We are not sure what the correct answer on the test will be.

HELPFUL TIP:

Do NOT give activated charcoal to patients with an altered mental status or who are otherwise unable to protect their airway. To prevent aspiration, do not give charcoal to a patient likely to have a seizure (such as with tricyclic overdose).

Question 1.1.4 Assuming you are using charcoal, for which of these overdoses is charcoal NOT indicated?

- A) Acetaminophen
- B) Aspirin
- C) Iron
- D) Digoxin
- E) Opiates

Answer 1.1.4 The correct answer is “C.” Charcoal will not bind iron. Charcoal will also not bind Caustics/corrosives, Heavy metals, Alcohols, Rapid-onset cyanide, Chlorine (or iodine), Other insoluble tablets, Aliphatics (hydrocarbons), or Laxatives (**mnemonic: CHARCOAL**). Some of you may have answered “A.” Theoretically, charcoal could interfere with the action of *N*-acetylcysteine, the antidote for acetaminophen ingestion by absorbing it. However, this is more of a theoretical concern than an actual one. First, the drugs should be used at different times. Charcoal should be given immediately, while *N*-acetylcysteine is given only after 4-hour levels are available. Second, the doses of *N*-acetylcysteine recommended are quite high, and you can give a higher dose if you will be using it with charcoal. Finally, intravenous (IV) *N*-acetylcysteine is available and is obviously not affected by

charcoal. “B,” “D,” and “E” are all incorrect. While we do have antidotes for digoxin and opiates (Digibind, naloxone), charcoal may still be indicated to reduce absorption within the first hour.

► Objectives: Did you learn to ...

- Manage a patient with an acute ingestion?
- Describe the appropriate use of gastric lavage and charcoal administration?
- Identify situations where charcoal may not be indicated?

QUICK QUIZ: BIOTERRORISM AND THE ATTACK OF GODZILLA

Oh, no. Godzilla is attacking Tokyo. And this time it is with weapons of mass destruction. Which of the following properly describes the isolation requirements of a patient with pulmonary anthrax?

- A) No isolation necessary. The patient may be in the same room with an uninfected patient
- B) Respiratory isolation only
- C) Respiratory and contact isolation
- D) Negative pressure room (such as with tuberculosis) + contact isolation

The correct answer is “A.” Pulmonary anthrax is NOT transmitted person to person. Contact isolation is indicated in those with cutaneous anthrax and GI anthrax (where diarrhea may be infectious).

Godzilla is not done yet... Which of the following drugs should be used as prophylaxis against inhaled anthrax, should exposure to aerosolized spores be documented?

- A) A first-generation cephalosporin
- B) Trimethoprim/sulfamethoxazole
- C) Ciprofloxacin
- D) A third-generation cephalosporin

The correct answer is “C.” Fluoroquinolones are the drugs of choice when treating those exposed to anthrax. Doxycycline may also be used. Cephalosporins and TMP/SMX are not active against anthrax.

Godzilla, frustrated by his failed anthrax attack, is now spreading smallpox. Which of the following is NOT true about smallpox?

- A) Isolation is best done at home if possible
- B) The patient is infectious until he or she becomes afebrile
- C) All lesions are generally in the same stage of evolution, unlike what is seen in varicella
- D) Smallpox immunization causes an encephalitis in 1:300,000 of which 25% of cases are fatal

The correct answer is “B.” The patient is infectious until all lesions crust over. Infectivity has nothing to do with the presence or absence of fever. “A” is true. Isolation is best done at

home since this will limit spread (as those in the household have likely already been exposed). “C” is also true; all lesions are in a similar state of evolution. Finally, “D” is true and is the reason we do not currently immunize against smallpox—well, that and the fact we eradicated it in the wild (Way to go, humans!).

▶ CASE 1.2

A 22-year-old female presents to the ED with an overdose. She has a history of depression, and there were empty bottles found at her bedside. The bottles had contained clonazepam and nortriptyline. The patient is unconscious with diminished breathing and is unable to protect her airway.

Question 1.2.1 The BEST next step is to:

- A) Intubate the patient
- B) Begin gastric lavage and administer charcoal
- C) Administer flumazenil, a benzodiazepine antagonist, to awaken her and improve her respirations
- D) Administer bicarbonate
- E) Administer lipid emulsion

Answer 1.2.1 The correct answer is “A.” This patient should be intubated. Remember in any emergency situation that the ABCs (airway, breathing, and circulation) are the priority. “B” is incorrect because, as noted earlier, patients who undergo gastric lavage have a higher incidence of pulmonary aspiration—an even greater concern in the obtunded patient. In fact, airway protection is MANDATORY before undertaking lavage. “C” is incorrect. Flumazenil *will* reverse the benzodiazepine. However, we know from experience that seizures in patients who have had flumazenil are particularly difficult to control. This would be particularly problematic in a patient with a mixed overdose, such as with a tricyclic, where seizures are common. Thus, it is recommended that flumazenil be used only as a reversal agent after procedural sedation in patients who are not on chronic benzodiazepines. “E” is incorrect. Lipid emulsion refers to the liquid fatty acids given as part of total parenteral nutrition and theoretically can be used to bind fat-soluble drugs in the blood. Case series support consideration of lipid emulsion for calcium channel blocker, beta-blocker, and tricyclic antidepressant overdoses, as well as other fat-soluble drugs but only in cases of refractory cardiac arrest or cardiovascular collapse—and certainly not before the airway has been secured. Keep reading for a discussion of answer “D.”

You notice that the patient begins to have an abnormal tracing on the cardiac monitor, so you order an ECG.

Question 1.2.2 Which of the following findings would you expect to find in a tricyclic overdose?

- A) Normal QRS complex
- B) Second- and third-degree heart block
- C) Widened QRS complex
- D) Sinus tachycardia
- E) Any of the above

Answer 1.2.2 The correct answer is “E.” All of the above findings can be seen with a tricyclic overdose. In fact, the most common presenting rhythm is a narrow-complex sinus tachycardia. As toxicity progresses, you can see a prolonged PR interval, a widened QRS complex, and a prolonged QT interval. A QRS >100 ms is predictive of seizures and QRS >160 ms is highly predictive of ventricular arrhythmia in patients with a tricyclic antidepressant overdose. Heart blocks (second- and third-degree) herald a poor outcome and may be seen late in the course. Asystole is not a primary rhythm in tricyclic overdose and tends to reflect the end stage of another arrhythmia.

YIKES!! The patient becomes unresponsive and you look at the monitor. You obtain an ECG which shows the following (Fig. 1-1).

Question 1.2.3 What is the patient’s rhythm?

- A) Monomorphic ventricular tachycardia
- B) Sinus tachycardia with a bundle branch block
- C) Paroxysmal supraventricular tachycardia
- D) Torsades de pointes
- E) Third degree heart block

Answer 1.2.3 The correct answer is “D.” This is torsades de pointes which is a subtype of polymorphic ventricular tachycardia. In French, it literally means “twisting of the points,” but in every language it means “bad news.” Torsades de pointes can be recognized by the varying amplitude of the complex in a somewhat regular pattern. “A” is incorrect because the complexes are not monomorphic. “B” is incorrect for two reasons. First, there are no P waves visible. Second, sinus tachycardia should not have varied amplitude. “C” is incorrect because, again, there are no P waves and the complexes are polymorphic. “E” is incorrect because there are no P waves.

Question 1.2.4 This patient needs treatment post haste. After taking care of the ABCs, what is the ONE BEST drug for the treatment of this arrhythmia in a patient with a tricyclic overdose?

- A) Esmolol
- B) Lidocaine
- C) Sodium bicarbonate
- D) Procainamide
- E) Amiodarone

Answer 1.2.4 The correct answer is “C.” The treatment of choice for arrhythmias in patients with a tricyclic overdose is sodium bicarbonate. Raising the pH and administering sodium seem to “prime” the sodium channels in the heart, reversing the toxicity of the tricyclic. Procainamide (“D”) and quinidine should not be used because they act in similar fashion to tricyclics and may worsen the problem. Lidocaine (“B”) can be used as can amiodarone (“E”), but they are not the best choices. Beta-blockers such as esmolol (“A”) can worsen hypotension and should be avoided.

FIGURE 1-1. ECG for patient in question 1.2.3.

This is not your patient's lucky day. She begins to seize after the administration of the bicarbonate.

Question 1.2.5 The treatment of choice for this seizing patient is:

- A) Lorazepam (Ativan)
- B) Repeat the bolus of sodium bicarbonate and start a bicarbonate drip
- C) Phenytoin (Dilantin)
- D) Fosphenytoin (Cerebryx)
- E) None of the above

Answer 1.2.5 The correct answer is "A." Benzodiazepines are the treatments of choice in tricyclic-induced seizures. While most seizures are self-limited, it is important to control seizures because the resultant acidosis can worsen tricyclic toxicity (beyond the fact that prolonged seizures can cause CNS injury). "B" is incorrect. This patient is already alkalinized, and although sodium bicarbonate is the preferred therapy for tricyclic-induced cardiovascular toxicity, sodium bicarbonate is not particularly effective in tricyclic-induced seizures. "C," phenytoin, can be used, but benzodiazepines and phenobarbital should be administered first if possible. In addition to not working well as an antiepileptic drug in tricyclic overdose, phenytoin is also a class Ib antiarrhythmic, which may further prolong the QRS and worsen the cardiac toxicity of the tricyclic. "D" is incorrect for two reasons. First, since fosphenytoin is metabolized to phenytoin, the concern about efficacy applies. Second, fosphenytoin is a prodrug and requires adequate circulation and renal and hepatic function to be converted into active drug. If our patient becomes hypotensive with poor liver and renal perfusion, adequate drug levels might not be achieved. Finally, both

phenytoin and fosphenytoin can cause hypotension—not what you need in this unstable patient.

You correct the arrhythmia and stop the seizures, and she is admitted to the intensive care unit.

HELPFUL TIP:

A patient who is *entirely* asymptomatic 6 hours after a tricyclic overdose is unlikely to have any serious consequences from the ingestion. They can be "medically cleared" at that point for admission to a psychiatric unit. Note that "symptomatic" may just be tachycardia or mild confusion. We mean the *entirely* asymptomatic patient.

► **Objectives: Did you learn to ...**

- Understand the importance of the ABCs in an unstable patient?
- Describe the role of flumazenil in toxicologic emergencies?
- Manage a tricyclic overdose?
- Recognize ECG findings in a tricyclic overdose?
- Recognize torsades de pointes and its treatment in the context of a tricyclic overdose?

QUICK QUIZ: DESIGNER AND CLUB DRUGS

An 18-year-old male presents after a party. He is having alternating episodes of combative behavior interspersed with episodes of coma. He becomes almost apneic during the episodes of coma. He has alternating bradycardia (while in coma) and

TABLE 1-1 TOXIDROMES

Drug Class	Examples	Signs and Symptoms
Anticholinergic	Tricyclics, diphenhydramine, scopolamine, loco weed (jimson weed), some mushrooms, etc.	Tachycardia, flushing, dilated pupils, low-grade temperature, and confusion. Mnemonic: Dry as a bone, red as a beet, mad as a hatter, blind as a bat
Opiates	Morphine, heroin, codeine, oxycodone, etc.	Pinpoint pupils, hypotension, hypopnea, coma, hypothermia
Cholinergic	Organophosphate or carbamate pesticides, some mushrooms	Lacrimation, salivation, muscle weakness, diarrhea, vomiting, miosis. Mnemonic: SLUDGE BBB (salivation, lacrimation, urination, diarrhea, GI upset, emesis ... Bradycardia, bronchorrhea, bronchospasm)
Sympathomimetic	Cocaine, ecstasy, methamphetamine	Tachycardia, hypertension, elevated temperature, dilated pupils (mydriasis)
Gamma-hydroxybutyrate (GHB)	GHB, liquid ecstasy, etc.	Alternating coma with agitation, hypopnea while comatose, bradycardia while comatose, and myoclonus

tachycardia when awake. The patient is also having myoclonic seizures. His serum alcohol level is zero, and his pupils are miotic.

The most likely drug causing this is:

- A) Ecstasy (MDMA)
- B) GHB (gamma-hydroxybutyrate aka “liquid ecstasy”)
- C) Methamphetamine
- D) LSD (lysergic acid diethylamine aka “acid”)
- E) Oxycodone

The correct answer is “B.” The episodic coma and bradycardia interspersed with episodes of extreme agitation are almost pathognomonic of GHB overdose. GHB intoxication also causes pinpoint pupils. “A” is incorrect because MDMA causes an amphetamine-like reaction with agitation, hypertension, hyperthermia, tachycardia, etc. “C” is incorrect for the same reason. “D” is incorrect because LSD rarely (if ever) causes coma. “E” is incorrect because patients with opioid overdoses are generally somnolent or comatose without interspersed episodes of agitation, although opioids *may* also cause miosis (be aware that not all narcotic overdoses are associated with pinpoint pupils). GHB is odorless and has slight salty taste. Besides being a street drug, GHB is available by prescription as “sodium oxybate” for narcolepsy (Xyrem). It has become a drug of choice for “date rape” since it cannot be detected in the urine. The toxicity tends to be self-limited and can be treated with intubation if needed along with tincture of time. The half-life is only 27 minutes.

QUICK QUIZ: TOXIDROMES

A patient presents to the hospital with a diphenhydramine overdose.

Which of the following signs and symptoms are you likely to find in this patient?

- A) Bradycardia, dilated pupils, flushing, and increased bowel sounds

- B) Bradycardia, pinpoint pupils, flushing, and decreased bowel sounds
- C) Tachycardia, dilated pupils, diaphoresis, and increased bowel sounds
- D) Tachycardia, dilated pupils, flushing, and decreased bowel sounds
- E) Tachycardia, pinpoint pupils, flushing, and increased bowel sounds

The correct answer is “D.” This patient has an anticholinergic toxidrome. Toxidromes are symptom complexes associated with a particular overdose that should be immediately recognized by the clinician. Common toxidromes are listed in Table 1-1.

CASE 1.3

A patient presents to your office with neck pain after a motor vehicle accident. He was restrained and the airbag deployed. He notes that he had some lateral neck pain at the scene. He continues to have lateral neck pain.

Question 1.3.1 Which of the following IS NOT a criterion for clearing the cervical spine clinically?

- A) Absence of all neck pain
- B) Normal mental status including no drugs or alcohol
- C) Absence of a distracting injury (such as an ankle fracture)
- D) Absence of paralysis or another “hard” sign that could be caused by a neck injury
- E) Absence of retrograde amnesia

Answer 1.3.1 The correct answer is “A.” Patients can have lateral neck pain and still have their cervical spines cleared clinically. However, no one will fault you for obtaining radiographs in patients with lateral muscular (e.g., trapezius) neck pain. Patients with central neck pain (e.g., over the spinous processes) DO need imaging (radiographs ± CT) to clear their cervical spine. All of the other criteria are required in order to clinically clear the cervical spine (Table 1-2). These criteria have been validated in both adult and adolescent patients.

TABLE 1-2 CLEARING THE CERVICAL SPINE CLINICALLY

No central neck pain on questioning or palpation
No distracting, painful injury (e.g., bone fracture)
No symptoms or signs referable to the neck (paralysis, stinger-type injury, etc.)
Normal mental status including no drugs or alcohol. This includes any retrograde amnesia, etc.

**HELPFUL TIP:**

CT has pretty much replaced plain x-rays in the evaluation of the bones of the neck. If you are doing plain films, the most common cause of missed fractures is an inadequate series of radiographs. An adequate series of radiographs for the cervical spine includes an AP film, a lateral film including the top of T-1, and an odontoid film. Flexion–extension views add little and should be avoided.

The patient's daughter, aged 4 years, was in the same motor vehicle accident and also had her cervical spine cleared by radiograph. However, you get a call from the ED 48 hours after the initial accident that she is paralyzed from just above the nipple line down (never a good thing—you quickly make a mental note to make sure your malpractice insurance premiums are paid up). You review the initial radiographs with the radiologist, which are negative as is a CT of the cervical spine bones done after the onset of the paralysis.

Question 1.3.2 The most likely cause of this patient's paralysis is:

- A) Missed transection of the thoracic cord
- B) Conversion reaction from the psychological trauma of the accident
- C) Subarachnoid hemorrhage
- D) SCIWORA syndrome
- E) Guillain–Barre syndrome

Answer 1.3.2 The correct answer is “D.” This likely represents SCIWORA syndrome (spinal cord injury without radiologic abnormality). SCIWORA has become a bit of a misnomer in the age of MRI, as up to two-thirds of children with this diagnosis will have abnormal MRI findings. This entity occurs from stretching of the cord secondary to flexion/extension-type movement in an accident. Patients with SCIWORA syndrome may be paralyzed at the time of initial presentation (in the event of cord transection) or may have a delayed presentation up to 72 hours after the injury. “A” is incorrect because a cord transection would present with paralysis immediately at the time of injury. “B” is incorrect because this child is 4 years old, and conversion reaction is unlikely in children. In addition, conversion reaction *is always* a diagnosis of exclusion. “C” and “E” are incorrect because this is neither the presentation of a subarachnoid hemorrhage (headache, stiff neck, perhaps focal neurologic symptoms) nor of Guillain–Barre

syndrome (progressive numbness and weakness from autoimmune myelitis).

Question 1.3.3 The next step in the management of this patient is:

- A) Avoid hypotension and hypoxia to prevent secondary insult to the cord
- B) Fluid restriction and diuretics to reduce cord edema
- C) Mannitol to reduce cord edema
- D) Neurosurgical intervention to decompress the cord
- E) Lollipop and a gift card for “service recovery”

Answer 1.3.3 The correct answer is “A.” Patients with a cord injury should be monitored closely to avoid hypotension and hypoxia, both of which will further damage the already compromised spinal cord. Neither diuretics (“B”) nor mannitol (“C”) will be useful in this situation. “D” is incorrect because the process of SCIWORA involves stretching of the cord (and subsequent dysfunction) rather than cord compression such as would be seen with a bony injury. “E” might be the right choice if you are taking this test as a “patient experience expert” instead of a doctor; but doctors should choose “A.”

**HELPFUL TIP:**

Don't use steroids for spinal cord injuries. It doesn't work. There are also secondary complications from the steroids, including hyperglycemia, myopathy, and infections (e.g., pneumonia).

Question 1.3.4 The father is, understandably, irate that his child is now paralyzed. You can tell him that the natural history of SCIWORA syndrome in THIS CHILD is likely to be the following:

- A) Continued paralysis with the necessity of long-term, permanent adaptation to the injury
- B) Progression of the injury over the next week to include further paralysis in an ascending fashion
- C) Resolution of paralysis and sensory symptoms over the next several months
- D) Resolution of all symptoms except sensory symptoms over the next several months
- E) Large lawsuit payout on the way. Do not pass go; do not collect \$200; go directly to a malpractice attorney

Answer 1.3.4 The correct answer is “C.” Generally, patients with SCIWORA syndrome regain their strength and sensory

abilities over time. **However, this depends on when they present with symptoms!** Patients who present with paralysis right after the accident may have complete cord transection and thus will not regain function. For this reason, it is important to obtain an MRI on all patients with SCIWORA syndrome (and any trauma-induced paralysis for that matter). Patients with significant spinal cord findings on MRI are more likely to have persistent deficits.

► **Objectives: Did you learn to ...**

- Clinically “clear” the cervical spine and decide when to order cervical spine radiographs?
- Understand the physiology, natural history, and management of SCIWORA syndrome?

► CASE 1.4

A patient with an extensive history of alcohol use presents to the ED after drinking a bottle of automobile winter gas treatment (Rothschild Vintage, 1954). He is intoxicated, has a headache, and describes a “misty” vision, “like a snowstorm” (if you live in southern Florida or Hawaii, call one of us in Iowa for a description). He is tachycardic and tachypneic. You start an IV and administer saline. You obtain a blood gas, which shows a mild metabolic acidosis.

Question 1.4.1 A metabolic acidosis is consistent with all of the following ingestions EXCEPT:

- A) Ethylene glycol
- B) Methanol
- C) Ethanol (e.g., vodka, gin)
- D) Petroleum distillates (e.g., non-alcohol-containing gasoline products)

Answer 1.4.1 The correct answer is “D.” Ethylene glycol, methanol, and ethanol can all cause a metabolic acidosis. Hydrocarbons (e.g., gasoline products) do not cause a metabolic acidosis. The main manifestation of hydrocarbon toxicity is secondary to the inhalation and aspiration of the hydrocarbon and the resulting pneumonitis.

.....

This patient’s electrolytes are as follows: sodium 135 mEq/L, bicarbonate 12 mEq/L, chloride 108 mEq/L, BUN 12 mg/dL, Cr. 1 mg/dL.

Question 1.4.2 This patient’s anion gap is:

- A) 13
- B) 15
- C) 23
- D) Unable to calculate the anion gap with the information provided

Answer 1.4.2 The correct answer is “B.” By convention, the anion gap is calculated without using a major cation, potassium. Thus, the anion gap is calculated as follows:

$$\text{sodium} - (\text{chloride} + \text{bicarbonate})$$

In this patient, the anion gap = $135 - (108 + 12) = 15$.

The normal anion gap is typically considered to be 12 or less. However, since albumin is the major unmeasured anion in the serum, the anion gap should be adjusted for hypoalbuminemia. Every 1 g decrease in albumin will decrease the anion gap by about 3. Therefore, you should subtract $(3 \times [\text{normal albumin} - \text{actual albumin}])$ to get the “real” anion gap. The normal albumin is considered to be 4. So, let us say we calculate an anion gap of 16 but the albumin is 2. In this case, the corrected anion gap will be $(16 - [3 \times (4 - 2)]) = 16 - 6$, or 10.

HELPFUL TIP:

In methanol ingestions, the severity of acid–base disturbance is generally a better predictor of outcome than serum methanol levels.

Question 1.4.3 All of the following are causes of an anion gap acidosis EXCEPT:

- A) Lactic acidosis
- B) Diabetic ketoacidosis
- C) Renal tubular acidosis
- D) Uremia
- E) Ingestions such as methanol

Answer 1.4.3 The correct answer is “C.” See Table 1-3 for more on causes of anion gap acidosis.

TABLE 1-3 CAUSES OF ACIDOSIS

Causes of an **elevated** anion gap acidosis

Lactic acidosis
Diabetic ketoacidosis
Ingestions such as ethanol, methanol, etc.
Uremia
Alcoholic ketoacidosis

Causes of a **normal** anion gap acidosis

GI bicarbonate loss (e.g., chronic diarrhea)
Renal tubular acidosis (types I, II, and IV)
Interstitial renal disease
Ureterosigmoid loop
Acetazolamide and other ingestions
Small bowel drainage

Question 1.4.4 Which of the following findings IS NOT frequently seen in patients with methanol ingestion?

- A) Hypopnea
- B) Optic disk abnormalities
- C) Abdominal pain and vomiting
- D) Basal ganglia hemorrhage
- E) Meningeal signs, such as nuchal rigidity

Answer 1.4.4 The correct answer is “A.” Hypopnea is not commonly seen in methanol poisoning until the patient is close to death. In fact, the reverse is true. Tachypnea is a frequent finding in methanol overdose. This makes sense. The patient is trying to compensate for a metabolic acidosis by blowing off CO₂. Optic disk abnormalities, abdominal pain and vomiting, basal ganglia hemorrhage, and meningeal signs are all seen as part of methanol toxicity. It is thought that many of these signs and symptoms are secondary to central nervous system (CNS) hemorrhage.

You can test for ethanol at your hospital but do not have a test for methanol on a stat basis and want to be sure that this patient is not just saying he has a methanol ingestion in order to obtain alcohol (a treatment for methanol ingestion—break out the single malt scotch!).

Question 1.4.5 What test is most likely to help you determine if the patient has methanol ingestion?

- A) Complete blood cell count (CBC)
- B) BUN/creatinine
- C) Liver enzymes
- D) Measured serum osmolality
- E) Amylase and lipase

Answer 1.4.5 The correct answer is “D.” With a measured serum osmolality, you can calculate the osmolar gap. To do so, subtract the total *measured* serum osmoles from the osmoles known to be due to ethanol (each 100 mg/dL of ethanol accounts for approximately 22 osmoles). If there is an elevated osmolar gap, it is evidence of a circulating, unmeasured osmole. A normal osmolar gap is usually about 6 mOsm/L or less. Any osmolar gap over 10 mOsm/L suggests a concurrent ingestion with the alcohol (such as in our case, methanol).

In this case, for example:

Measured serum osmolality = 368

Blood alcohol = 200 mg/dL or about 44 osmoles

Calculated osmolality = $2(\text{Na}) + \text{BUN}/2.8 + \text{glucose}/18$
 $= 280 + 6 + 8 = 294$

So, osmolar gap = $368 - (294 + 44) = 30$

This means that there are 30 unmeasured osmoles that could, in the clinical context of the case, represent methanol. Thus, we

know that the patient did not simply overindulge on ethanol (methanol, such as “gas dry,” will make one intensely drunk ... but has obvious downsides).

You decide that there is sufficient evidence that this patient has ingested methanol to institute treatment.

Question 1.4.6 Appropriate treatment(s) for this patient include:

- A) Fomepizole (4-MP)
- B) Acetylsalicylic acid
- C) Ethanol
- D) A and C
- E) All of the above

Answer 1.4.6 The correct answer is “D.” Both fomepizole (4-MP) and ethanol are used for methanol ingestion. The idea is to slow down the metabolism of the methanol. The toxicity of methanol is caused by formic acid, which is a by-product of methanol metabolism. Ethanol is metabolized by alcohol dehydrogenase, the same enzyme that breaks down methanol. Thus, methanol metabolism is competitively inhibited by ethanol. The same holds true for fomepizole, which is a competitive inhibitor of alcohol dehydrogenase. Fomepizole and ethanol can both be used for ethylene glycol ingestion as well. “B” is incorrect. Acetylsalicylic acid (ASA), or aspirin, has no role in methanol ingestion, and would likely worsen any gastritis or hemorrhaging.

HELPFUL TIP:

Hemodialysis should be available for any patient who has ingested methanol. Indications for hemodialysis include methanol level >50 mg/dL, severe and resistant acidosis, and renal failure.

► **Objectives: Did you learn to ...**

- Recognize manifestations of alcohol ingestion?
- Identify causes of metabolic acidosis with elevated and normal anion gaps?
- Use the osmolar gap to narrow down the differential diagnosis of metabolic acidosis?

QUICK QUIZ: BETA-BLOCKER OVERDOSE

Which of the following has been shown to be useful in beta-blocker overdose when conventional, adrenergic vasopressors are ineffective?

- A) Calcium chloride
- B) Glucagon
- C) Milrinone
- D) High-dose insulin
- E) All of the above

The correct answer is “E.” In beta-blocker overdoses, the following findings may be observed: bradycardia, AV block, hypotension, bronchospasm, nausea, emesis, and *hypoglycemia*. This is very similar to the presentation of a calcium channel blocker overdose, but calcium channel blocker overdose often lacks bronchospasm and patients are *hyperglycemic* as insulin release from the islet cells is calcium dependent. When a beta-blocker overdose has been identified, the usual treatments are employed (e.g., IV fluids, vasopressors, airway protection). If conventional vasopressors have failed, glucagon in a dose of 3 to 5 mg IV bolus and a drip at 1 to 5 mg/hr may be effective in treating beta-blocker overdose. It is generally preferred over atropine in this situation. Milrinone and other phosphodiesterase inhibitors may also be used but are considered third-line agent. Likewise, calcium is considered a third-line agent in beta-blocker overdose. Calcium chloride may potentiate the action of glucagon. There is also a growing body of literature supporting use of high-dose insulin (while maintaining *euglycemia*) for beta-blocker, calcium channel blocker, or combination overdoses. The insulin is started at 0.5 U/kg/hr and titrated to as high as 10 U/kg/hr, titrated by hemodynamic improvement (*Clin Toxicol (Phila)*. 2011;49(4):277–283). Dextrose infusion may be required to maintain *euglycemia*. Does it seem counterintuitive to give glucagon and insulin? Both appear to mitigate the deleterious effects of beta-blockers on cardiac myocyte metabolism, although the mechanism is not completely understood. Both can be given (usually in sequence with the glucagon first) to the same patient for beta-blocker overdose. **Remember to maintain *euglycemia* if using insulin for beta-blocker or calcium channel blocker overdose.**

QUICK QUIZ: TOXICOLOGY 1

Which of the following can be used to increase the metabolism of alcohol in an intoxicated patient?

- A) IV fluids
- B) Charcoal
- C) Forced diuresis
- D) GABA antagonists such as flumazenil
- E) None of the above

The correct answer is “E.” Drunk patients, no matter how much they annoy you, will just have to sleep it off. The rate of alcohol metabolism is fixed with zero-order kinetics at lower doses (fixed metabolic rate) and first-order kinetics at higher doses (rate proportional to levels). In general, this rate is in the range of 9 to 36 mg/dL/hr, with 20 mg/dL/hr being the accepted norm. At this point, there are no available agents to increase the metabolism of ethanol. “B” is incorrect because ethanol is too rapidly absorbed for charcoal to be of any benefit. “C,” forced diuresis, will just result in an incontinent, sleeping patient and does not hasten metabolism.

QUICK QUIZ: TOXICOLOGY 2

The best therapy for seizures secondary to an isoniazid overdose is:

- A) Lorazepam
- B) Phenytoin
- C) Pyridoxine
- D) Thiamine
- E) Phenobarbital

The correct answer is “C.” Isoniazid is a vitamin B6 antagonist. Thus, pyridoxine (in massive doses!) is the drug of choice in isoniazid-induced seizures. These seizures are often resistant to conventional therapy. Look for this type of overdose in patients who are being treated for active or latent tuberculosis; often these patients are immigrants and were exposed to TB in their country of origin.

▶ CASE 1.5

A family of four comes into your ED after being exposed to carbon monoxide (CO). They were in an idling car in the garage and were running the engine and heater to stay warm. You want to get a carboxyhemoglobin level on the whole family, but cannot get an arterial blood gas from the youngest child.

Question 1.5.1 What is your response?

- A) Check pulse oximetry, and if the oxygen saturation is normal, be reassured
- B) Check end-tidal carbon dioxide
- C) Check a venous carboxyhemoglobin level
- D) Check a venous carboxyhemoglobin and correct for the difference between venous and arterial samples

Answer 1.5.1 The correct answer is “C.” A venous carboxyhemoglobin is just as accurate as an arterial carboxyhemoglobin—in fact, no correction is needed, which is why “D” is wrong—and, a venous gas much less painful to draw. “A” is incorrect because the pulse oximeter does not reflect hypoxia in carbon monoxide poisoning. Thus, standard pulse oximetry is useless in determining the carboxyhemoglobin level. “B” is incorrect because end-tidal carbon dioxide is measuring CO₂ and not CO.

Question 1.5.2 When determining which patients need hyperbaric oxygen on the basis of a carboxyhemoglobin level, the level to rely upon is:

- A) The carboxyhemoglobin level on arrival to the ED
- B) The carboxyhemoglobin level at 4 hours after exposure
- C) The carboxyhemoglobin level projected to “time zero” (e.g., at the time of exposure)
- D) None of the above

Answer 1.5.2 The correct answer is “C.” A major consideration regarding the initiation of hyperbaric oxygen therapy is

the patient's clinical situation. More severely ill patients with CO poisoning (e.g., severe acidosis, unconscious, unresponsive) should be considered candidates for hyperbaric oxygen, and some hyperbaric oxygen centers will treat regardless of measured carboxyhemoglobin level in these patients. If the treatment decision is made based on the carboxyhemoglobin level, the level projected to time zero gives the most accurate information about the degree of exposure. The rest of the answers are incorrect.

The father has a headache and a time zero carboxyhemoglobin level of 12%. The mother, who is pregnant, is asymptomatic and has a time zero carboxyhemoglobin level of 18%. Both of the children are asymptomatic. The 6-year-old has a time zero carboxyhemoglobin level of 18% while the 8-year-old has a level of 23%.

Question 1.5.3 The first step in the treatment of these patients is:

- A) Start an IV and administer saline
- B) Start N-acetylcysteine, which is a free radical scavenger
- C) Start continuous positive airway pressure (CPAP) to maximize airflow by keeping the airways from collapsing
- D) Administer 100% oxygen
- E) Intubate the most severe patient, 100% oxygen for the others

Answer 1.5.3 The correct answer is "D." Because CO competitively binds to hemoglobin in place of oxygen and in fact has greater affinity for hemoglobin than oxygen, high-flow 100% oxygen is the cornerstone of treating CO poisoning. The half-life of CO in a patient breathing room air is approximately 300 minutes; this is reduced to 90 minutes when breathing high flow oxygen and reduced to 30 minutes when breathing 100% hyperbaric oxygen. Thus, *the first step in CO poisoning is to administer 100% oxygen*. The rest of the answers are incorrect. If the patient is not ventilating well and requires intubation, this would be appropriate, and the FiO₂ should be set to 100%, regardless of the patient's pulse oximetry or arterial oxygen readings. However, in our patients who are breathing without difficulty, there will be no advantage (and much higher risk) to intubation.

Question 1.5.4 Which of the following can be seen with carbon monoxide poisoning?

- A) Rhabdomyolysis
- B) Cardiac ischemia
- C) Long-term neurologic sequelae, including dementia
- D) Pulmonary edema
- E) All of the above

Answer 1.5.4 The correct answer is "E." All of the above can be seen with carbon monoxide poisoning. Additional findings include lactic acidosis, seizures, syncope, and headache. "C" deserves a bit more discussion. Long-term neurologic sequelae can develop from days to months after the exposure and include cognitive deficits, focal neurologic deficits, movement disorders, and personality changes. It appears that using hyperbaric

oxygen in the appropriate patient can reduce long-term neurologic sequelae.

Your closest diving chamber is about 90 minutes away and will hold only one patient at a time. You need to make a decision about who to send for hyperbaric oxygen.

Question 1.5.5 Which patient will benefit most from hyperbaric oxygen therapy?

- A) Asymptomatic pregnant mother, time zero carboxyhemoglobin of 18%
- B) Asymptomatic 6-year-old, time zero carboxyhemoglobin of 18%
- C) Asymptomatic 8-year-old, time zero carboxyhemoglobin of 23%
- D) Adult male with mild headache only, time zero carboxyhemoglobin level of 12%

Answer 1.5.5 The correct answer is "A." Generally accepted criteria for hyperbaric oxygen include: mental status changes, asymptomatic carboxyhemoglobin levels >25%, acidosis, cardiovascular disease, and age >60. Obviously, these are relative criteria. An otherwise normal 61-year-old with a mild exposure need not have hyperbaric oxygen. *Pregnancy is an indication for hyperbaric oxygen therapy* because fetal hemoglobin has a high affinity for carbon monoxide, with the fetus acting as a "sink" for CO. The high aerobic metabolic activity of fetal development is impacted greatly by exposure to the anaerobic environment created by carbon monoxide.

Question 1.5.6 All of the following are well-established consequences of hyperbaric oxygen EXCEPT:

- A) Seizures
- B) Psychosis
- C) Myopia
- D) Ear and pulmonary barotraumas
- E) Direct pulmonary oxygen toxicity

Answer 1.5.6 The correct answer is "B." All of the rest are found as a result of hyperbaric oxygen. "C," myopia, is found in up to 20% of patients being treated with hyperbaric oxygen. It is due to direct toxicity of oxygen on the lens and usually recovers within weeks to months.

► **Objectives: Did you learn to ...**

- Diagnose and manage patients with carbon monoxide poisoning?
- Describe complications of carbon monoxide poisoning?
- Identify patients who may benefit from hyperbaric oxygen therapy?
- Describe the complications of hyperbaric oxygen therapy?

► CASE 1.6

A 50-year-old man comes to your ED after being bitten by a stray dog outside your hospital. Apparently, there is a problem with roving packs of feral dogs in your part of town. The

bite was unprovoked and is on the abdomen. The patient has no other health history of note and has not taken antibiotics for over a year. There is a 3-cm laceration on the abdomen.

Question 1.6.1 All of the following are true about dog bites EXCEPT:

- A) They tend to be primarily crush-type injuries
- B) In general, the infection rate is similar to a laceration from any other mechanism (e.g., knife cut), except on the hands and feet
- C) A common organism in infected dog bites is *Staphylococcus aureus*
- D) Primary closure of dog bite wounds is an acceptable option (except perhaps on the hands and feet)
- E) They always require antibiotics

Answer 1.6.1 The correct answer is “E.” All of the rest are true statements. Dog bites (except, perhaps, for those from teacup poodles named Fifi) tend to be crush injuries (as contrasted with cat bites and Fifi, which are primarily puncture wounds). The infection rate is about the same as other lacerations. Bites on the hands and feet tend to have a higher rate of infection. Most dog bite infections are polymicrobial with mixed aerobic and anaerobic bacteria. *S. aureus* is often present, along with other organisms including *Pasteurella* and *Capnocytophaga* (say that one ten times fast). Other organisms include *Streptococcal* species and Gram-negative species. Dog bites do not generally require antibiotic prophylaxis, except under certain circumstances (e.g., presentation >9 hours after bite, immunocompromised, large, or complicated wound, perhaps hands and feet).

Question 1.6.2 You are concerned about rabies prophylaxis. Which of the following is the best next step?

- A) Isolate the suspect animal for 3 days
- B) Sacrifice the suspect animal and examine the liver
- C) Administer rabies immune globulin IM
- D) Administer rabies immune globulin IV followed by rabies vaccination series
- E) Administer rabies immune globulin by infiltrating it around the wound followed by rabies vaccination series

Answer 1.6.2 The correct answer is “E.” You should infiltrate rabies immune globulin around the wound and then begin the rabies vaccination series. Infiltrate as much of the immune globulin as possible around the wound and administer the remainder IM at a different site. **Do not give more than the recommended dose of immunoglobulin. This can reduce the immunogenicity of the vaccine.** “A” is incorrect because the animal needs to

be isolated for 10 days, not 3. “B” is incorrect. If captured, the animal can be sacrificed, but the brain should be examined—not the liver. “C” and “D” are both incorrect methods of administering the vaccine and immune globulin. Note that the average incubation period of rabies is 85 days. So, immunizing up to 3 months (90 days) after the bite-event is indicated.

Question 1.6.3 Which of the following requires rabies prophylaxis in all cases?

- A) Stray rabbit bites
- B) Stray rat bites
- C) Stray bat bites
- D) Stray squirrel bites
- E) Stray snake bites

Answer 1.6.3 The correct answer is “C.” All bats should be considered rabid unless available for observation and testing. See Table 1-4 for detailed recommendations. Also, see the CDC or your state public health website for information about rates of infection in wild animals in your area. Of note, there have been rabid squirrels in Iowa City, our illustrious home: Google it.

HELPFUL TIP:

Patients should receive a tetanus booster every 10 years. For a contaminated wound, the tetanus booster should be within the last 5 years. Patients should receive at least one dose of Tdap (tetanus, diphtheria, and acellular pertussis) between ages 11 and 18 and a single dose between ages 18 and 64. In addition, health-care workers and those > 65 years of age who will be around infants should receive a single dose of Tdap (for pertussis prophylaxis). Pregnant women should have a Tdap with every pregnancy to protect the infant (week 27–30 seems optimal; Healy CM et al. *JAMA* 2018 Oct 9).

HELPFUL TIP:

If a patient at risk for tetanus has not had a primary series of tetanus immunizations, administer tetanus immune globulin, *and* start the primary tetanus series. Children who have had at least 3 doses of their primary series (routinely given at age 2, 4, and 6 months) are considered “immune” and can be given a booster as needed as listed above. DTaP is appropriate for children aged 6 weeks to 7 years.

You decide to irrigate this patient’s wound.

TABLE 1-4 GUIDELINES FOR RABIES PROPHYLAXIS

General Rule	Animals
Always assume rabid unless available for testing	Foxes, bats, raccoons, skunks, dogs, cats, ferrets, other carnivores
Judge on an individual basis	Rodents (rats, mice, etc.), lagomorphs (rabbits, etc.), squirrels
Never require rabies prophylaxis	Non-mammals (snakes, lizards, etc.)

Question 1.6.4 Which of the following statements is true about irrigating a wound and subsequent risk of wound infections?

- A) Povidone-iodine as a 50% irrigation solution (e.g., Betadine) in the wound will decrease the infection rate
- B) Irrigation with normal saline is the only recommended method of cleaning a wound
- C) Irrigation with normal saline and irrigation with tap water are equally effective in reducing wound infection rates
- D) Use of lidocaine with epinephrine in a wound increases the rate of infection
- E) Irrigation of a wound with either alcohol or hydrogen peroxide will reduce the rate of wound infection

Answer 1.6.4 The correct answer is “C.” Infection rates (in the United States) are the same whether the wound is irrigated with normal saline or tap water. “A” is incorrect. Povidone-iodine is toxic to tissue and polymorphonuclear leukocytes and actually may **increase** infection rates unless a solution of 1% or less is used. Full strength povidone-iodine **can** be used on intact skin as a cleanser but should not be used in a wound. “B” is incorrect because other solutions (poloxamer 188, balanced salt solutions, etc.) can be used but are more expensive and do not offer any benefit in reduction in infection rates. “D” and “E” are both incorrect. Use of lidocaine with epinephrine (“D”) may be warranted for local anesthesia for further wound exploration and/or closure. It has **not** shown to increase rates of infection. As with povidone-iodine, alcohol (“E”) may be used for cleaning skin, but should be kept out of the wound. It is toxic to tissue and acts as a fixative. Hydrogen peroxide (“E”) is also toxic to tissue and should not be used in open wounds—no matter what grandma says! Chlorhexidine can also be used on intact skin (not in the wound) and is more bactericidal than Povidone-Iodine.

Question 1.6.5 How long after a laceration occurs can the wound be closed primarily?

- A) 6 hours
- B) 12 hours
- C) 18 hours
- D) 24 hours
- E) Any of the above can be correct depending on the wound

Answer 1.6.5 The correct answer is “E.” There is no arbitrary time limit to when a wound can be closed. Facial wounds may be closed up to 24 hours after injury for cosmetic reasons, while you may not want to close other, contaminated wounds more than 12 hours after injury. Some wounds you may not want to close at all (e.g., bites to the hand, wounds contaminated with grease, wounds contaminated with manure, human bite wounds), rather allowing them to close by secondary intention.

► **Objectives: Did you learn to ...**

- Describe the indications for rabies prophylaxis?
- Recognize the issues that arise with animal bites and indications for closure and/or prophylactic antibiotics?
- List recommendations for tetanus prophylaxis and boosting?

- Use various wound irrigation solutions for cleansing wounds?
- Decide upon the time frame for wound closure?

► CASE 1.7

A 52-year-old male presents to your ED via ambulance complaining of a headache after a fall. He was working and fell approximately 10 ft. He notes no injury except for head and neck pain. A quick survey reveals that he has a BP of 128/86 mm Hg, pulse 100 bpm, and respirations of 12. There was no loss of consciousness at the scene. He “saw stars” and was clumsy, dazed, and cognitively slowed at the scene without any focal neurologic deficit. He is now back to his baseline.

Question 1.7.1 A concussion is defined as:

- A) Any neurologic symptoms (e.g., clumsy, dazed, or slow, nausea, dizziness) after head injury
- B) Loss of consciousness followed by return to baseline
- C) Loss of consciousness with continued neurologic symptoms
- D) Confusion after head trauma regardless of whether the patient lost consciousness or not
- E) Any traumatic injury to the head

Answer 1.7.1 The correct answer is “A.” A concussion is defined as *any* neurologic symptom after head trauma. **Note that a concussion does not require a loss of consciousness.** For this reason, “B” and “C” are incorrect. “D” is incorrect because manifestations of concussion are not limited to confusion, but also include protracted vomiting, transient amnesia, slowed mentation, “dizziness,” and other neurologic symptoms. “E” is incorrect because by definition, a concussion requires neurologic symptoms.

.....
Your patient opens his eyes spontaneously, follows commands, answers all orientation questions correctly, but appears unsteady when ambulating.

Question 1.7.2 His Glasgow Coma Scale (GCS) is:

- A) 5
- B) 10
- C) 14
- D) 15
- E) 20

Answer 1.7.2 The correct answer is “D.” The Glasgow Coma Scale (GCS) is a scale used to indicate the severity of neurologic dysfunction and is often applied to victims of head trauma. Remember, however, that it does not predict mortality or morbidity, but is only used as a descriptive scale of the patient’s current state. Only the maximum score of 15 is considered a normal GCS. There are three components to the GCS, listed in Table 1-5.

TABLE 1-5 GLASGOW COMA SCALE

Eye opening Mnemonic: “4 eyes”	Spontaneous = 4 To speech = 3 To pain = 2 No response = 1
Verbal response Mnemonic: “Jackson 5”	Alert and oriented = 5 Disoriented conversation = 4 Nonsensical speech = 3 Moaning = 2 No response = 1
Motor response Mnemonic: “Six Cylinders”	Follows commands = 6 Localizes pain = 5 Withdraws from pain = 4 Decorticate flexion = 3 Decerebrate extension = 2 No response = 1

**HELPFUL TIP:**

Your chair and refrigerator each have a GCS of 3. Remember that *nothing* can have a GCS less than 3.

Question 1.7.3 In patients with head injury, and independent of other factors, a GCS score of 15 indicates that:

- A) The patient does not require a head CT scan
- B) There is essentially no possibility that this patient has an intracranial injury requiring surgical intervention
- C) There is little or no possibility that this patient has any focal intracranial bleed
- D) There is up to a 4% chance this patient will need neurosurgical intervention
- E) None of the above

Answer 1.7.3 The correct answer is “D.” In appropriately selected patients (e.g., those with a significant mechanism of injury), about 18% with a GCS of 15 will have some intracranial lesion, and up to 4% will eventually require neurosurgical intervention. These are generally patients who have a depressed skull fracture but a normal GCS. “A” is incorrect since a normal GCS in and of itself does not allow one to forgo head CT in patients with a significant mechanism of injury. “B” and “C” are also incorrect for the reasons noted earlier. Remember that the GCS is *not* linear; a GCS of 14 is bad. Patients with a GCS of 14 *must* have a CT scan—unless another factor in the clinical decision-making dictates otherwise (e.g., the finding is preexisting from dementia or otherwise).

Question 1.7.4 In an adult patient with a significant head injury, which of the following is NOT an indication for a head CT scan?

- A) Intoxication with drugs or alcohol
- B) Persistent vomiting
- C) Amnesia or memory deficit
- D) Age greater than 40
- E) Seizure

Answer 1.7.4 The correct answer is “D.” Older patients are at greater risk of developing serious intracranial injuries, and the age of 60 is usually considered an independent indication for a head CT *with significant injury*. While there is no “upper limit of normal” for vomiting after head trauma, the best data available suggest that any vomiting after head trauma in an *adult* indicates the need for a head CT. The currently recommended criteria for a CT of the head in various age groups are listed in Table 1-6.

You obtain the head CT and find a subdural hematoma. You arrange to transfer this patient for neurosurgical intervention in order to drain the subdural hematoma. It is about a 4-hour drive by ambulance to the nearest facility that has a neurosurgeon.

Question 1.7.5 Which of the following is indicated as prophylaxis against increased intracranial pressure in this patient?

- A) Hyperventilation after intubation
- B) IV mannitol
- C) Trendelenburg position
- D) IV dexamethasone
- E) None of the above

Answer 1.7.5 The correct answer is “E.” None of the above is indicated as prophylaxis for increased intracranial pressure. “A” is incorrect for two reasons. First, this patient does not need to be intubated. Second, routine hyperventilation as prophylaxis for increased intracranial pressure is of no benefit. This has been well studied. What happens is that hyperventilation *does* cause vasoconstriction reducing intracranial blood flow and therefore intracranial pressure. However, hyperventilation also causes ischemia around the area of the injury secondary to the vasoconstriction and may worsen outcomes. “B” is incorrect because prophylactic mannitol, like prophylactic hyperventilation, confers no benefit. “C” is incorrect. Trendelenburg positioning, or elevating the legs above the heart, would result in increased intracranial pressure. There is very limited data to support or

TABLE 1-6 INDICATIONS FOR HEAD CT BY AGE

Patient Age	Indications for Head CT after Trauma with a Significant Mechanism
Adult	Intoxication Age >60 Any memory deficit Vomiting (number of times undefined) Seizure Headache
PECARN Rules for Pediatric Head Trauma and Need for CT Scan (<i>The Lancet</i>. 2009;374(9696):1160–1170)	
CT needed if:	
Children >2 year	GCS <15 Signs of a basilar skull fracture Agitation, somnolence, slow responses, or perseveration Vomiting Loss of consciousness Severe headache Severe mechanism (Fall >5 ft, MVC with ejection, roll over, fatality) Bike/pedestrian vs. car without helmet High impact object If there are changes during observation (MS change, worsening headache, new or persistent vomiting), consider CT based on clinical judgment
Children <2 years	GCS <15 Palpable skull fracture Agitation, somnolence, slow responses, perseveration Scalp hematoma (except for frontal) LOC >5 seconds Severe mechanism (fall >3 ft, MVC with ejection, roll over, fatality) Bike/pedestrian vs. car without helmet High impact object If there are changes during observation (MS change, worsening headache, new or persistent vomiting), consider CT based on clinical judgment. If child <3 months of age, consider parenteral preference and consider scanning

refute prophylactic elevation of the head of the bed to *prevent* increased intracranial pressure; while this will reduce intracranial pressure, cerebral perfusion pressure will also be mildly reduced. For *treatment* of increased intracranial pressure, there is slightly more evidence for benefit of elevating the head of the bed (i.e., *reverse* Trendelenberg). “D” is incorrect since steroids are not useful acutely in head trauma. However, steroids are useful in cerebral edema secondary to tumor.

**HELPFUL TIP:**

About two-thirds of patients with a mild head injury (not deemed severe enough to obtain a CT scan) will have some measurable decrement in function at 1 month secondary to post-concussion syndrome. Symptoms include headache, dizziness, difficulty concentrating, personality changes, etc. (*J Emerg Med*. 2011;40:262).

- Manage patients presenting with potential intracranial injuries?

▶ **CASE 1.8**

A 23-year-old male is in a bar fight. He only had “two beers” and was just standing there “minding my own business” when he was jumped by those infamous “two dudes” (how can those two dudes be in so many places at once?). He presents to you about 1 hour after the event with facial trauma. His vitals are normal and he is mentating well (with the exception of some impaired judgment secondary to the alcohol). His blood alcohol level is 150 mg/dL, showing that he is legally intoxicated. On examination, you notice that the patient has some epistaxis and a quite swollen nose. In addition, there is one avulsed tooth and one tooth that is displaced.

Question 1.8.1 The best way to transport an avulsed tooth is:

- A) In sterile water
- B) In the buccal mucosa after thorough washing with soap

▶ **Objectives: Did you learn to ...**

- Use the GCS?
- Recognize which patients with head trauma are appropriate to obtain a head CT?

- C) In a glass of milk
- D) Wrapped in saline-soaked gauze
- E) Under a pillow

Answer 1.8.1 The correct answer is “C.” The best way to transport an avulsed tooth is (1) in a glass of milk, (2) in Hanks’ balanced salt solution (good luck finding this when you need it!), or (3) in the buccal mucosa or under the tongue in a patient in whom the risk of aspiration is not a concern. “A” is incorrect because sterile water is hypotonic and may damage the tooth root decreasing the success rate of reimplantation. “B” is incorrect because *washing the tooth with soap* is not appropriate. Again, you want to maintain the viability of the root if possible. “D” is incorrect as well. If this is the only option available to you, it is better than nothing, but a glass of milk or under the buccal mucosa is preferred. “E” is acceptable only if you are a tooth fairy.

You call the dentist who is (of course) out of town. A dentist will not be available for at least 12 hours.

Question 1.8.2 Your best course of action at this point is:

- A) Continue to keep the tooth viable in a glass of milk
- B) Continue to keep the tooth viable in the buccal mucosa
- C) Clean the tooth and keep it sterile and dry for reimplantation in 12 hours realizing that a bridge will probably be needed to hold the tooth in position
- D) Reinsert the tooth into the socket yourself

Answer 1.8.2 The correct answer is “D.” If there is going to be any delay in reimplantation by a dentist, the best course of action is to reinsert the tooth into the socket yourself. “A,” “B,” and “C” are all incorrect because they will reduce the rate of successful reimplantation.

HELPFUL TIP:

Primary (“baby”) teeth should NOT be re-inserted into the socket! They ankylose to the bone preventing the eruption of the permanent tooth and cause a cosmetic deformity.

HELPFUL TIP:

Any patient who is in the ED, says he only had three beers, and was “minding his own business” is probably not telling the truth on either account.

You now turn your attention to this patient’s bloody nose and are trying to decide whether or not to get an x-ray.

Question 1.8.3 The BEST timing for a radiograph of the nose is:

- A) As soon as possible after the trauma, once other injuries are stabilized and more important problems are addressed

- B) As soon as possible to assure that there are no bone fragments threatening the brain
- C) There is no need for a radiograph acutely. You can wait for 3 or 4 days
- D) There is never any indication for nasal radiographs

Answer 1.8.3 The correct answer is “C.” There is no need for radiographs acutely except in extraordinary circumstances. The reasons for a radiograph are to document a fracture *and* to assist in reduction. Because of swelling, it is difficult to get a good cosmetic result reducing a nasal fracture acutely. Thus, a radiograph is indicated in 3 to 4 days *only* if there is evidence of nasal deformity once swelling has resolved. If there is good cosmesis and the patient can breathe through his (they are almost always male) nose, a radiograph is unnecessary just to document a fracture. “A” and “B” are incorrect because, as noted earlier, there is no reason to do a radiograph at all unless there is evidence of deformity once the swelling is resolved. “D” is incorrect for the reasons noted earlier.

Question 1.8.4 You get the epistaxis stopped and examine the nasal mucosa. Which one of these is considered an emergency?

- A) Closed nasal fracture
- B) Septal hematoma
- C) Trauma to Kiesselbach plexus
- D) A deviated septum

Answer 1.8.4 The correct answer is “B.” A septal hematoma is considered an emergency. The problem is that the perichondrium, which supplies nutrition to the septum, is no longer in contact with the septum because of the intervening hematoma. Thus, the septal cartilage can necrose leading to a perforated septum. Septal hematomas should be drained acutely and the nose packed to keep the perichondrium in contact with the septal cartilage. “A” is incorrect (see previous question). “C” is incorrect. Kiesselbach plexus is in the anterior nose and is a venous plexus. Bleeding is easily controlled and generally is self-limited. “D,” a deviated septum, may indicate an underlying fracture but in and of itself is not an emergency.

You continue to evaluate this patient and note that he has the loss of upward gaze in the right eye, the side on which he was hit. All of the other extraocular motions are intact.

Question 1.8.5 The most likely diagnosis in this patient is:

- A) Blowout fracture with entrapment of the inferior rectus
- B) Blowout fracture with dysfunction of the superior rectus
- C) Injury to cranial nerve III, which controls the superior AND inferior rectus muscles
- D) Volitional refusal to perform upward gaze on the right side in this intoxicated patient

Answer 1.8.5 The correct answer is “A.” The most likely diagnosis is blowout fracture with entrapment of the inferior rectus. The force of a blow to the globe is transmitted to the inferior orbital wall, which is the weakest point in the orbit. This can

cause entrapment of the contents of the inferior orbit, including the inferior rectus, causing an inability to perform upward gaze. Due to disconjugate gaze, patients with entrapment of the inferior rectus muscle from a blowout fracture may complain of diplopia. “B” is incorrect because a blowout fracture generally refers to the inferior orbital wall, which would not entrap the superior rectus. In addition, patients with an entrapped superior rectus would have difficulty with downward gaze. “C” is incorrect because it is unlikely that being hit in the face would cause an injury to CN III. In addition, a CN III lesion would affect all extraocular muscles except for the lateral rectus (CN VI) and the superior oblique (CN IV). “D” is incorrect because it is impossible to move the eyes independently of one another unless you are a chameleon or particularly talented.

**HELPFUL TIP:**

Note that a blowout fracture may be a good thing. Having the fracture allows pressures to equilibrate and prevents orbital compartment syndrome (proptosis, visual loss, etc.). Proptosis with visual loss is a surgical emergency mandating an immediate lateral canthotomy (easy to do ... check YouTube).

The patient has had a long night of partying, and it is 3:00 AM Saturday morning when you call your consultant about the blowout fracture. The consultant is not happy and refuses to see the patient acutely. He wants you to send him to the office in 3 days (Tuesday morning).

Question 1.8.6 Your response is:

- A) To call another consultant; a blowout fracture should be attended to immediately
- B) Do nothing; evaluation in 2 to 3 days for a blowout fracture, even with inferior rectus entrapment, is appropriate
- C) Start steroids to reduce muscle edema to facilitate the spontaneous release of the entrapped muscle
- D) Start antibiotics and hospitalize the patient so that he can be seen in the morning when the consultant makes rounds
- E) Stick pins in a voodoo doll of your consultant

Answer 1.8.6 The correct answer is “B.” While blowout fractures with muscle entrapment require close follow-up, there is no need to intervene acutely. In fact, a decision to operate may be delayed for up to 14 days. If the entrapment spontaneously resolves when the swelling goes down (not uncommon) and there is no diplopia or other complicating symptoms, surgery is not needed. The other answers are all incorrect because acute intervention is not required in this patient. “E,” however, may be of some benefit—depending on your voodoo skills.

**HELPFUL TIP:**

Caveat to the above: In the pediatric population, immediate surgical repair should be undertaken in trapdoor fractures. A trapdoor fracture is one in which

there is significant entrapment of the inferior rectus muscle. If the muscle is left entrapped in the pediatric population, restriction and fibrosis may occur, so immediate evaluation by a surgeon is warranted. **Oral steroids** at a dose of 1 mg/kg may decrease edema in the first 7 days limiting ultimate fibrosis. In patients with significant sinus disease, antibiotics may be considered, usually a penicillin or cephalosporin.

The patient mentioned above has a “friend” who was also in the altercation. He, too, was just “minding his business”—like everyone in the bar—until there was a gentleman’s disagreement that could only be resolved with a broken beer bottle. He has a simple laceration of the chin, which you repair. This patient has a blood alcohol level of 150 mg/dL (the legal limit in most states is 80 mg/dL). Since he is intoxicated, the nurses are reluctant to allow the patient to leave because of liability issues. He seems initially very cooperative and competent. However, the nurse manager reminds you of the legal issues. The patient is getting more agitated; he wants to go home.

Question 1.8.7 Your response is:

- A) Sedate the patient with haloperidol and observe him until sober
- B) Sedate the patient with a benzodiazepine and observe him until sober
- C) Call the police to remove this patient from your ED
- D) Use restraints on the patient and observe him until sober, as sedative drugs may prolong time in the ED
- E) Let the patient leave the ED with a competent adult

Answer 1.8.7 The correct answer is “E.” The patient was initially cooperative and competent. Competence *is not* based on a blood alcohol level but rather on your judgment of the patient’s ability to make rational decisions. We allow patients on narcotics to make decisions about their own care all of the time despite having narcotics on board. There are patients who will have capacity and are safe at a blood alcohol of 200 mg/dL and others who may be impaired at 80 mg/dL. So, judge capacity individually.

► Objectives: Did you learn to ...

- Treat acute dental trauma?
- Diagnose and manage nasal and periorbital trauma?
- Care for the intoxicated patient with minor trauma?

► CASE 1.9

A 17-year-old female fell asleep with her contact lenses in her eyes last evening. This morning she notes quite a bit of eye pain and photophobia. You evert the eyelids (something that should be done in all cases of possible foreign body) and find no evidence of a foreign body. When you stain her eye, you find a corneal ulcer.

Question 1.9.1 The treatment for this patient is:

- A) Debridement with a burr and systemic antibiotics
- B) Debridement with a cotton swab and systemic antibiotics
- C) Topical antibiotics, topical cycloplegia, and ophthalmologic referral
- D) Copious irrigation, systemic antibiotics, and cycloplegia

Answer 1.9.1 The correct answer is “C.” This is an ophthalmologic emergency that requires topical antibiotics, cycloplegia (for pain control), and referral to an ophthalmologist. These ulcers can become quite deep and result in a ruptured globe.

You consult with your ophthalmologist who would like you start a cycloplegic agent in this patient prior to transfer.

Question 1.9.2 The drug you would choose for a cycloplegic agent is:

- A) Pilocarpine eye drops
- B) Timolol eye drops (e.g., Timoptic)
- C) Tetracaine eye drops
- D) Cyclopentolate eye drops

Answer 1.9.2 The correct answer is “D.” Cyclopentolate is the only cycloplegic agent listed above. Cycloplegic agents paralyze the ciliary muscle dilating the pupil (mydriasis) so that the eye cannot accommodate. Pilocarpine (“A”) is a miotic agent. Timolol (“B”) is a beta-blocker used in the treatment of glaucoma. Tetracaine (“C”) eye drops are a topical anesthetic. Thus, “D” is the only correct answer. Other cycloplegic agents include homatropine and atropine. However, these have a prolonged effect.

Question 1.9.3 If your patient just had a simple corneal abrasion, you would not have had to think so hard! Regarding corneal abrasions, you realize that:

- A) Patching an eye after a corneal abrasion reduces pain and promotes healing
- B) If a topical antibiotic is needed after a large corneal abrasion, gentamicin ophthalmic ointment is the drug of choice
- C) Tetracaine is a good topical anesthetic and should be considered for home use in patients with a painful corneal abrasion
- D) Patients should avoid wearing contact lenses until the eye has been healed for at least a week

Answer 1.9.3 The correct answer is “D.” A is incorrect because patching an eye may actually increase pain and decrease healing. Whether or not to use a patch should be a matter of patient comfort only. “B” is incorrect because gentamicin ophthalmic ointment (as well as other topical aminoglycosides) actually reduces healing of the cornea, and antibiotics are not necessary unless there are signs of infection. “C” is incorrect because patients should never be sent home with a topical anesthetic. They reduce healing and can lead to further injury if the patient, whose eyes are now insensate, continues a harmful activity, rubs his/her eyes, etc. The thinking on this is changing a bit (*Ann Emerg Med.* 2018;71:767–778), but most still avoid sending a patient home with topical anesthetics.

**HELPFUL TIP:**

To differentiate a topical ophthalmologic problem from iritis, put in some tetracaine. If the pain resolves, it is likely, **but does not prove**, that the problem is superficial (e.g., corneal abrasion). Posttraumatic iritis is manifested by ciliary flare, anterior chamber cells, and marked photophobia. These patients really need a slit lamp examination.

► Objectives: Did you learn to ...

- Recognize a corneal ulceration and treat it appropriately?
- Treat corneal abrasions?
- Understand the proper use of cycloplegic agents?

**QUICK QUIZ: EYE TRAUMA**

You are on call for your group and a welder who was welding and grinding presents at 2:00 AM with severe bilateral eye pain. When he left work at 5:00 PM the day before, he did not notice any problem. He notes that he was wearing his dark goggles some of the time while he was welding but did quite a bit of work without goggles as well.

The most likely diagnosis in this patient is:

- A) Foreign body
- B) Ultraviolet (UV) keratitis
- C) Globe penetration secondary to the welding and a foreign body
- D) Iritis

The correct answer is “B.” This patient likely has UV keratitis. The others are not likely because they generally present unilaterally. In addition, in the cases of “A” and “C,” they should present directly after the event rather than 9 hours later, as in our patient. UV keratitis is found in patients who are welders or have been out in the sun for an extended period of time (at the beach, snow skiing [“snow blindness”], tanning bed, etc.). UV keratitis generally presents as severe, bilateral, eye pain about 6 to 10 hours following the activity. It is treated with cycloplegic agents and pain medication, often requiring narcotics.

**HELPFUL TIP:**

Patients who have a foreign body in the eye following a high-speed injury (e.g., grinding wheel) should be assumed to have a globe perforation until proven otherwise.

**QUICK QUIZ: ORTHOPEDIC EMERGENCIES****Which of the following is most commonly associated with significant vascular injury?**

- A) Pubic ramus fracture
- B) Knee dislocation

- C) Shoulder dislocation
- D) Elbow dislocation
- E) Ankle dislocation

The correct answer is "B." In up to 33% of knee dislocations (*not patellar dislocations*), a popliteal artery injury can be identified. It is debated as to whether all patients with knee dislocations require angiography or CT angiography or if physical examination and ankle-brachial indices are sufficient to rule out popliteal artery injury, but vascular injury is a major cause of limb loss and morbidity. "A" is incorrect because pubic ramus fractures are relatively minor injuries without vascular involvement, requiring only pain control. Shoulder dislocations ("C") are commonly associated with injury to the axillary nerve. Elbow dislocations ("D") can be associated with injury to the median nerve and brachial artery. However, arterial injuries are much less common than with knee dislocations. Ankle dislocations ("E") are rarely associated with vascular injury.

► CASE 1.10

A 55-year-old male farmer is injured by a grass-fed cow that pins him against a fence. His leg was trapped against the fence for several minutes. Being a typical Midwestern farmer, he ignores the injury until his wife convinces him later that afternoon to have it evaluated. He presents to your office complaining of severe pain in the calf area. A radiograph is normal, and the patient has normal distal pulses. The calf (his leg, not the cow) is tender with increased pain on passive stretch. His pain seems to be out of proportion to his injury. The calf (the cow) may also be tender and USDA grade prime.

Question 1.10.1 Which of the following is true?

- A) Since the patient has excellent pulses, a compartment syndrome is not likely
- B) Compartment syndrome is defined as compartment pressure >30 mm Hg
- C) Compartment syndrome is only associated with significant crush injuries or fractures
- D) Pain out of proportion to the injury is a red flag for compartment syndrome

Answer 1.10.1 The correct answer is "D." Pain out of proportion to the injury is a red flag for compartment syndrome. "A" is incorrect because pulses can be maintained until there is significant increase in compartment pressures and significant injury to muscle and nerves. "B" is incorrect because it is difficult to define a specific cutoff for compartment syndrome. Some patients tolerate higher pressures and others cannot tolerate 30 mm Hg (normal compartment pressure is zero). However, when the pressure gets above 20 to 30 mm Hg, strong consideration should be given to the presence of compartment syndrome. "C" is incorrect. Compartment syndrome can be due to a number of factors including electrical injury, excessive muscle use, tetany, reperfusion after ischemia, aggressive volume resuscitation, etc.

HELPFUL TIP:

The classic findings of arterial insufficiency (the "5 Ps" being pulselessness, paresthesia, pallor, pain, and paralysis) are often considered necessary for compartment syndrome to be diagnosed. This is incorrect. Of these, pain is often the only symptom; the second most frequent would be paresthesia. If your patient has compartment syndrome with the "5 Ps" present, there is likely extensive injury.

You decide that it is likely that this patient has a compartment syndrome.

Question 1.10.2 Which of the following labs will be the most helpful in guiding treatment for this patient?

- A) CBC
- B) Urinalysis
- C) Glucose
- D) Sodium
- E) PT/PTT

Answer 1.10.2 The correct answer is "B." One of the major complications of compartment syndrome is rhabdomyolysis. This will manifest itself as a urine which is dipstick positive for blood, but with a negative microscopic examination for red blood cells. The positive dipstick is picking up myoglobin in the urine. Rhabdomyolysis can be confirmed by a serum level of creatine phosphokinase (CPK). CBC, glucose, sodium, and coagulation studies may be appropriate depending on the clinical situation, but are not useful in establishing the presence of myoglobinuria.

HELPFUL TIP:

Myoglobin can be measured in the urine. However, many laboratories have stopped doing this test favoring the positive dipstick/negative microscopic examination approach. **There can be other causes of a heme positive dipstick.** Thus, always check a CPK as well if rhabdomyolysis is a consideration.

The patient has a positive dipstick for blood with no red blood cells on microscopic examination (presumptive myoglobinuria). His serum CPK is 32,000 U/L, which is well above five times the upper limit of normal (the cutoff for consideration of rhabdomyolysis; although levels of >15,000 U/L are common when one has symptomatic rhabdomyolysis), so you make the diagnosis of rhabdomyolysis.

Question 1.10.3 The most common adverse consequence and greatest danger of rhabdomyolysis is:

- A) Disseminated intravascular coagulation (DIC)
- B) Acute kidney injury
- C) Seizure from hypocalcemia

- D) Acute gout from hyperuricemia
E) Cardiac arrhythmia from hyperkalemia

Answer 1.10.3 The correct answer is “B.” Myoglobin precipitates in the renal tubules causing acute kidney injury. “A,” DIC, can occur but is rare. “C,” seizures from hypocalcemia, have not been reported in this condition, nor has “D,” gout. The potassium elevation from rhabdomyolysis may reach a level sufficient to cause arrhythmias (“E”); however, this is not as common as “B”; this is exacerbated by possible coexistent hypocalcemia.

Question 1.10.4 The primary treatment for rhabdomyolysis is:

- A) Mannitol infusion
B) Saline infusion
C) Furosemide
D) Dialysis

Answer 1.10.4 The correct answer is “B.” The most important treatment for rhabdomyolysis is saline infusion. Lactated Ringers should be avoided as it contains potassium, which may further contribute to hyperkalemia as mentioned above. Previously, there has been debate over alkalinization of the urine (using IV sodium bicarbonate) and whether it has any additive benefit for preventing acute kidney injury over saline alone, but there is no evidence to support this practice. “A,” mannitol, can be used to increase urine flow, but this is really a treatment that is secondary to good hydration and may cause hypovolemia compounding the problem. “C,” furosemide, is controversial and has no outcome benefit but can be used for fluid overload. “D,” dialysis, is what we are trying to avoid using saline.

HELPFUL TIP:

In adult patients with rhabdomyolysis, the goal is to maintain urine output of 200 to 300 cc/hr.

The patient is able to maintain urine output after you institute saline.

Question 1.10.5 What treatment are you going to suggest for the underlying compartment syndrome?

- A) Fasciotomy
B) Immobilization and traction
C) Hot packs and elevation of the affected limb
D) Ice and elevation of the affected limb
E) Below knee amputation

Answer 1.10.5 The correct answer is “A.” The treatment of compartment syndrome is fasciotomy. A rapid surgical or orthopedic consultation is critical in the treatment of compartment syndrome. “E” is what we are attempting to avoid by urgent treatment with fasciotomy. The other options will not treat compartment syndrome and should not delay urgent treatment with fasciotomy.

The patient does well and everyone is happy ... except for the cow, who finds his way onto the table as the centerpiece of Christmas dinner.

► **Objectives: Did you learn to ...**

- Recognize manifestations of compartment syndrome and understand that compartment syndrome can be present with pain alone?
- Identify patients at risk for compartment syndrome and rhabdomyolysis?
- Manage compartment syndrome?
- Diagnose and treat rhabdomyolysis?

► **CASE 1.11**

A 24-year-old African-American male presents to the ED complaining of fever, chills, and dyspnea. He has chest pain that is respirophasic (“pleuritic”) in nature. He is noted to be tachypneic with a respiratory rate of 36 and an oxygen saturation of 90% on room air. He has a history of sickle cell disease and has had a number of sickle cell crises in the past. He is up to date on immunizations, including *Streptococcus pneumoniae* and *Haemophilus influenzae* vaccines.

Question 1.11.1 The patient’s current symptoms are MOST concerning for and suggestive of:

- A) Pneumothorax
B) Pulmonary embolism
C) Acute chest syndrome
D) Sickle cell–related pericarditis
E) Thoracic aortic aneurysm dissection

Answer 1.11.1 The correct answer is “C.” This patient likely has acute chest syndrome, which is associated with sickle cell anemia and may be indistinguishable from pneumonia. Acute chest syndrome is characterized by pleuritic chest pain, fever, cough, chills, dyspnea, rales, and rhonchi. The etiology is unknown, but it may be secondary to infarction of the lung and/or fat emboli. All of the other diagnoses should also be entertained at this point, but acute chest syndrome is most likely. Sickle cell–related pericarditis (“D”) is a rare complication of the disease.

Question 1.11.2 All of the following are recommended in the initial treatment of acute chest syndrome EXCEPT:

- A) Hydroxyurea
B) Oxygen
C) IV normal saline
D) Morphine

Answer 1.11.2 The correct answer is “A.” Hydroxyurea, while useful for the chronic treatment of sickle cell anemia, is not indicated for the treatment of acute chest syndrome. However, it can reduce the incidence of acute chest syndrome by 50% when used chronically. Management of acute chest syndrome includes alleviating hypoxia (“B”), IV fluid resuscitation (“C”),

and appropriate analgesia (“D”). Other treatments include IV antibiotics to cover for community-acquired pneumonia (although acute chest syndrome is *not bacterial*). It is prudent to cover these patients with antibiotics because adult patients with sickle cell are de facto splenectomized and the initial presentation of acute chest syndrome can be easily confused with pneumonia.

The patient continues to be hypoxic despite your therapy. His CBC shows a slight elevation in the WBC count and a hemoglobin of 9 g/dL. A chest radiograph indicates progression of infiltrates.

Question 1.11.3 The next step in treating this patient is:

- A) Fresh frozen plasma
- B) Pentoxifylline
- C) Packed red blood cells
- D) Exchange transfusion
- E) Any of the above

Answer 1.11.3 The correct answer is “D.” Patients with acute chest syndrome who remain hypoxic with progressing infiltrates are candidates for exchange transfusion to bring the level of HbS to <30% of the total. Simply administering blood (“C”) will not resolve the problem because HbS will still be present in significant amounts. If this patient had a more significant anemia, packed red cell transfusion would be a more viable option. But transfusion at a level of 9 g/dL of hemoglobin is not indicated (generally the threshold is 7 g/dL in the hemodynamically stable patient). “A” and “B” are also incorrect. Fresh frozen plasma has no role in the treatment of acute chest syndrome, nor does pentoxifylline.

Your patient recovers from this episode. He has had numerous pain crises in the past, as well as hospitalizations for other reasons. You have an opportunity to provide some patient education. You answer a few of your patient’s questions and then review potential manifestations of sickle cell disease.

Question 1.11.4 Which of the following may be a manifestation of sickle cell disease?

- A) Joint and bone pain
- B) Acute abdominal pain
- C) Acute sequestration syndrome
- D) Aplastic crisis
- E) All of the above

Answer 1.11.4 The correct answer is “E.” All of the above can be associated with sickle cell anemia (keep reading for additional information).

Question 1.11.5 Which of the following infections is a common cause of aplastic crisis in sickle cell anemia?

- A) Parvovirus B-19
- B) Influenza virus
- C) CMV virus

- D) Parainfluenza virus
- E) None of the above

Answer 1.11.5 The correct answer is “A.” Patients with sickle cell anemia can develop aplastic anemia in response to a parvovirus B-19 infection. Epstein–Barr virus and some bacteria have also been reported to cause aplastic crisis in patients with sickle cell anemia.

Question 1.11.6 Acute sequestration syndrome is a manifestation of sickle cell anemia. In which group does acute sequestration syndrome occur?

- A) Younger than 5 years
- B) 5 to 12 years old
- C) 12 to 25 years old
- D) Older than 25 years
- E) Older than 65 years

Answer 1.11.6 The correct answer is “A.” Acute sequestration syndrome occurs when the spleen sequesters red blood cells, leading to a drop in hemoglobin. The presentation can be quite dramatic with severe left upper quadrant pain, splenomegaly, and profound anemia, sometimes resulting in hypovolemic shock and death. Because it requires a functional spleen, it is most common in children younger than 5 years. Patient with sickle cell anemia who are older than 5 years generally do not have a functioning spleen; most often it is infarcted so that acute sequestration syndrome no longer occurs. The mortality of acute sequestration syndrome is 15% per episode and 50% recur.

HELPFUL TIP:

Exchange transfusions to reduce the percent of HbS to <30% is also indicated in stroke. Also, keep the hemoglobin >9 g/dL in those with a sickle cell–related stroke.

► Objectives: Did you learn to ...

- Recognize acute chest syndrome?
- Manage a patient with acute chest syndrome?
- Use exchange transfusion in a patient with sickle cell anemia?
- Recognize various other manifestations of sickle cell anemia?

► CASE 1.12

A 52-year-old truck driver presents to your ED after being out in subzero temperatures for several hours trying to repair his truck. He is hypothermic when you use a low-reading rectal thermometer with appropriate calibration (“Thanks for getting the most accurate temperature, doc!”). His initial core temperature is noted to be 28°C. He has a pulse of 24 bpm, a BP of 70/30 mm Hg, and slowed mentation. However, he is awake, and thus able to joke about a thermometer in his rectum.

Question 1.12.1 The appropriate first-line treatment for this patient's profound bradycardia is:

- A) Atropine
- B) Epinephrine
- C) Dopamine
- D) Lidocaine
- E) Re-warming

Answer 1.12.1 The correct answer is "E." The hypothermic heart is generally resistant to drugs. Thus, the best treatment for this patient is re-warming. Bradycardia from other causes can be treated with atropine 0.5 mg IV push or infusion of epinephrine or dopamine depending on the underlying rhythm.

Question 1.12.2 All of the following are acceptable methods of re-warming THIS patient EXCEPT:

- A) Active external re-warming (e.g., hot packs)
- B) Immersion in 40°C water
- C) Passive external re-warming (e.g., blankets)
- D) Heated, humidified oxygen
- E) Thoracic lavage with warm fluids

Answer 1.12.2 The correct answer is "C." Patients with a temperature below 30°C generally do not have enough endogenous heat production to effectively re-warm themselves. Thus, external or internal **active** re-warming is indicated. All of the other options are acceptable methods of re-warming this patient. Extracorporeal blood warming via ECMO or dialysis along with thoracic cavity lavage via chest tubes and warm crystalloid are also effective. Gastric, rectal, and bladder lavage with warm fluids are generally not very effective because of the limited surface area involved. Plus, they can cause large electrolyte shifts.

Question 1.12.3 Rapid re-warming of the extremities is associated with:

- A) Alkalosis, hypokalemia
- B) Acidosis, hypokalemia
- C) Acidosis, hyperkalemia
- D) Alkalosis, hyperkalemia
- E) Mixed acid–base disorder

Answer 1.12.3 The correct answer is "C." Re-warming of the extremities can lead to return of cold blood to the core leading to a paradoxical drop in body temperature. In addition, hypothermia causes lactic acidosis with hyperkalemia in the extremities. As the peripheral blood is re-warmed and peripheral vasodilation occurs, the hyperkalemic, acidotic blood is mobilized to the patient's central circulation, with resultant systemic metabolic acidosis and hyperkalemia.

Question 1.12.4 Which of the following is NOT associated with an increased risk of hypothermia?

- A) Diabetes mellitus
- B) Obesity
- C) Alcohol use
- D) Old age
- E) Chronic illness

Answer 1.12.4 The correct answer is "B." In Iowa, we start to work on our winter fat layer in October for just this reason. Why do you think we eat all that candy corn? Obese patients have a smaller body surface area-to-mass ratio, which is somewhat protective for hypothermia. "C," alcohol use, causes patients to be relatively insensate to cold (thus the term "liquid jacket"), causes a peripheral vasodilatation, increasing heat loss, and causes poor choices (like not wearing a real jacket). Thermoregulation is impaired as we age. Thus, "D," old age, is associated with a greater propensity toward hypothermia. Diabetes ("A") and any chronic illness ("E") can also predispose to hypothermia.

The patient's mental status clears and he complains that his fingers and toes, which were numb and cold, are now quite painful. You note that there is probably freezing of tissue (frostbite).

Question 1.12.5 The best method of re-warming the frostbite is:

- A) Slowly in tepid water
- B) Rapidly in the hottest water he can stand (tested by you, of course, to ensure that there will be no burns)
- C) Using a hot air source such as a hair dryer
- D) Using moist heat via a heating pad
- E) Wearing mittens

Answer 1.12.5 The correct answer is "B." Frostbitten parts should be re-warmed as quickly as possible in hot water between 37°C and 40°C. Water temperature cooler and hotter than this can lead to increased tissue loss. The other methods "A," "C," "D," and "E" are not recommended. *Do not re-warm parts that may become frozen again* (i.e., if you are in the field). Re-freezing will cause additional damage.

The patient has a lot of pain after thawing and reperfusion. You control the pain with morphine.

Question 1.12.6 Which of the following is the most appropriate dose of morphine in this hemodynamically stable 100-kg male?

- A) 2 mg IV
- B) 4 mg IV
- C) 6 mg IV
- D) 8 mg IV
- E) 10 mg IV

Answer 1.12.6 The correct answer is "E." The appropriate dosing of morphine in acute pain is a never-ending source of amazement to our resident physicians who prefer to start with 1 to 2 mg IV. Nonetheless, the correct dose of IV morphine is 0.1 mg/kg or 10 mg in this 100-kg male. Similarly, the correct dose of fentanyl is 1 µg/kg (100 µg in a 100-kg adult) and the dose of hydromorphone is 0.015 mg/kg (1–2 mg in a 100-kg adult). However, there really is no "fixed" dose of narcotic pain medication in the ED. Titrate the dose until you obtain pain relief—with the patient still breathing.

It is 2 days later. The patient is noted to have black eschar on multiple fingers and toes. There is no obvious perfusion to these areas.

Question 1.12.7 The best course at this point is:

- A) Debridement of the nonviable tissue
- B) Skin grafting over open areas after debridement
- C) Observation for a number of weeks despite the black eschar
- D) Amputation of the nonviable distal digits

Answer 1.12.7 The correct answer is “C.” It can take weeks for the proper demarcation line for debridement and grafting to become apparent. Thus, aggressive intervention at this point is counterproductive and may lead to additional tissue loss. For this reason, “A” and “D” are incorrect. Skin grafting is also not appropriate at this time because debridement of the eschar is not appropriate.

► **Objectives: Did you learn to ...**

- Identify severe bradycardia in hypothermia and treat it appropriately?
- Manage a patient with hypothermia?
- Use methods of re-warming and identify complications of re-warming?
- Recognize risk factors for hypothermia?
- Diagnose and manage frostbite?

QUICK QUIZ: DANGER IN THE LAUNDRY ROOM

Which of the following is true about the ingestion of household bleach?

- A) Patients who drink household bleach are at a high risk of esophageal and gastric burns
- B) Oral burns are a good predictor of esophageal burns
- C) All patients who ingest household bleach should be referred for upper endoscopy to rule out burns
- D) Household bleach ingestions are generally benign and require no treatment if the patient is not symptomatic

The correct answer is “D.” Most household bleach ingestions are benign and need no therapy if the patient is asymptomatic. However, this does not extend to industrial bleach or drain cleaner. There is a high risk of esophageal and gastric burns with industrial bleach. “B” is incorrect. The oral mucosa may be normal in industrial bleach or drain cleaner ingestion and there may still be significant esophageal and gastric burns. For this reason, all patients with drain cleaner or industrial bleach ingestion should undergo upper endoscopy. “C” is incorrect; patients with household bleach ingestions do not require upper endoscopy unless symptomatic.

► CASE 1.13

An 18-year-old male was working outside in the heat and humidity. The outside temperature reached 105°F with 90%

humidity. He usually lives in northern Canada and works for the government tracking the migration of caribou—but he is here in Iowa on a job detasseling corn. (This is a real thing. Look at www.teamcorn.com—seasonal hard work that pays well.) His friends noticed that he became confused, complained of a headache and muscle cramps, and became light-headed. On arrival to your ED, he is not sweating and is lethargic. His rectal temperature is 41.5°C. He says with a smile, “Guess I just can’t handle the heat, eh?”

Question 1.13.1 All of the following are indicated in the treatment of this patient EXCEPT:

- A) Pack the patient in ice to reduce core temperature
- B) IV fluids
- C) Use a fan and spray water on the patient to promote evaporative cooling
- D) Administer glucose if the patient is hypoglycemic

Answer 1.13.1 The correct answer is “A.” Packing patients in ice is contraindicated. Total body immersion in ice water is useful but packing the person in ice actually reduces cooling for two reasons. First, it causes cutaneous vasoconstriction. Second, it does not allow conductive cooling such as would be seen in ice water submersion: solid ice does not have as much skin contact as water or the circulation to conduct away the heat. Remember that submersion in ice is also associated with causing hypothermia. The appropriate treatment of heat exhaustion/heat stroke (heat stroke being defined as CNS dysfunction with a change in the level of consciousness) is cool water-soaked blankets and towels with fans aimed at the patient. This allows evaporative cooling and also conductive heat loss (to the water in the towels). Antipyretics are generally not effective because by this point, the patient’s endogenous thermoregulation is kaput.

Question 1.13.2 Which of the following IS NOT a contributing factor to heat exhaustion/heat stroke?

- A) Use of stimulants such as ephedra or amphetamines
- B) Dehydration
- C) Anticholinergic drugs
- D) Thin body habitus
- E) Extremes of age

Answer 1.13.2 The correct answer is “D.” This is why Iowans start to work on their swimsuit figures in April—it’s a matter of life-or-death, not narcissism. A thin body habitus is not a risk factor for heat stroke/exhaustion; the opposite is true. Obesity predisposes to heat stroke/exhaustion because there is less evaporative surface area per kilogram of weight. All of the others predispose to heat-related illness. “A” and “C” reduce sweating and, in the case of “A,” increase metabolic rate. Both of these predispose to heat-related disease. Of particular note is “E.” Small children sweat less readily than do adults. This predisposes them to heat-related disease but makes them less stinky than adults. The elderly do not have the same compensatory ability as younger adults.

**HELPFUL TIP:**

Up to 80% of patients with heat stroke will not have a prodrome of nausea, lightheadedness, confusion, headache, etc., which is seen in heat exhaustion. Make sure you check hepatic enzymes in patients in whom you suspect heat stroke. They are almost uniformly elevated (beware they may take several hours to rise) and normal liver enzymes should cause you to question your diagnosis.

► **Objectives: Did you learn to ...**

- Recognize and manage heat exhaustion/heat stroke?
- Recognize risk factors for heat exhaustion/heat stroke?

► **CASE 1.14**

A 19-year-old female presents to the ED with complaints of wheezing. She has a history of asthma. You have been following her since her eighth birthday when her mother noticed that she couldn't blow out her candles. In general, she has mild asthma controlled with occasional albuterol and not requiring an inhaled steroid. However, over the past several months, things have accelerated, and she now uses her rescue inhaler daily. On examination, she is tachypneic, using accessory muscles of respiration with a respiratory rate of 30 and wheezing in all fields. Her oxygen saturation is 95% on room air. Pulse is 110 bpm with a normal BP. Her blood gas is as follows: pH 7.40, CO₂ 40 mm Hg, O₂ 80 mm Hg, and HCO₃ 24 mEq/L.

Question 1.14.1 A normal blood gas in this patient suggests that:

- A) This is a mild exacerbation that should respond well to therapy
- B) She has a respiratory acidosis
- C) She has a respiratory alkalosis
- D) This is a severe exacerbation that will require aggressive therapy
- E) She can safely be discharged

Answer 1.14.1 The correct answer is "D." A pH of 7.4 with a CO₂ of 40 mm Hg in a patient who is asthmatic and tachypneic is a bad sign. The CO₂ *should* be low in a tachypneic patient because they will be blowing off CO₂. Thus, a normal CO₂ and normal pH indicate that the patient is retaining CO₂. This is just another case where looking at the patient is more important than looking at the labs. Even though the blood gas itself is technically within normal limits, this patient clinically appears sick. "B" and "C" are both incorrect since the blood gas indicates neither an acidosis nor alkalosis.

Question 1.14.2 Which of the following tests are indicated in routine evaluation of a patient with an asthma exacerbation?

- A) Chest x-ray
- B) CBC

- C) Arterial blood gas
- D) All of the above
- E) None of the above

Answer 1.14.2 The correct answer is "E." None of the above tests are indicated in the routine evaluation of an asthma exacerbation. A chest x-ray ("A") should be reserved for those patients in whom pneumonia or other pulmonary process is suspected. A CBC ("B") is not going to change your therapy in the routine asthma exacerbation and is not indicated. Likewise, an ABG ("C") is unnecessary in most asthma exacerbations. It can be used to assist in your clinical evaluation to determine whether or not the patient is retaining CO₂; however, even in the "crashing patient," an ABG is not necessary because **intubation is a clinical decision and should not be based on the blood gas.**

Question 1.14.3 You decide to initiate therapy for this patient. Of the following options, the *initial* treatment of this patient is:

- A) Subcutaneous epinephrine
- B) Albuterol MDI (metered-dose inhaler) with spacer
- C) Nebulized ipratropium
- D) Oral steroids
- E) IV steroids

Answer 1.14.3 The correct answer is "B." The initial treatment for this patient—and any patient presenting with an asthma exacerbation—is a bronchodilator. A beta-agonist is preferred, in this case albuterol. It makes little difference whether this is via nebulizer or MDI, as long as one uses adequate doses. One albuterol nebulization is equal to about 8 to 10 puffs of an albuterol MDI with a spacer. "A" is incorrect because subcutaneous epinephrine is second or third line in the treatment of asthma. "C" is incorrect. While ipratropium *is* effective in asthma, it may be given with albuterol (Duoneb) and should not be given alone. "D" and "E" are incorrect. Steroids are indicated, but bronchodilator therapy is the primary treatment in acute asthma exacerbations.

There is no albuterol MDI available to you in your ED, so the patient receives nebulized albuterol. However, she continues to wheeze.

Question 1.14.4 How many albuterol treatments can this patient safely receive?

- A) One every other hour
- B) One per hour
- C) Two per hour
- D) Three per hour
- E) Continuous nebulization of albuterol is safe

Answer 1.14.4 The correct answer is "E." Albuterol can be administered via nebulizer continuously if needed, even in the pediatric age group. Tachycardia, one of the main side effects of albuterol treatment, will often **improve** with continuous albuterol. This occurs because the patient's tachycardia is often driven by hypoxia. Once the asthma is adequately treated, oxygenation improves, and the pulse comes down.

The patient does not respond well to albuterol alone, so you add ipratropium. At this point, you also want to order steroids.

Question 1.14.5 Which of the following statements about steroid use in asthma exacerbation is true?

- A) IV steroids are superior to PO steroids in the treatment of asthma
- B) All patients who are steroid dependent should have additional systemic steroids even if they have already taken their dose for the day
- C) The effective dose range for steroids in asthma is well established
- D) Only patients requiring admission should have oral or parenteral steroids

Answer 1.14.5 The correct answer is “B.” All patients who are steroid dependent should get steroids if they present to the ED with an acute exacerbation of asthma. “A” is incorrect. IV steroids and oral steroids have the same efficacy in acute asthma exacerbations. Thus, the choice of route depends mostly on convenience and cost. “C” is incorrect. Multiple steroid dosing regimens and ranges of doses have been used in asthma with success. “D” is incorrect. Discharged patients who have anything more than a minor asthma exacerbation should receive steroids.

HELPFUL TIP:

When compared with oral steroids, IV steroids *may* increase hospitalizations, cost, and treatment failure in those with chronic obstructive pulmonary disease. Use oral steroids whenever possible; the bioavailability is high (JAMA. 2010;303(23):2359–2367).

HELPFUL TIP:

Magnesium sulfate (2 g over 10 minutes in adults, 25 mg/kg in children) can be used in patients with status asthmaticus. Magnesium is a direct smooth muscle relaxant. Not all patients will respond, and in patients who do respond, you can expect a 60- to 90-minute effect. Avoid using magnesium in patients with renal failure since they may become toxic.

The patient responds to nebulizers and steroids. You decide to send her home.

Question 1.14.6 Which of the following is true?

- A) You should discharge the patient on 2 puffs of an albuterol MDI via spacer to be used PRN
- B) You should place the patient on a steroid, tapering the dose over 3 weeks
- C) You should discharge the patient on 8 to 10 puffs of an albuterol MDI via spacer to be used every 6 hours around the clock

- D) You should start the patient on a steroid inhaler
- E) You should start the patient on a long-acting bronchodilator inhaler

Answer 1.14.6 The correct answer is “D.” The patient should be started on a steroid inhaler to prevent recurrent exacerbations. She has been using her albuterol daily, indicating poor control. Overlapping this with oral steroids will give the inhaled steroid a chance to work while the patient is being covered with the oral steroids. “A” is incorrect. One nebulization is equal to 8 to 10 puffs of an MDI. If you simply go back to low-dose albuterol, the patient is more likely to do poorly. We tend to underdose albuterol inhalers; patients can safely take more than 2 puffs. “B” is incorrect because patients *do not need a steroid taper* if they are not on chronic steroids and will not be taking steroids for more than 10 days. You can simply treat the patient (e.g., with prednisone 40 mg PO QD for 5–10 days) and then stop. No taper is needed. *Note that this is not true for patients on chronic steroids who clearly do need a taper.* “C” is incorrect because scheduled albuterol is not as effective as PRN use. In addition, albuterol can certainly be used more than every 6 hours. “E” is incorrect because long-acting inhaled bronchodilator therapy should not be used alone in asthma due to the potential to increase mortality; it should only be used with an inhaled steroid.

► **Objectives: Did you learn to ...**

- Recognize clinical and blood gas manifestations of a severe asthma exacerbation?
- Evaluate a patient presenting with an asthma exacerbation?
- Initiate treatment for asthma in the ED?
- Formulate a plan for discharging an asthma patient from the ED?

► **CASE 1.15**

A 7-year-old presents to the ED with wheezing and hives after being stung by a “bee.” He was evidently throwing rocks at a yellow-jacket nest when he was stung, so hopefully, he at least learned something. On examination, the patient has hives and wheezing with a normal BP for his age. He is mildly tachycardic.

Question 1.15.1 Potentially useful treatments for this patient include all of the following EXCEPT:

- A) IV diphenhydramine
- B) Intramuscular (IM) epinephrine
- C) Subcutaneous (SC) diphenhydramine
- D) IV cimetidine

Answer 1.15.1 The correct answer is “C.” Subcutaneous diphenhydramine can cause skin necrosis and is contraindicated. Either IV or IM diphenhydramine can be used. Of the others, *intramuscular* (not SC) epinephrine should be used in the patient with anaphylaxis; **epinephrine is the drug of choice for anaphylaxis.** Subcutaneous epinephrine is erratically

absorbed. Remember that diphenhydramine will not reverse bronchospasm or hypotension. If hypotension persists despite IM epinephrine and IV fluids, IV epinephrine should be administered. Intravenous H₂ blockers (e.g., cimetidine, ranitidine) *may be* effective in the treatment of anaphylaxis and should be used routinely in these patients.

HELPFUL TIP:

Only honeybees generally leave a stinger. Remove it by any means possible. The amount of envenomation is directly proportional to the amount of time the stinger is in the skin and *not* to how you remove it (credit card, forceps, etc.).

The patient responds well to the therapy. As you are going to discharge him and want to write his prescriptions.

Question 1.15.2 The patient should be discharged with which of the following?

- A) Diphenhydramine every 6 hours for the next 48 hours
- B) Cimetidine every 12 hours for the next 48 hours
- C) An anaphylaxis (“bee sting”) kit
- D) All of the above medications

Answer 1.15.2 The correct answer is “D.” Patients can have biphasic reaction mediated by “slow reacting substance of anaphylaxis,” which is now believed to be a neutrophil chemotactic factor. This recurrence may occur up to 48 hours after the initial event. Thus, prescribing medications such as antihistamines (diphenhydramine) and H₂ blockers (cimetidine) to prevent the recurrence is prudent (“A” and “B”). However, the rate of recurrence is <1% (*Ann Emerg Med.* 2014;63:736). Also, the patient should have a “bee sting” kit available (“C”), which should include a pre-filled syringe for epinephrine injection (e.g., Epi-Pen). It is recommended that patients have two syringes available at home as the failure rate with one injection is fairly high.

The parents are concerned about this child who likes to play outside. They worry that he will get stung again.

Question 1.15.3 You let them know that:

- A) Any sting should be treated as an emergency
- B) He will continue to be allergic to “bee stings” in the future
- C) He should take prophylactic medication before going out to play in the woods or other areas where he might get stung
- D) None of the above

Answer 1.15.3 The correct answer is “D.” Here is why. Patients who are allergic to one species of hymenopteran are not necessarily allergic to others. In general, the allergy is species specific. Thus, most stings will be benign in an allergic patient *unless* it is a sting from the offending species. “B” is incorrect. Many children tend to “outgrow” “bee sting” allergies. This is in contrast to adults in whom reactions tend to get

worse over time. “C” is incorrect. Obviously, the child should be careful not to irritate yellow jackets (did any of you hurl rocks at wasp nests as a kid?), but prophylactic treatment is not routinely indicated.

HELPFUL TIP:

Adults with a systemic allergic reaction to an insect sting have a 30% to 60% risk of experiencing another systemic reaction upon being stung again. Therefore, adults are more likely to benefit from venom testing and prophylaxis (which can reduce the risk to 5%). All patients with a history of anaphylaxis should be provided with an anaphylaxis kit.

► **Objectives: Did you learn to ...**

- Describe the physiology and natural course of bee sting reactions?
- Treat a patient with an anaphylactic reaction to a bee sting?

► CASE 1.16

A 14-year-old otherwise healthy male presents to the ED with acute onset left testicular pain when running 1 hour prior to presentation. He denies any trauma to the region. He states that his pain is severe and only on the left. The pain is increased with ambulation and movement. He has had nausea and vomiting. He denies diarrhea, fever, chills, dysuria, hematuria, or penile discharge.

Vital signs: temperature 37°C, pulse 110 bpm, respirations 18, and BP 120/85 mm Hg. He is in distress secondary to pain. **Abdomen:** normal bowel sounds, nontender, soft, no masses. **Genitourinary:** circumcised male, no penile lesions, no discharge. The left testicle is tender to palpation and has a normal lay in the scrotum. The cremasteric reflex is normal bilaterally.

Question 1.16.1 What is the significance of the normal lay and cremasteric reflex?

- A) The cremasteric reflex should be abnormal in epididymitis
- B) The presence of a cremasteric reflex effectively rules out testicular torsion
- C) The normal lay of the testicle in the scrotum effectively rules out testicular torsion
- D) The presence or absence of a cremasteric reflex is not helpful in ruling out testicular torsion

Answer 1.16.1 The correct answer is “D.” The presence or absence of a cremasteric reflex (cremasteric contraction with elevation of the testis in response to stroking of the same side upper thigh) is neither sensitive nor specific enough to confirm or rule out the presence of testicular torsion. Likewise, the lay of the testicle can be normal in patients with testicular torsion. An abnormal testicular lay and the absence of the cremasteric reflex may point toward testicular torsion. However, you cannot rely on these findings to rule out torsion.

Question 1.16.2 The LEAST likely diagnosis in this patient is:

- A) Torsion of testis
- B) Epididymitis
- C) Torsion of appendix testis
- D) Torsion of appendix epididymis
- E) Testicular tumor

Answer 1.16.2 The correct answer is “E.” Testicular torsion is characterized by acute onset of unilateral testicular pain, often during activity such as running. It has a bimodal age distribution, during the first year of life and again during puberty. The differential diagnosis is dependent on the patient’s age. If the patient is younger than 15 years, the differential consists of testicular torsion, epididymitis, torsion of appendix testis or appendix epididymis, orchitis, hydrocele, and varicocele. In patients older than 15 years, the differential includes all of these diagnoses plus testicular tumor. However, testicular tumors are generally painless and should not present with acute symptoms.

Question 1.16.3 What is the most reliable method for diagnosing testicular torsion?

- A) Doppler (Duplex color)
- B) Radionuclide scan
- C) Surgical exploration
- D) X-ray
- E) MRI

Answer 1.16.3 The correct answer is “C.” Every patient with suspected testicular torsion should have surgical exploration of the scrotum. All of the other studies are adjunctive. For example, radionuclide scan (“B”) may result in a false-negative and takes several hours to perform. Ultrasound (“A”) is operator dependent and may miss cases of torsion. Surgical exploration is the only definitive diagnostic tool. The window of opportunity for surgery is about 6 hours, after which the testicle may not be salvaged. Orchiopexy should be performed on the involved and uninvolved sides to prevent torsion. Manual detorsion can be attempted and requires sedation and pain medications. Twist testis like you are opening a book (the right testis counterclockwise and the left clockwise). If pain resolves, you have detorsed the testis.

► **Objectives: Did you learn to ...**

- Examine a patient presenting with acute scrotal pain?
- Generate a differential diagnosis for scrotal pain based on the patient’s age?
- Evaluate a patient with suspected testicular torsion?

QUICK QUIZ: UROLOGIC INFECTION 1

What is the most common agent causing epididymitis in a 21-year-old male?

- A) *Escherichia coli*
- B) *Neisseria gonorrhoeae*
- C) *Chlamydia trachomatis*
- D) *Pseudomonas* species
- E) *Ureaplasma urealyticum*

The correct answer is “C.” In young males, epididymitis is usually the result of sexually transmitted diseases. Of these, *C. trachomatis* is currently the most common etiologic agent. *N. gonorrhoeae* is second most common in this age group. It is therefore essential to treat for both agents when the diagnosis of epididymitis is suspected.

QUICK QUIZ: UROLOGIC INFECTION 2

What is the most common agent causing epididymitis in a 55-year-old male?

- A) *E. coli*
- B) *N. gonorrhoeae*
- C) *C. trachomatis*
- D) *Pseudomonas* species
- E) *U. urealyticum*

The correct answer is “A.” Gram-negative rods are the most common cause of epididymitis in older men. Of these, *E. coli* is the most common etiologic agent, followed by *Klebsiella* and *Pseudomonas* species.

► CASE 1.17

A 22-year-old otherwise healthy female college student presents to the ED with dysuria and urinary frequency of 2 days duration. She denies any abdominal/pelvic pain, flank pain, hematuria, fever, chills, vaginal discharge, nausea, vomiting, or diarrhea. Her last menses was 2 weeks ago, and she states she is not sexually active. She is on oral contraceptives to treat menstrual cramps and denies any allergies.

Question 1.17.1 A urine beta-HCG is NOT indicated for which of the following patients who presents with abdominal pain?

- A) A 32-year-old female who has had a tubal ligation
- B) A 16-year-old female who by history has never been sexually active
- C) A 25-year-old female who has had a normal period 1 week ago and swears on a stack of Bibles that she couldn’t possibly be pregnant
- D) A 24-year-old, married, professional female who is taking oral contraceptives and had a normal menses 1 month ago
- E) A 25-year-old male

Answer 1.17.1 The correct answer is “E.” Of course males do not need a pregnancy test (although the HCG may be elevated in testicular cancer). All female patients of reproductive age, except for those who have had a hysterectomy, must have a pregnancy test as part of the evaluation of abdominal pain. There are several reasons for this position. First, many patients may not be candid about their sexual activity. In fact, in one study, almost one-third of patients who said “they could not possibly be pregnant,” including one who denied ever having intercourse, were pregnant. Second, the failure rate of tubal ligation is up to 5%

over 10 years depending on the technique used (laparoscopic tubal ligation is the least reliable). To raise your concern a little higher, almost all of the pregnancies in patients who have had a tubal ligation are ectopic.

HELPFUL TIP:

When examining a patient whose history is consistent with vulvovaginitis, remember that a KOH preparation is only 65% to 80% sensitive for *Candida* and treatment based on symptoms and physical findings is certainly reasonable. There are PCR and DNA probe tests available as well. The DNA probe has a rapid turnaround time and is less expensive than the PCR.

You get a urinalysis (UA) on this patient, mostly out of habit. The UA shows 5 to 10 WBCs/HPF, 2 + bacteria, 2 + leukocyte esterase, and 1 + nitrite.

Question 1.17.2 Which of the following antibiotic regimens IS NOT indicated for the treatment of simple cystitis?

- A) 3-day course of trimethoprim-sulfamethoxazole (TMP-SMX)
- B) 3-day course of a fluoroquinolone
- C) 5-day course of nitrofurantoin
- D) Single dose of fosfomycin

Answer 1.17.2 The correct answer is “B.” The usual causative agents for uncomplicated cystitis are Gram-negative organisms such as *E. coli*. In areas that have high rates of resistance to TMP-SMX (>30% or more of isolated *E. coli* bacteria resistant), nitrofurantoin can be used. As to “B,” fluoroquinolones would be effective, but are not indicated for uncomplicated cystitis. There are several FDA warnings about systemic use of fluoroquinolones including concerns for tendinopathy, hypoglycemia, irreversible neurological symptoms, etc. Cephalexin is effectively used in pregnant females, although a 7-day course is recommended. Fosfomycin has a lower cure rate than the other regimens and is more expensive.

HELPFUL TIP:

A false-negative urinalysis is common in women with uncomplicated cystitis. Empiric treatment of urinary tract infection (UTI) is reasonable in a female of child-bearing years presenting with one or more typical symptoms (urgency, frequency, dysuria) and no vaginal symptoms. The sensitivity of symptoms is 90% while that of a dipstick is only 70%.

Question 1.17.3 All of the following patients with pyelonephritis should be admitted EXCEPT:

- A) A 22-year-old G1 P0 female <24 weeks of gestation, hemodynamically stable
- B) A 22-year-old female unable to tolerate PO fluids or medications

- C) A 22-year-old female with unreliable social situation and/or compliance
- D) A 22-year-old female with an unclear diagnosis or extreme pain

Answer 1.17.3 The correct answer is “A.” The old adage that all pregnant patients with pyelonephritis must be admitted has gone out of favor. It is safe to send patients home who are <24 weeks of gestation, compliant, have stable vital signs, and are accessible by telephone. Patients should be given clear instructions to return for any complications. All of the other situations require in-hospital care.

► Objectives: Did you learn to ...

- Decide which patients should have a urine beta-HCG in the ED?
- Provide appropriate antibiotic treatment to a patient with an uncomplicated UTI?
- Identify patients with pyelonephritis who require hospital admission?

► CASE 1.18

A 63-year-old male presents to the ED with a 2-day history of fever, urinary frequency, dysuria, and difficulty initiating the urinary stream. He also relates having some perineal pain. On examination, his vitals are stable except for a temperature of 38.5°C. His rectal examination is remarkable for a tender, warm, edematous prostate. There are no perirectal masses and the stool is heme negative. He has no penile lesions, discharge, scrotal masses, or tenderness. He does not exhibit any costovertebral angle tenderness. His UA is positive for 10 WBCs/HPF, 1+ nitrite, 1+ leukocyte esterase.

Question 1.18.1 What is the most likely diagnosis in this patient?

- A) Pyelonephritis
- B) Perirectal abscess
- C) Epididymitis
- D) Acute prostatitis
- E) Cystitis

Answer 1.18.1 The correct answer is “D.” This patient’s symptoms most closely fit those of someone with acute prostatitis. Although his UA is also consistent with pyelonephritis or cystitis, his examination findings are more suggestive of acute prostatitis. He lacks costovertebral angle tenderness (pyelonephritis), and he has a significant temperature that argues against a simple cystitis. In the absence of scrotal tenderness, epididymitis is also quite unlikely.

Question 1.18.2 What should be included in the treatment regimen for this patient?

- A) Oral fluoroquinolone or TMP-SMX for at least 3 weeks
- B) Instructions for hydration, sitz baths, stool softeners, and nonsteroidal anti-inflammatory drugs (NSAIDs)
- C) Admission for IV antibiotics if he appears toxic or hemodynamically unstable

- D) Foley or suprapubic catheter if urinary retention is a problem
E) All of the above

Answer 1.18.2 The correct answer is “E.” Patients with acute prostatitis should be treated for at least 3 weeks with oral antibiotics to prevent chronic prostatitis; some suggest up to 42 days. Treatment should be initiated with a fluoroquinolone while urine cultures are pending since sulfa resistance is high in some areas of the country.

While this patient is still in the ED, he develops acute urinary retention. A Foley catheter is placed without difficulty and 300 cc of slightly cloudy urine is obtained. Your patient feels much better and thanks you for alleviating his pain. You decide to discharge him home with the Foley catheter and a leg bag after discussion with a urologist and follow-up arrangement.

Question 1.18.3 Which of the following are causes of urinary retention in men?

- A) Phimosis, urethral stricture, benign prostatic hyperplasia (BPH), calculi
B) Anticholinergics, sympathomimetics, narcotics, antipsychotics
C) Psychogenic
D) Cauda equina syndrome, diabetes, spinal cord injuries
E) All of the above

Answer 1.18.3 The correct answer is “E.” All of the above can cause urinary retention in men. By far, the most common cause of acute urinary retention is BPH. The categories of acute urinary retention may be divided into neurogenic (spinal cord injuries, cauda equina syndrome, diabetes, syringomyelia, etc.), obstructive (BPH, phimosis, paraphimosis, calculi, urethral stricture, etc.), pharmacologic (anticholinergics, antihistamines, narcotics, antipsychotics, tricyclics, etc.), and psychogenic, which is a diagnosis of exclusion.

HELPFUL TIP:

Sending patients home on an alpha-blocker (e.g., doxazosin, tamsulosin) may reduce the need for re-catheterization after the catheter is removed.

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of acute prostatitis?
- Treat a patient with acute prostatitis?
- Identify causes of urinary retention in a male?

QUICK QUIZ: FORBIDDEN FORESKIN

Which of the following is characterized by a swollen, painful, retracted foreskin that cannot be reduced back to its normal position?

- A) Phimosis
B) Paraphimosis

- C) Balanoposthitis
D) Meatal stenosis

The correct answer is “B.” Paraphimosis is a condition in which the foreskin is retracted, swollen, and unable to reduce into its normal position. Ice and steady manual compression often permit reduction. Surgery is indicated if manual reduction fails. “A,” phimosis, is a condition in which the distal foreskin is too tight to be retracted to allow exposure of the glans. It is often confused with penile adhesions in those younger than 2 years. “C,” balanoposthitis, is a form of cellulitis involving the foreskin and glans in the uncircumcised male associated with poor hygiene. Treatment is with warm soaks, antibiotics, and possible circumcision. The use of antibiotics is dictated by the nature of the disease. Bacterial balanoposthitis is usually related to streptococcal, staphylococcal, gonococcal, or chlamydial infection. Treat based on your clinical suspicion. Candida, etc., require only topical antifungals. Good hygiene is a must. “D,” meatal stenosis, is common in *circumcised* males, associated with an inflammatory reaction involving the meatus. Symptoms that indicate the need for surgical treatment include spraying of the urine stream or dorsal deflection of the stream.

QUICK QUIZ: FORESAKEN FORESKIN

Until what age is it normal to have adhesions between the glans and foreskin in uncircumcised males?

- A) Adhesions are always abnormal
B) Age 6 months
C) Age 1 year
D) Age 2 years
E) Age 3 years

The correct answer is “E.” Some adhesions are normal in young children. However, the foreskin should be fully retractable in uncircumcised males by the age of 3 to 5 years. Before this, no action need be taken.

► **CASE 1.19**

A 20-year-old female presents to your ED complaining of low abdominal pain. She is on “the ring” for contraception and has been faithfully using it. She has had regular menses and has not noticed any change in her pattern of menses. Her pain had a sudden onset but is not associated with any vaginal bleeding. On vaginal examination, you find marked cervical motion tenderness but no palpable adnexal mass.

Question 1.19.1 Based on this information you decide that:

- A) The absence of an adnexal mass effectively rules out ectopic pregnancy
B) All forms of contraception reduce the risk of ectopic pregnancy (if the patient gets pregnant despite using contraception)

- C) The fact the patient has had normal periods effectively rules out an ectopic pregnancy
- D) Cervical motion tenderness effectively clinches the diagnosis of pelvic inflammatory disease
- E) None of the above is true

Answer 1.19.1 The answer is “E,” none of the above. “A” is incorrect because only 10% of patients with an ectopic pregnancy will have a palpable mass in the adnexa. “B” is incorrect because both intrauterine devices and tubal ligation *increase* the risk of ectopic pregnancy if the patient becomes pregnant. “C” is incorrect because 15% to 20% of patients with ectopic pregnancy have no history of missed menses. “D” is incorrect because cervical motion tenderness can be present not only in pelvic inflammatory disease but also in other illnesses such as ovarian torsion, ectopic pregnancy, etc.

Question 1.19.2 Risk factors for ectopic pregnancy include all of the following EXCEPT:

- A) Prior ectopic pregnancy
- B) Oral contraceptive use
- C) History of pelvic inflammatory disease
- D) Treatment for infertility
- E) Current intrauterine device use

Answer 1.19.2 The correct answer is “B.” All of the others increase the risk of an ectopic pregnancy. Other risk factors include cigarette smoking, recent elective abortion, previous tubal surgery, and tubal ligation.

You decide that this patient may have an ectopic pregnancy. A urine HCG test is positive for pregnancy.

Question 1.19.3 The significance of a positive pregnancy test is that:

- A) An ultrasound will be able to detect an ectopic pregnancy if one is present
- B) The serum level of HCG is *at least* 1,000 mIU/mL
- C) Combined with the patient’s abdominal pain and cervical motion tenderness, it effectively rules in an ectopic pregnancy
- D) The urine HCG is 98% sensitive for pregnancy 7 days after implantation

Answer 1.19.3 The correct answer is “D.” “A” is incorrect. The pregnancy test is positive very early and ultrasound may not be positive by an experienced operator until 6 weeks of pregnancy. “B” is incorrect. The urine may be positive at serum HCG levels of 25 to 50 IU/L. Patients may not have an HCG level of 1,000 IU/L until 6 weeks of pregnancy. “C” is incorrect because patients with a normal pregnancy may also have abdominal pain and cervical motion tenderness.

The patient’s serum HCG is 440 IU/L. You order an ultrasound and find no evidence of an intrauterine or ectopic pregnancy.

Question 1.19.4 Your next step is to:

- A) Reassure the patient that she does not have an ectopic pregnancy
- B) Recheck the serum HCG in 48 hours
- C) Refer for a laparoscopy to rule out ectopic pregnancy
- D) Recheck an HCG in 1 to 2 weeks
- E) Follow the patient clinically

Answer 1.19.4 The correct answer is “B.” In a normal pregnancy, the HCG should double every 1.8 to 3 days. If the HCG *is not* doubling in this time frame, it is likely an ectopic pregnancy. Remember, the fact that you did not see an ectopic pregnancy on ultrasound is irrelevant. By an HCG of 6,500 IU/L, an experienced ultrasonographer should certainly be able to see an intrauterine pregnancy on ultrasound; if not seen, an ectopic should be reconsidered. “A” is incorrect because of the above. “C” is incorrect. This is invasive and not needed. “D” is incorrect because of the time frame; the HCG should be rechecked in 24 to 48 hours. An ectopic may well rupture within 1 to 2 weeks. “E” is incorrect. If you follow the patient clinically, you are basically saying that you will wait until the ectopic ruptures before addressing the problem.

Question 1.19.5 You recheck the HCG in 48 hours and it is now 1,000 IU/L (prior level 440 IU/L). Your interpretation is that:

- A) This patient does not likely have an ectopic pregnancy
- B) This patient has a molar pregnancy
- C) This patient has a blighted ovum
- D) The patient has fetal demise of an intrauterine pregnancy
- E) All of the above are possible

Answer 1.19.5 The correct answer is “A.” Since the HCG doubled as expected in a normal pregnancy, it is *not* likely that this is an ectopic pregnancy, a blighted ovum (“C”) or intrauterine fetal demise (“D”). In all of these conditions, the HCG would not double. “B” is also not likely because in a molar pregnancy, the HCG would rise dramatically.

► **Objectives: Did you learn to ...**

- Evaluate a fertile female with pelvic pain?
- Diagnose an ectopic pregnancy?

QUICK QUIZ: TWISTED SISTER

Which of the following is typical of ovarian torsion?

- A) Periumbilical pain gradually migrating to both the right and left quadrants
- B) Sudden onset of colicky abdominal pain with vaginal bleeding
- C) Sudden onset of colicky abdominal pain in one of the lower quadrants
- D) Sudden low back pain with radiation to the perineum

The correct answer is “C.” Patients with ovarian torsion present with sudden onset of severe lower abdominal pain. The pain

is frequently colicky. Since only one ovary is involved, the pain is located in one side or the other. Spontaneous torsion/detorsion may also occur so that the pain may remit spontaneously. Ovarian torsion can be diagnosed by Doppler ultrasound that examines flow to the ovaries. However, many gynecologists consider this a clinical diagnosis, so obtain consultation early for suspected ovarian torsion cases. The treatment is surgical (think of it as equivalent to a torsed testis in a male).

► CASE 1.20

A middle-aged unresponsive, disheveled patient is brought by emergency medical services (EMS) to your ED. They had been called by his girlfriend who had seen him lying in the grass outside his home this morning. He has spontaneous respirations and shallow respirations of 20 per minute and a weak but palpable pulse at 110 beats per minute.

Question 1.20.1 What should be your first steps in assessment and treatment?

- A) Oxygen by nonrebreather mask (NRB), stat serum glucose, naloxone, and thiamine
- B) Oxygen by NRB, ECG, head CT
- C) Oxygen by NRB, intubate, ECG, head CT
- D) Intubate, ECG, head CT

Answer 1.20.1 The correct answer is “A.” There are several causes of unresponsiveness that can be immediately corrected. A helpful algorithm to recall in the initial treatment for an unresponsive patient is “DON’T”: Dextrose, Oxygen, Naloxone, Thiamine (the so-called “coma cocktail”). Answer “A” is correct because naloxone and oxygen are administered and glucose is checked. If a rapid blood sugar test is unavailable, empirical administration of dextrose would be appropriate. Rapid treatment of hypoxia, hypoglycemia, and narcotic overdose can improve mental status and thus avoid intubation. ECG and head CT (“B”) may be indicated later in the evaluation. You could argue for intubation in this patient since he is unresponsive (“C” and “D”), but the next steps would not be ECG and head CT. So “A” is the most appropriate answer.

The patient is found to be hypothermic, hypoglycemic, and hypoxic. He is placed on oxygen and given warm normal saline, an amp of D50W, and naloxone. The patient now is saturating at 98% on NRB. He is responding to painful stimuli by moaning and withdrawing his extremities but is not opening his eyes. He has gurgling respirations and still has no gag reflex.

Question 1.20.2 What is your next step?

- A) Intubate
- B) Obtain head CT
- C) Obtain ECG
- D) Continue on an NRB
- E) Obtain an ABG

Answer 1.20.2 The correct answer is “A.” Although the patient has improved and has normal oxygen saturation, his level of consciousness is still too low to protect his airway. Thus, he should be intubated before further diagnostic studies are performed. A simple method to determine the need for intubation is the GCS (Table 1-5). Patients with a GCS of 8 or less should be intubated, as they cannot protect their airway from aspiration of oral secretions and/or emesis. The rhyme “GCS of 8, intubate” assists in recollection of this rule. Those with a GCS of > 8 may also require intubation. Remember, intubation is a clinical decision and not all patients will follow the “GCS of 8 intubate” rule (e.g., someone you expect to have a rapidly downhill course such as in a subarachnoid hemorrhage). This patient has a GCS of 7 (eyes 1, verbal 2, movement 4). He has gurgling respirations, and you cannot ensure he is able to protect his airway. Therefore, he should be intubated before other studies or interventions. “D” is incorrect because he cannot protect his airway. “E” is incorrect because the decision to intubate is a clinical one and not tied directly to the blood gas!

The girlfriend arrives and gives further history that the patient is an alcoholic and had told her he had quit drinking 2 days ago. She states he has had a seizure in the past when he stops drinking. As if she had uttered the magic words, he starts to seize before your eyes.

Question 1.20.3 What should you do now?

- A) Give lorazepam and admit for probable delirium tremens (DTs)
- B) Give lorazepam, obtain a head CT, blood cultures, and ECG
- C) Give lorazepam, extubate, and admit for probable DTs
- D) Give phenytoin and admit for probable DTs

Answer 1.20.3 The correct answer is “B,” give lorazepam to abort the seizure. Even though it is easy to assume that the patient had a seizure from DTs, which may have resulted in hypoxia, hypothermia, and hypoglycemia, this kind of thinking can lead to errors. It is still possible that the patient has a spontaneous or traumatic brain hemorrhage, thus the need for a head CT. It is also possible that the patient is septic—remember that hypothermia can be seen with sepsis. Thus, blood cultures should be obtained and possibly an LP performed. Finally, an ECG can show a myocardial infarction or arrhythmia that may also result in seizure. “D” is incorrect because phenytoin is not the first drug of choice for an actively seizing patient, and phenytoin does not work in alcohol withdrawal seizures; a benzodiazepine such as lorazepam should be administered. New guidelines suggest up to 8 mg of lorazepam in a seizing patient (*Epilepsy Curr.* 2016;16(1):48–61). If you don’t have an IV, give it IM. “C” is incorrect; the patient still has a GCS of less than 8 and is unable to protect his airway so he should not be extubated.

► **Objectives: Did you learn to ...**

- Rapidly assess and treat an unresponsive patient?
- Use the GCS to determine need for intubation?

▶ CASE 1.21

You are working in a rural ED and get a call that the volunteer ambulance service is bringing an unresponsive, adult male patient status post motor vehicle collision. They bring the patient on a backboard with a c-collar.

Question 1.21.1 The primary survey of a trauma patient includes all of the following EXCEPT:

- A) Check for pulses
- B) Immobilize the c-spine, evaluate the airway, and listen for breath sounds
- C) GCS
- D) Abdominal examination
- E) Unclothe the patient

Answer 1.21.1 The correct answer (and what you do NOT want to do in the primary survey) is “D.” The primary survey is the initial evaluation performed on every trauma patient by the algorithm “ABCDE.” **A:** Airway assessment includes c-spine immobilization; opening the airway by jaw thrust/chin lift; and, when indicated, bag-valve mask, intubation, or cricothyrotomy. **B:** Breathing includes listening for breath sounds, administering oxygen, and treating pneumothoraces. **C:** Circulation requires assessment of BP, checking pulses, and treatment of hypotension and tachycardia with crystalloids and blood. **D:** Disability is the rapid neurologic examination for potential cord injury and GCS. **E:** Exposure involves disrobing the patient and rolling them to assess any injury to the back.

On the primary survey, the patient was not protecting his airway and was intubated with an 8-mm endotracheal tube (ETT) with rapid sequence intubation (RSI). The patient is noted to have breath sounds on the right but no breath sounds on the left.

Question 1.21.2 What is the next best step in evaluation and treatment of this patient?

- A) Remove the ETT; you must be in the esophagus
- B) Get a chest x-ray to confirm tube placement
- C) Do needle decompression of left chest
- D) Insert a left chest tube
- E) Check ETT for depth at the teeth and position

Answer 1.21.2 The correct answer is “E.” This patient has breath sounds on the right; therefore, esophageal intubation is unlikely, making “A” incorrect. The most likely and easily recognizable source of absent breath sounds on the left is a right main stem bronchus intubation. Thus, looking at the depth of placement of the ETT at the teeth (“E”) is the initial evaluation indicated. The ETT should be placed at about three times the size of the ETT (i.e., $3 \times 8 = 24$ cm) assuming that the size of ETT was correctly chosen. This is an important calculation to remember, as it also applies to pediatric patients. A chest x-ray can also evaluate for right main stem intubation but should not be the first step. A pneumothorax

may be the cause of unilateral breath sounds, but right, or less commonly, left, main stem intubation should be considered first.

Question 1.21.3 You now note that there is an open chest wound to the left lateral rib cage. Funny ... you didn't notice that before. What is the initial treatment of this new finding?

- A) Needle thoracostomy
- B) Chest tube placement
- C) Occlusive dressing
- D) Chest x-ray

Answer 1.21.3 The correct answer is “C.” This patient has an open “sucking” chest wound. Each time the patient inspires, air can be sucked into the chest cavity acting as a one-way valve. This can result in a tension pneumothorax. Thus, the initial treatment is to apply an occlusive dressing to the wound (e.g., such as petrolatum gauze).

Following the placement of the occlusive dressing, the patient continues to have absent breath sounds on the left, is now hypotensive, and has distended neck veins. The presumed diagnosis is a tension pneumothorax.

Question 1.21.4 What should you do now?

- A) Chest x-ray
- B) Chest tube placement through wound
- C) Chest tube placement through separate site
- D) Remove occlusive dressing

Answer 1.21.4 The correct answer is “D.” The occlusive dressing itself may cause a tension pneumothorax, so its placement should be immediately followed by chest tube placement. If a tension pneumothorax develops before the tube is placed, removing the dressing (“D”) can usually alleviate the tension component. Emergency medical technicians will often place a dressing that is closed only on three sides to serve as a release valve and avoid this possibility. The diagnosis of tension pneumothorax is clinical. The time required to obtain a chest x-ray may result in the death of the patient. When placing a chest tube in a patient with an open wound, **never pass the tube through the wound**, as it is likely to follow the path of the initial penetration into lung parenchyma.

HELPFUL TIP:

Needle thoracostomy is useful in a tension pneumothorax and should be the initial step in most cases. You may need a long needle in an obese patients.

The patient now has a chest tube in place but remains hypotensive. Two large bore (18 gauge or larger) IVs were established. No external source of bleeding is identified.

Question 1.21.5 When should blood be administered?

- A) Immediately
- B) If patient is hypotensive
- C) If persistent hypotension after 1 L of normal saline
- D) If persistent hypotension after 4 L of normal saline
- E) If FAST examination shows intra-abdominal free fluid

Answer 1.21.5 The correct answer is “C.” If a patient arrives hypotensive with no signs of external bleeding, 1 L of crystalloid (normal saline) should be given immediately. The traditional teaching has been to start blood after hypotension unresponsive to 2 L of saline. This has changed in the most recent ATLS guidelines. If the patient continues to be hypotensive, packed red blood cells should be started along with additional normal saline. The FAST examination is a rapid bedside ultrasound to identify free fluid in the trauma patient’s abdomen and pericardial sac. Persistent hypotension with positive FAST examination for intra-abdominal blood is an indication for emergent exploratory laparotomy.

► Objectives: Did you learn to ...

- Employ the primary assessment of a trauma patient?
- Treat an open chest wound?
- Resuscitate an unstable trauma patient?

**HELPFUL TIP:**

Tranexamic acid 1 g can be used as a hemostatic agent in hypotensive trauma patients *who present within 3 hours of the initial injury*. It may worsen outcomes if given outside of the 3 hour window. If you are going to transfuse a large amount of blood, the best evidence suggests RBCs:FFP:platelets in a 1:1:1 ratio.

**QUICK QUIZ: CHEST PAIN**

A 54-year-old female presents to your ED with a chief complaint of chest pain. She states it came on suddenly while she was trying to rid her garden of a plague of thistles (or garlic mustard—your choice). She describes it as “sharp” and it radiates through to her back. She reports difficulty breathing. Her past medical history is pertinent for hypertension, breast cancer, and obesity. She is a smoker.

Based on this history, what diagnosis can be excluded from your differential?

- A) Acute myocardial infarction
- B) Aortic dissection
- C) Pulmonary embolism
- D) Pneumothorax
- E) None of the above

The correct answer is “E.” The patient’s history is most suggestive of pulmonary embolism with her complaint of sharp chest pain, trouble breathing, cancer history, and smoking. However, at this point in time, all of the etiologies listed—and more—must

be considered. Women often have atypical presentations of cardiac chest pain. In addition, patients often use the term “sharp” to describe “intense” or “strong” pain.

**QUICK QUIZ: AORTIC DISSECTION**

In aortic dissection, the BP is different between the extremities in less than 30% of cases. If you diagnose thoracic aortic dissection, and the patient’s BP is different in the upper extremities, what limb should you use to guide BP management?

- A) Right arm
- B) Left arm
- C) Either lower extremity
- D) The limb with the highest BP
- E) The limb with the lowest BP

The correct answer is “D.” An aortic dissection may impair the blood flow to certain extremities due to the false lumen. The BP should be maintained at a systolic BP of 100 to 120 mm Hg (or a bit lower) in the extremity with the highest BP. This will decrease the forces propagating the dissection.

**HELPFUL TIP:**

Patients with an aortic dissection should be started on an IV beta-blocker (e.g., esmolol) with a pulse goal of 60 BPM. Once this is achieved, add a vasodilator drip (e.g., nitroprusside, nitroglycerin) if the BP is still over 120 systolic. This minimizes stress to the aortic wall. The goal is a pulse of approximately 60 bpm and a systolic blood pressure of 100–120 mm Hg. Remember that lowering the pulse rate is just as important as reducing the blood pressure. The treatment of “Type A” dissection (dissection of the ascending aorta... the heart to left subclavian artery) is generally surgical. Descending aortic dissections (“Type B,” distal to the left subclavian artery) can be managed medically. Either way, get your vascular or thoracic surgeon involved.

► CASE 1.22

A mother brings her 3-year-old child into the ED. She states that the child has been vomiting and complaining of abdominal pain all afternoon. He has had between 8 and 10 episodes of emesis; the last two have contained small amounts of bright red blood. He has had a little non-bloody diarrhea. He has not been tolerating fluids. On examination, you find the child to be moderately ill appearing with normal color, but he seems less interactive than you would expect. His vitals reveal a temperature of 36.5° C, a pulse of 170 bpm, a respiratory rate of 28, and a BP of 98/58 mm Hg. His abdomen is slightly and diffusely tender. He has dry mucous membranes.

Question 1.22.1 In general (not specifically in this patient), what is the initial treatment of a moderately dehydrated child?

- A) 20 cc/kg bolus of D5 1/2 NS
- B) 10 cc/kg bolus of isotonic crystalloid fluid
- C) Oral challenge of a small amount of electrolyte solution
- D) 12.5 mg promethazine suppository

Answer 1.22.1 The correct answer is “C.” Many children who are vomiting and have diarrhea will be able to tolerate small (5 cc) sips of fluid administered every few minutes. Oral fluids should be attempted prior to IV therapy. One might also administer ondansetron to help reduce vomiting (2 mg in those <15 kg, 4 mg in those >15 kg). In children who are severely dehydrated, as evidenced by altered mental status or change in skin turgor, IV fluid resuscitation should begin immediately. If IV rehydration is considered appropriate, use normal saline in 20 cc/kg aliquots. Therefore, answers “A” and “B” are not correct. Promethazine (“D”) is an antiemetic that has been used in children in the past. However, promethazine has received a “black box” warning from the FDA for children younger than 2 years, as there is a risk of respiratory depression. The black box warning goes on to say promethazine should be used with caution even in those children over 2 years of age.

You obtain some lab work and notice that the child has normal renal function but low serum bicarbonate, indicating a possible metabolic acidosis. In speaking with his mother, you discover that earlier in the day, he was playing unsupervised in the bathroom, where she keeps her prenatal vitamins. Upon questioning the child, he states that he ate a bunch of “candy” in the bathroom about 3 hours ago (all the more reason to keep things up high and away from children!).

Question 1.22.2 What component of prenatal vitamins is most concerning for toxicity?

- A) Folic acid
- B) Iron
- C) Calcium
- D) Vitamin D

Answer 1.22.2 The correct answer is “B.” Folic acid, calcium, and vitamin D are all tolerated well in high doses, as their absorption from the GI tract is limited. Iron, however, can continue to be absorbed while the pills remain in the GI tract. Iron is a direct irritant to the GI mucosa (causing bloody emesis and diarrhea) and interferes with the electron transport chain and aerobic metabolism.

Question 1.22.3 The nurse asks if you should add on an iron level to the blood that was drawn 3 hours after the ingestion. You respond:

- A) “No thanks. Iron levels are not helpful”
- B) “No thanks. It’s too early. We need to wait until at least 12 hours have elapsed”

- C) “Yes, please. If it’s normal, we don’t need any further treatment”
- D) “Yes, please. It may help us determine the severity of toxicity”

Answer 1.22.3 The correct answer is “D.” The iron level between 2 and 4 hours after ingestion is the most accurate; beyond this period, the majority of the iron is moving intracellularly and cannot be measured. For slow-release iron, serum concentrations should be measured at 6 to 8 hours after ingestion. These measures will give you a peak serum iron concentration that correlates well with the severity of toxicity. *However, a low serum level of iron does not mean the symptomatic patient is OK. Treatment is based on clinical findings and NOT on serum iron levels.* Once the iron moves into the periphery, the serum levels can be low despite significant toxicity. You should also check LFTs and a glucose in addition to the BUN/Cr/electrolytes that you have already ordered.

Question 1.22.4 How do patients with an iron overdose present?

- A) Abdominal pain, vomiting, and diarrhea
- B) Hematemesis, shock, and coma
- C) Relatively asymptomatic
- D) All of the above

Answer 1.22.4 The correct answer is “D.” Patients who have had an iron overdose classically pass through five different phases. The first phase is characterized by nausea, vomiting, diarrhea, and abdominal pain. There may be hematemesis and hematochezia as the GI mucosa becomes irritated. The second phase is a relatively asymptomatic period as the GI symptoms resolve. During this quiet phase, iron is absorbed and transported to the periphery where it causes the interruption of aerobic metabolism. In the next (third) phase, patients become hypotensive, acidotic, and can develop multisystem organ failure and coma. It is this shock that is the usual cause of death in iron toxicity. The fourth phase is heralded by hepatic necrosis. Liver failure, which does not occur in all patients, is the second most frequent cause of death in cases of iron toxicity. Finally, the patient may develop bowel obstructions 2 to 4 weeks or longer after the ingestion due to stricture formation at the site of mucosal irritation. See Table 1-7.

Question 1.22.5 Abdominal films reveal radiopaque pills in the stomach. What is the best next step in treatment for this patient?

- A) Whole bowel irrigation with polyethylene glycol solution
- B) Gastric lavage
- C) Activated charcoal
- D) Syrup of ipecac

Answer 1.22.5 The correct answer is “A.” Gastric lavage and induced vomiting both entail a fair amount of risk (aspiration and pneumonitis) and neither has been shown to be beneficial. And, syrup of ipecac is no longer manufactured in the United States; therefore, “B” and “D” are not correct. Iron, lithium, and lead will not adsorb to activated charcoal; therefore, it is of no benefit in such cases, and “C” is incorrect. Treatment for iron

TABLE 1-7 MANIFESTATIONS OF IRON TOXICITY

First (or early) phase	Hours 0–6 (rarely > 6 hours)	Vomiting and diarrhea, often bloody Metabolic acidosis Shock
Second (or quiescent) phase	3–48 hours (time variable)	Resolving acidosis Resolving hypovolemia Frequently, asymptomatic
Third phase	12–48 hours (time variable)	GI hemorrhage Lethargy, coma, shock Cardiovascular collapse Metabolic acidosis Renal failure (variable)
Fourth phase	2 days or more	Hepatotoxicity Hepatic necrosis Coma
Fifth phase	2–4 weeks	GI obstruction due to strictures and scarring

toxicity involves whole bowel irrigation with polyethylene glycol solution to flush the iron out of the GI tract. There are various doses and rates of administration published, but 10 to 15 mL/kg/hr, up to 2,000 cc/hr, seems to be a reasonable place to start. This requires the placement of a nasogastric tube. If a patient does not tolerate the volume of the infusion, the rate should be decreased by 50%. The irrigation should continue until the rectal effluent is clear and there are no visible pill fragments. If follow-up radiographs demonstrate persistent iron tablets in the stomach, consider the possibility of a bezoar having formed, which may require endoscopic or surgical intervention for removal.

**HELPFUL TIP:**

Patients who are *entirely* asymptomatic 6 hours after iron ingestion *and* do not have any radiographic evidence of iron in the GI tract are not at risk for toxicity. They can be safely discharged with close follow-up. The caveat is that chewable multivitamins are not radiopaque and will not show up on x-ray.

Question 1.22.6 The patient is symptomatic (vomiting and diarrhea), acidotic, and also has an iron level 650 µg/dL, which puts him at significant risk for toxicity. What is your next step?

- A) Correction of acid–base disturbance and aggressive fluid resuscitation
- B) EDTA
- C) Deferoxamine
- D) A and B
- E) A and C

Answer 1.22.6 The correct answer is “E.” In addition to symptoms and acidosis, an iron level >500 µg/dL and ingestion of more than 60 mg/kg of elemental iron are considered high-risk situations, and chelation with deferoxamine is warranted. Deferoxamine is used to chelate iron, while EDTA is a chelation

treatment for lead poisoning. Fastidious supportive care, with correction of the patient’s volume and acid–base disturbances, is imperative. Ensuring that the patient is euvolemic is especially important when using chelation therapy, given that the major side effect of deferoxamine is hypotension. The dose of deferoxamine is 15 mg/kg/hr for 24 hours, but may be slowed down if the patient becomes hypotensive.

**HELPFUL TIP:**

Dialysis does not remove iron from the blood stream nor the intracellular space, where the majority of it will be found. Dialysis may be indicated to treat renal failure or persistent profound acidosis.

**HELPFUL TIP:**

The much touted “deferoxamine challenge” to see if there is free iron in the blood is not an accurate predictor of toxicity. The test is done by giving an individual a single challenge dose of deferoxamine and seeing if the urine changes to a “vin rose” color reflecting circulating free iron. However, this does not predict who needs therapy, since the iron may already be working its evil in the periphery.

► **Objectives: Did you learn to ...**

- Rehydrate a child with GI symptoms?
- Recognize the manifestations of iron poisoning?
- Manage a child with an iron ingestion?

► **CASE 1.23**

A 25-day-old female newborn is brought to the ED by her parents. They state that she has not been breastfeeding well this morning and has felt warm. They measured her axillary

temperature as 100.6°F with an axillary digital thermometer at home. They have not noticed any rhinorrhea, cough, or rashes. The baby is having five to six wet diapers per day and five to six yellow, seedy, stools per day. The child has not had any sick contacts. She slept normally last night but was a little hard to wake up from her morning nap today. The baby was the 7 lb 8 oz product of an uncomplicated term gestation, born via normal spontaneous vaginal delivery to a group B *streptococcus* (GBS)–negative mother. There were no complications in the early neonatal period, and the baby was discharged with the mother at 2 days of life after receiving routine neonatal care. At her 2-week weight check, she seemed to be gaining weight well and her doctor had no concerns.

Question 1.23.1 Which of these is NOT a common cause of serious infections in children younger than 1 month?

- A) *Listeria monocytogenes*
- B) *Neisseria meningitides*
- C) Group B *Streptococcus* (GBS)
- D) *Pseudomonas aeruginosa*

Answer 1.23.1 The correct answer is “D.” “A,” *L. monocytogenes*, is an obligate intracellular anaerobe that is transmitted transplacentally from mother to child. “B,” *N. meningitides*, is a Gram-negative diplococcus that colonizes the respiratory tract of up to 15% of healthy individuals. It is usually spread through close contact. “C,” GBS, is a Gram-positive organism that colonizes the genital tract of normal healthy women. GBS may be the most common cause of bacterial infection in the newborn. The peak incidence of GBS disease is in the first 7 days of life, but there may be a delayed presentation out to 30 days. *Pseudomonas* (“D”) infections are not commonly seen in the neonatal period.

HELPFUL TIP:

Look carefully for cold sores or other vesicular lesions on children with rashes. Also try to get a history of any close contacts between the patient and people with cold sores. Herpes virus infection can be devastating to the newborn, and they may require treatment with antiviral medication.

The child is seen in her father’s arms. She appears to have normal color and tone. She is sleeping but arouses after some stimulation. She seems fussy but can be consoled by her parents. Vitals: temperature 38.7°C rectally, pulse 165 bpm, and respiratory rate 32. She appears to be well hydrated, and otherwise has a completely normal physical examination.

Question 1.23.2 What further evaluation is indicated now?

- A) CBC, blood cultures, catheterized urine for analysis and culture
- B) CBC, blood cultures, bag urine for analysis and culture

- C) CBC, blood cultures, chest radiograph, catheterized urine for analysis and culture
- D) CBC, blood cultures, catheterized urine for analysis and culture, lumbar puncture, and chest radiograph

Answer 1.23.2 The correct answer is “D.” It is important that a complete evaluation and septic workup be performed on all febrile children younger than 28 days old without a definite source of infection. This includes CBC, blood cultures, catheterized urine specimens for analysis and culture, and a lumbar puncture. A chest x-ray need not be done in the patient without respiratory symptoms but is highly recommended. LP is mandatory. Even if you suspect a pneumonia or UTI, an LP should still be considered as it is impossible to tell if the bacteria have spread hematogenously to the meningeal space.

HELPFUL TIP:

Do not delay antibiotic therapy to obtain a lumbar puncture. Lumbar punctures performed within 2 to 4 hours of receiving antibiotics should still yield valid results.

HELPFUL (AND CONTROVERSIAL) TIP:

Some would argue that a bag urine should be done as the initial urine examination. While not as specific as a catheterized urine, it is more sensitive for UTI. If the bag UA comes back positive, a catheterized specimen should be sent for culture. About 13% of children with a UTI will not have pyuria; use clinical judgment (*Pediatrics*. 2016 July).

Question 1.23.3 You are awaiting lab results. Should you play World of Warcraft, Minecraft, or start antibiotics? You decide to start antibiotics. Which antibiotics are most appropriate for empiric therapy in this patient?

- A) Ampicillin and gentamicin
- B) Ceftriaxone
- C) Valacyclovir
- D) Amoxicillin with or without clavulanate
- E) Any of the above are equally valid choices

Answer 1.23.3 The correct answer is “A.” Ampicillin and gentamicin cover all of the common causes of serious bacterial infection in the newborn, and both antibiotics penetrate into the cerebrospinal fluid (CSF) well. Ceftriaxone also penetrates the CSF well, but is highly bound to albumin and may displace bilirubin. There have been case reports of kernicterus following the administration of ceftriaxone in newborns, so its use is not recommended in children younger than 1 month. If there is concern for a herpes virus infection, acyclovir IV would be preferred over valacyclovir, but neither of these is used on an empiric basis routinely. Amoxicillin, with or without clavulanate, does not penetrate the CSF as well as ampicillin and is thus not preferred when meningitis is a possibility.

Question 1.23.4 What is the appropriate disposition for this child?

- A) Admission to the general pediatrics floor
- B) Admission to the pediatric intensive care unit
- C) Monitor for 3 hours in the ED, and decide based on laboratory results
- D) Discharge with 24-hour follow-up

Answer 1.23.4 The correct answer is “A.” This child does not look toxic and can probably be managed appropriately on a general pediatrics floor instead of an intensive care unit. This child should be admitted, regardless of what the laboratory results demonstrate. Some experienced practitioners will discharge a nontoxic febrile child from the ED if he or she is older than 2 months and has follow-up within 24 hours. However, there is some risk inherent in this practice—namely, that deterioration in the patient’s condition may go unrecognized at home and that the family will fail to follow-up. The standard of care is to admit all children who have a fever when they are less than 30 days old.

**HELPFUL TIP:**

With the advent of the polyvalent pneumococcal vaccine and the implementation of universal screening for GBS, the incidence of occult serious bacterial infection is falling. It may be that in the near future, the way in which febrile infants younger than 3 months are evaluated and treated will change. However, the practice outlined in Table 1-8 represents the current standard of care.

**HELPFUL TIP:**

Even when present, otitis media **is not** considered a source of fever when evaluating the neonate. You should continue with your clinical and laboratory evaluation as if you did not even see the ears!

► **Objectives: Did you learn to ...**

- Describe common bacterial agents causing infection in the early neonatal period?
- Evaluate the febrile newborn?
- Manage the febrile newborn?

► **CASE 1.24**

A 6-month-old male is brought to the ED by his father. He has had a little bit of rhinorrhea for the last 36 hours but no fevers. A few hours ago, he began coughing and seemed to be having some difficulty breathing. He has been taking his bottle and rice cereal well. His father states that there have been no changes in his stools. He is fully vaccinated, has no significant past medical history, and has had no known sick contacts.

Question 1.24.1 What is the most common cause of respiratory distress in a 6-month-old (and not necessarily the diagnosis in this child)?

- A) Pneumonia
- B) Foreign body aspiration
- C) Bronchiolitis
- D) Second-hand smoke exposure

TABLE 1-8 CURRENT RECOMMENDATIONS FOR EVALUATING THE FEBRILE CHILD**Age ≤28 days**

- These neonates are assumed to have bacteremia and potential seeding of the CSF, even if a source is discovered.
- Workup should include cultures of blood, urine, CSF, and stool (if GI symptoms present) and CXR (if respiratory symptoms present).
- CBC and/or CRP can be obtained, but the decision about whether or not to proceed with evaluation should not be based on these results!
- The child should be admitted for IV antibiotics until cultures are negative.

Age 1–3 months

- It is safest to assume they are still unable to contain bacterial infections at this age.
- Patients at low risk of having a serious bacterial infection have the following labs:
 - WBC >5,000, <15,000/mm³ with band count <1,500/mm³
 - Normal urinalysis
 - Normal CSF
 - Stool microscopy <5 WBC/HPF if diarrhea present
- If no source is found on examination, it is reasonable for patients meeting these low-risk criteria to be managed with intramuscular ceftriaxone in the ED/clinic—if follow-up can be arranged to receive a second dose in 24 hours.
- It should be emphasized that these infants are still vulnerable to dissemination of bacterial infections. Therefore, those with an obvious source, those who appear clinically ill, or those who do not meet the low-risk criteria should be cultured and admitted for IV antibiotics until cultures are negative.

Age 3–36 months

- Management of fever in this group is somewhat controversial, as the advent of Prevnar (pneumococcal vaccine) and continued use of Hib vaccine will presumably reduce the risk of invasive bacterial disease.
- It is generally accepted that well-appearing children with fevers less than 39°C do not require further evaluation or antibiotics.
- Up to 5% of children with temperature >39°C who appear clinically well will have positive blood cultures (occult bacteremia), putting them at risk for serious infections. One approach is to obtain screening WBC on those with fevers >39°C. If WBC <5,000 or >15,000/mm³ or bands >1,500/mm³, then further evaluation of blood, urine, and CSF should be considered.

Answer 1.24.1 The correct answer is “C.” Bronchiolitis is very common, especially in the winter months. It is usually caused by the respiratory syncytial virus, but can also be caused by parainfluenza, influenza, and human metapneumovirus. Bronchiolitis is usually associated with profuse rhinorrhea, bronchospasm, and mucus plugging of the bronchiole tree. Although, “A,” pneumonia is a serious cause of respiratory problems, it is not terribly common in infants. “B,” foreign body aspiration, is something that must be always considered in an infant, especially a 6-month-old who is becoming more mobile (and to whom everything looks like food). Second-hand smoke exposure can cause chronic irritation to the respiratory tract and can exacerbate bronchospasm, but it is infrequently the sole cause of respiratory distress.

As you examine the child, you note that he is mildly tachypneic with some suprasternal, subcostal, and intercostal retractions. He makes a whistling, wheezing sound on inspiration (stridor) that seems to get worse the harder he breathes. He also has a brassy-sounding cough that does not seem to be productive.

Question 1.24.2 What is the most likely diagnosis at this point?

- A) Pneumonia
- B) Croup
- C) Laryngomalacia
- D) Asthma

Answer 1.24.2 The correct answer is “B.” Croup, or laryngotracheobronchitis, is a common infection of the upper and lower respiratory tract. It is most commonly caused by parainfluenza virus, but may also be caused by influenza and respiratory syncytial virus. Classically, croup affects children younger than 5 years, although it is occasionally seen in older children. As the glottis swells, children develop a wheeze/whistle on inspiration (inspiratory stridor) and a characteristic brassy “seal-like” barking cough. The vast majority of cases are mild. Occasionally, however, children may require control of the airway due to hypoxia. “A,” pneumonia, is an infection of the lower airways that can be either bacterial or viral in nature. These children generally have a fever and productive cough. They may be tachypneic and have an increased work of breathing, but they usually do not have inspiratory stridor. “C,” laryngomalacia, is a congenital disorder. These children usually develop symptoms at a few weeks of age and present with inspiratory stridor that gets worse with crying. It tends to be a little better when the child is calm and in the supine position. Laryngomalacia resolves spontaneously in the majority of children as the larynx becomes firmer and the airway diameter increases, but some children will require surgical intervention to facilitate feeding and growth. The child in this vignette is presenting with a new problem, as opposed to a chronic one, so this is not laryngomalacia. “D,” asthma, is another disease of the lower airways, and wheezing is expiratory in nature.

You decide to do a radiograph of this child’s neck to aid in the diagnosis (although this is certainly not necessary nor

advocated in most cases—but this is a board review book, not real life).

Question 1.24.3 You are most likely to see which of the following on cervical radiograph?

- A) Thumb sign
- B) Quincke sign
- C) Spine sign
- D) Retropharyngeal space swelling
- E) Steeple sign

Answer 1.24.3 The correct answer is “E.” Radiographs in croup may show the “steeple sign,” which is a subglottic narrowing of the trachea from edema, giving it a steeple-like appearance. “A,” the thumb sign, is seen in epiglottitis. “B,” Quincke sign, is incorrect, as it has nothing to do with radiology. Quincke sign is the unequal capillary pulsation associated with aortic insufficiency—it’s rare, not seen in children, and nearly useless knowledge... but that is what you are paying us for! “C,” the spine sign, is loss of progressive radiolucency of the spine on lateral chest radiograph. This is seen when something—classically an infiltrate indicative of pneumonia—is overlaying the lower thoracic spine, making the vertebral bodies appear more dense. Finally, “D,” retropharyngeal space swelling, is seen in retropharyngeal abscess.

Question 1.24.4 What is the most appropriate definitive therapy for this patient at this time?

- A) Epinephrine 0.01 mg SQ
- B) Nebulized albuterol
- C) Dexamethasone 0.6 mg/kg PO/IM/IV
- D) High flow oxygen and prepare to intubate

Answer 1.24.4 The correct answer is “C.” Corticosteroids help to decrease the glottic edema. One dose of dexamethasone 0.3 to 0.6 mg/kg (maximum of 10 mg) can be given via multiple routes (PO/IM/IV) and is usually sufficient to improve the airway swelling enough to allow the child to breathe comfortably. The advantage of dexamethasone over prednisone or another corticosteroid is that its long half-life obviates the need for further dosing at home. While waiting for the dexamethasone to work, epinephrine may be administered via nebulizer for severe cases. This usually leads to significant clinical improvement and gives time for the steroid to begin to take effect. Subcutaneous epinephrine is usually unnecessary. Albuterol, while helpful for bronchospasm, does not do anything to treat the glottic edema that is causing the majority of the respiratory distress. Intubation is not indicated at this point if the child is not in impending respiratory failure, hypoxic, or minimally responsive.

HELPFUL TIP:

While classically we have used racemic epinephrine, the “d” isomer is inactive. In addition, racemic epinephrine is more expensive and must be kept refrigerated if a multidose vial is used. L-epinephrine, 5 cc of 1:1,000, delivered by nebulizer is as—if not more—effective,

than racemic epinephrine, is cheaper, and is the same dose for everyone (our favorite since we can't do simple math!).

You administer the appropriate dose of dexamethasone to the child along with a treatment of nebulized epinephrine. He improves markedly. You watch him for 2 hours. He is able to tolerate oral fluids well and is active and playful. He still has a brassy cough, but no inspiratory stridor.

Question 1.24.5 What should his disposition be?

- A) Admit for 23 hours of observation
- B) Administer second dose of racemic epinephrine and re-evaluate
- C) Discharge to home with close outpatient follow-up
- D) Administer albuterol and re-evaluate

Answer 1.24.5 The correct answer is “C.” After administering dexamethasone and epinephrine, it is imperative to observe children for at least 2 hours. If the child redevelops stridor at rest, he should receive a second dose of epinephrine. Any child who needs a second treatment has more severe croup, is at higher risk of having complications, and should be considered for hospital admission. If the child is free of stridor 2 hours after nebulized epinephrine, he can be safely discharged with close outpatient follow-up (within 24 hours) as long as the parents are reliable, able to monitor the child, comfortable with the plan, and able to return if the child's condition should deteriorate.

HELPFUL TIP:

Remember that an oxygen saturation of less than 95% is singularly abnormal in a child.

► **Objectives: Did you learn to ...**

- Describe common causes of respiratory distress in children?
- Manage pediatric airway problems?
- Treat children with croup?

QUICK QUIZ: FOREIGN BODY

A 3-year-old boy and his 5-year-old sister were being silly, avoiding bedtime, and jumping on their parent's bed. Naturally, the boy had a nickel in his mouth that he'd found on the floor. When their mother walked in to wrangle them into their pajamas, they predictably collided in mid-air and both fell off the bed and onto the floor. She was unable to find the nickel after the incident. Coincidentally, the 3-year-old feels like he has something stuck in his throat—something with Thomas Jefferson's head on it.

When the family arrives in your office, he takes liquids without much trouble but won't take anything solid. He says his “throat hurts.” He's not drooling or having any trouble breathing.

How do you confirm that the coin is not in the airway?

- A) CT of the larynx and chest without IV contrast
- B) CT of the larynx and chest with IV contrast
- C) AP and lateral plain films of the neck
- D) Direct laryngoscopy
- E) Call a pulmonologist for emergent fiberoptic bronchoscopy

The correct answer is “C.” Fortunately coins are radiopaque—at least as of the printing of this book (maybe we'll have wooden coins again someday!). Some plastic toys legally contain barium and are radiopaque while others are inadvertently radiopaque (like those old toys contaminated with lead ... a mixed blessing at best!). The esophagus tends to collapse from anterior to posterior when there is nothing in the lumen. Therefore, a coin in the esophagus should look round on an AP x-ray. By contrast, the trachea is supported by cartilaginous rings around most of its circumference. The posterior part of the trachea, however, abuts the esophagus and has no cartilage. Therefore, coins that fall into the trachea generally have an end-on appearance on AP radiographs and look like a disc on a lateral film.

The coin fell into the stomach on the way to x-ray and the little boy feels better.

What foreign bodies in the stomach need to be removed emergently?

- A) A button battery
- B) A paperclip that is folded in its original form
- C) Two small magnets
- D) A doll's shoe

The correct answer is “C.” Two magnets can attract each other through opposing loops of bowel, causing bowel necrosis and perforation. One magnet should not cause any trouble, but two should be taken seriously. **Button batteries lodged in the esophagus need to be removed emergently. However, once a button battery transitions to the stomach, it will likely pass without causing any difficulty. However, it should be removed if it remains in the stomach for more than 48 hours or is ≥ 15 mm in size.** Other smooth or rounded objects are unlikely to cause any trouble. Even small sharp objects (e.g., pushpins) generally pass without causing perforation or other significant damage.

► **CASE 1.25**

A 67-year-old female with a history of end-stage renal disease on hemodialysis presents slumped over and complaining of generalized weakness. By the time she is in a room, her eyes are closed, she is nonverbal, withdraws from painful stimuli and does not follow commands but has a palpable pulse at 80 bpm. Her husband notes that she has been using “light salt,” which contains potassium. You remember the “coma cocktail” from earlier in this chapter: glucose, naloxone, thiamine, and oxygen. You also remember that not all narcotic overdoses are associated with pinpoint pupils. You treat her appropriately. The patient's blood sugar is 211 mg/dL.

The patient's husband states that dialysis was not performed today. The patient also missed her last dialysis appointment 2 days ago because she felt ill at home. Her mental status is unchanged after the "coma cocktail"; she is unable to protect her airway. Husband confirms patient is full code. You decide to proceed with intubation.

Question 1.25.1 The best medications to use in this patient are (induction agent/paralytic agent):

- A) Etomidate/succinylcholine
- B) Etomidate/ketamine
- C) Etomidate/rocuronium
- D) An induction agent and a paralytic are unnecessary in this patient since she is only responsive to deep stimuli

Answer 1.25.1 The correct answer is "C." Rocuronium would be the paralytic of choice in this patient. In a patient with chronic kidney disease on hemodialysis, assume the presence of hyperkalemia until proven otherwise. Succinylcholine may cause hyperkalemia (and cardiac arrest) so it is contraindicated in patients with a high likelihood of hyperkalemia. Succinylcholine should also be avoided in crush injuries, neurologic injuries/myopathies, and burn patients where it may cause malignant hyperthermia. A sedative should be used for induction to prevent pain and either etomidate or ketamine may be used—not both.

You secure the airway. A STAT potassium returns at 7.9. Darn! You look at the monitor and notice the QRS is looking a little wide. Double darn!

Question 1.25.2 While you are waiting for an ECG to be obtained, you administer:

- A) Kayexalate
- B) Sodium bicarbonate
- C) Calcium gluconate
- D) Insulin/glucose
- E) Albuterol nebulizer

Answer 1.25.2 The correct answer is "C." In hyperkalemia with evidence of ECG changes (peaked T waves, wide QRS, sine wave), calcium needs to be administered immediately. The calcium stabilizes cardiac cell membranes within 1 minute. Calcium gluconate 1 g or calcium chloride 1 g may be given. Calcium chloride is irritating to veins and may cause necrosis if it extravasates; central line administration is preferred. All of the other answers do lower potassium levels (including continuously nebulized albuterol), but when there is evidence of ECG changes, giving calcium is your top priority. The other agents may take as long as 30 to 60 minutes to act. As a note, bicarbonate may not be particularly effective in patients with chronic kidney disease, another reason to use calcium first in this patient.

After 2 doses of calcium gluconate, the QRS narrows and you want to get the excess potassium out of your patient's body.

Question 1.25.3 Which of the following removes potassium from the body?

- A) Hemodialysis
- B) Insulin/glucose
- C) Kayexalate (sodium polystyrene)
- D) Albuterol
- E) A and C

Answer 1.25.3 The correct answer is "E." Both hemodialysis and sodium polystyrene will remove potassium from the body. Insulin/glucose will drive it intracellularly in 30 to 60 minutes, but does not rid the body of potassium. Be careful: sodium polystyrene exchanges sodium for potassium and thus may worsen congestive heart failure. **The use of sodium polystyrene with sorbitol is discouraged.** It is associated with bowel ischemia and necrosis. **In addition, be careful using sodium polystyrene in those with GI problems (ileus, stricture, etc.) for the same reason.** Note that patiromer (Veltassa), a second potassium binder is also available. However, it may not lower potassium for up to 7 hours after administration and is NOT approved for the acute lowering of potassium. Remember that *both* patiromer and sodium polystyrene (Kayexalate) bind many medications and reduce their bioavailability significantly. Finally, sodium zirconium cyclosilicate (Lokelma) has recently been released. It seems to work within 1 hour and will likely become the potassium binder of choice.

The patient does well and, in the future, knows to avoid "light" salt (KCl) (of course, "light" is now spelled "lite" for some unknown reason).

► **Objectives: Did you learn to ...**

- Describe contraindications of succinylcholine in intubation?
- Treat hyperkalemia in the acute situation?

► CASE 1.26

A 24-year-old male presents to your ED complaining of "dental pain." He reports a long history of poor dental hygiene and has not seen a dentist in several years. He smokes two packs of cigarettes per day (and proudly wears a "Marlboro" hat) and admits drinking a 2-L bottle of "Hillbilly Holler (Sugared)" every day at work. (It includes a free coupon for dental service after 100 bottles, but he has never availed himself of this.) The pain is described as constant and throbbing in nature located in the right lower jaw area.

Question 1.26.1 What findings during your examination would raise your concern regarding the patient's clinical condition?

- A) Large amounts of secretions
- B) Decreased ability to open his mouth for the examination
- C) Swollen and elevated tongue
- D) Pain and decreased range of motion of the neck
- E) All of the above

Answer 1.26.1 The correct answer is “E.” If a patient is having trouble swallowing secretions (“A”), it should raise concern for swelling in the posterior pharynx which can compromise not only the ability to swallow one’s saliva but can also signal a high risk for upper airway occlusion secondary to swelling. Trismus (“B”) is also concerning because it may indicate deeper infection involving the muscles of mastication. “C,” a swollen and elevated tongue, may indicate the development of Ludwig angina, a life-threatening infection of the floor of the mouth, which can spread to the deeper tissues of the submandibular and submaxillary spaces. “D,” pain and decreased range of motion of the neck, could indicate the possibility of a retropharyngeal abscess.

HELPFUL TIP:

Adult epiglottitis often presents with sore throat and neck tenderness. So, if the patient has neck tenderness out of proportion to what you would expect, consider epiglottitis or a retropharyngeal abscess.

Luckily, the patient is otherwise clinically stable aside from the focal dental pain. Your examination shows the tissues around tooth number 29 (we can never remember that pesky numbering scheme either) to be swollen and inflamed with signs of fluctuance and severe tenderness on palpation. An orthopantomogram shows a periodontal abscess.

Question 1.26.2 Which antibiotic is NOT an appropriate choice for this clinical condition?

- A) Penicillin VK
- B) Clindamycin
- C) Amoxicillin/clavulanate
- D) Trimethoprim-sulfamethoxazole

Answer 1.26.2 The correct answer is “D.” Penicillin VK, clindamycin, and amoxicillin/clavulanate all provide good coverage for anaerobic bacteria including anaerobic Gram-negative cocci, which are the main culprits in dental infections. TMP-SMX has some Gram-negative coverage but lacks the anaerobic coverage needed to treat infections of the oral cavity.

The same gentleman returns to you 3 weeks later complaining of a sore throat. On examination, he looks toxic and has fever, chills, dyspnea/cough, and unilateral neck swelling. His throat looks similar to a streptococcal tonsillitis. However, the neck is tender, and this guy really looks sick. Pulse is 130 bpm and BP is 80/50 mm Hg. He was seen last week by someone else for a mild sore throat and given a “Z-Pak” (azithromycin—mostly on a whim). He has gotten progressively worse. Chest x-ray shows infiltrates and small abscesses.

Question 1.26.3 Your presumptive diagnosis is:

- A) Mononucleosis
- B) *Fusobacterium*
- C) *Arcanobacterium hemolyticum*
- D) Viral URI

Answer 1.26.3 The correct answer is “B.” *Fusobacterium* is an anaerobic infection that has been found with increasing frequency in adolescent/college-age patients. It can initially present similarly to a strep throat but may go on to “Lemierre syndrome,” which is a septic thrombophlebitis of the internal jugular vein. This can then lead to septic emboli to the lungs, sepsis, and multiorgan failure. The point here is that penicillin is still the drug of choice for strep throat, and it covers *Fusobacterium*, which the macrolides do not. As for the other answers, this is not likely mononucleosis (“A”), since the neck swelling is unilateral and patients with mono usually are not this toxic nor have infiltrate on chest x-ray. “C,” *A. hemolyticum*, is also common in college-age students and is initially clinically indistinguishable from strep throat. However, 50% of patients will have a maculopapular or scarlatiniform rash starting on the extremities and involving the trunk and back but sparing the head; as opposed to the rash of scarlet fever, the rash does not peel. It rarely causes invasive disease such as pneumonia or meningitis. It will respond to erythromycin or clindamycin and less so to penicillin. “D” is obviously incorrect and if you chose this one, back to medical school for you!

The patient spends 3 weeks in the ICU and eventually succumbs to his disease. Not good (way for us to end on a “downer” you say, but at least you get the message that “Z-paks” aren’t always the answer).

► **Objectives: Did you learn to ...**

- Diagnose and treat a dental abscesses?
- Identify *Fusobacterium* and *Arcanobacterium* infections

CASE 1.27

An 82-year-old female slumps over in church (it’s always the bathroom or church—avoid these and you will live forever). Luckily, there is a nurse present who just happens to have a monitor/defibrillator. The nurse lets you know she can’t feel a pulse. You quickly hook the patient up a cardiac monitor and see the rhythm in Figure 1-2.

Question 1.27.1 “Uh-oh,” you think. You astutely identify the rhythm as:

- A) Atrial fibrillation
- B) Ventricular tachycardia
- C) Ventricular fibrillation
- D) PEA

Answer 1.27.1 The correct answer is “C.” Note absence of p-waves, no complexes—just a sinusoidal pattern of rapid, irregular ventricular activity that results in no functional contractions (thus no cardiac output, and thus no pulse).

Question 1.27.2 Aside from starting CPR, the first-line treatment for this is:

- A) Amiodarone
- B) Epinephrine

FIGURE 1-2. Rhythm strip for question 1.27.1.

- C) Electrical defibrillation
- D) Adenosine

Answer 1.27.2 The correct answer is “C.” The initial treatment for ventricular fibrillation or pulseless ventricular tachycardia is electrical defibrillation. CPR should be in process as defibrillation is set up. Epinephrine (“B”) and amiodarone (“A”) are part of the algorithm but are not the first treatment. “D” is just wrong.

HELPFUL TIP: “SHOCKING!”

The “stacked defibrillations” (100J, 200J, 360J) are no more. Defibrillate at 360J once or 150 to 200J with a biphasic defibrillator.

Question 1.27.3 Shock delivered! Now what?

- A) Check your rhythm
- B) Check for a pulse
- C) Perform CPR
- D) Check rhythm and pulse at the same time
- E) Intubate and check rhythm

Answer 1.27.3 The correct answer is “C,” perform CPR. Current ACLS guidelines recommend 2 minutes of CPR following defibrillation (Not like the TV shows, where patients just jump up and walk out, right?). You can check for a pulse (“B”) and check your rhythm (“A”) after that 2 minutes of CPR is completed. Intubation (“E”) may be considered during a code, *but if you are able to effectively bag a patient, it is more important to continue high-quality CPR.* Intubation is no longer considered mandatory—and, in fact, outcomes seem to be better *without* intubation.

As you are continuing CPR, you ask the nurse to give epinephrine 1 mg (vasopressin is out of the ACLS guidelines). The medication is administered. On next pulse check, you see sinus tachycardia on the monitor, but there is no pulse with palpation. You identify that the patient currently is in pulseless electrical activity (PEA).

Question 1.27.4 Now what?

- A) Defibrillation
- B) CPR and epinephrine
- C) CPR and defibrillation
- D) Call an end to the code

Answer 1.27.4 The correct answer is “B,” CPR and epinephrine. Epinephrine should continue to be administered every 3 to 5 minutes. PEA is NOT an indication for defibrillation (“A” and “C”). It seems a little premature to call the code (“D”) at this time.

HELPFUL TIP:

When a patient is in PEA, always think through the potentials’ causes. A mnemonic of “5Hs and 5Ts” will help you remember them all.

Hs: Hypovolemia, hypothermia, hypo/hyperkalemia, hypoxia, hydrogen ion (acidosis)

Ts: Tension pneumothorax, tamponade (cardiac), toxins, thrombosis (PE), thrombosis (coronary)

Success! On next rhythm check there is a pulse. Well done!

Clinical Pearls

- Avoid CT scans in patients with known urolithiasis who have the same symptoms again unless you suspect a post-obstructive infection or have reason to believe it could be an aortic problem (e.g., at-risk patients over 50 years old).
- Avoid the use of narcotics for migraine headaches if possible. Prochlorperazine or metoclopramide work well with prochlorperazine IV being the preferred agent.
- Do not do a chest CT (or d-dimer) if a patient is PERC negative and is low risk for a PE. Besides the expense, the cancer risk for a 20-year-old female from a single 64-slice chest CT is approximately 1 in 250.
- Do not do a head CT for patients with simple syncope: syncope is not a brain disease. It is generally a problem of CNS perfusion; you have to knock out both hemispheres simultaneously to lose consciousness.
- Do not do a head CT in low-risk patients with head trauma. Use a prediction rule. However, it is reasonable to CT those on anticoagulants.
- Do not do a head CT looking for the cause of vertigo; it is almost always useless. If you need imaging, do an MRI but recognize that an MRI will be negative for posterior circulation stroke in 30% of cases within the first 24 hours.
- Do not do a head CT of children with a first uncomplicated seizure.

- Do not get back imaging for acute low back pain unless there are red flags, such as fever, cancer history, significant trauma (not just twisting or picking something up), neurologic symptoms or signs.
- Only give as much blood as is necessary. Giving one unit is fine. As a general rule, don't transfuse a stable patient with a hemoglobin of 7 g/dL or greater.
- Phenytoin and fosphenytoin do not work for alcohol withdrawal seizures, seizures caused by drug overdose or withdrawal (in general). Use a benzodiazepine.

Cardiology

Mark A. Graber and Jason K. Wilbur

We are going to start this chapter with a knock-down, drag-out, fight about blood pressure. What is this? Medicine or hockey? There is considerable controversy over what constitutes an appropriate blood pressure goal for a wide range of adult patients. In this chapter, we are following the recommendations of the Eighth Joint National Committee (JNC 8) which have been endorsed by the American College of Physicians and the American Academy of Family Physicians—and which we assume will be on the test (*Ann Intern Med.* 2017;166:430). The American College of Cardiology and the American Heart Association (ACC/AHA) disagree.

For the record, the ACC/AHA prefer the following:

Blood Pressure	Action	Further Action
<120/80 mm Hg	Reassess annually	
120/80–129/80 mm Hg	Life style modification	Reassess in 1 month
Hypertensive: 130–139/80–89 mm Hg	Calculate 10-year risk using the ACC/AHA ASCVD risk calculator (see: https://www.mdcalc.com/ascvd-atherosclerotic-cardiovascular-disease-2013-risk-calculator-aha-acc)	If >10% 10-year ASCVD risk, start antihypertensive; otherwise, life style changes
>140/90 mm Hg	Start antihypertensive pharmacotherapy	Reassess in 1 month
Goal blood pressure < 130/80 mm Hg for everyone		

Note that this table represents a simplification of the ACC/AHA guidelines. Much more detail is available in the full report (*J Am Coll Cardiol.* 2018;71:e127).

We are going to continue our fight with aspirin for **primary** prevention. Four words: **Don't do it routinely.** The consensus based on new data is that aspirin for primary prevention increases bleeding risk and does not reduce cardiovascular events, disability-free survival, or all-cause mortality (*N Engl J Med.* 2018;379:1519). **Continue to use it in patients who have**

had a cardiovascular event (angina, PVD, stroke, etc.) where the benefit does outweigh the risk. To continue, omega-3s from fish oil still don't help prevent cardiac disease or cancer (*N Engl J Med.* 2019;380:23–32). Finally, there are competing 2013 and 2018 lipid guidelines. The ACP and AAFP have not endorsed the 2018 guidelines. However, we do discuss them toward the end of the chapter.

▶ CASE 2.1

A 35-year-old female presents with a 1-hour history of chest pain, which resolved spontaneously. The pain is described as a chest pressure radiating to both arms. The patient is a smoker but has no other risk factors (no family history of cardiac disease, hypertension, diabetes, hyperlipidemia, etc.). The patient is diaphoretic and has a normal blood pressure. Physical examination reveals that the patient has tenderness to palpation of the anterior chest wall that reproduces the chest pressure. She is now otherwise free of chest pain and all her lab assays, including cardiac enzymes, are normal.

Question 2.1.1 Which of the following is true about this patient's physical findings and history?

- A) Pain radiating to both arms makes it unlikely that this patient's pain is cardiac
- B) The physical findings that are most highly associated with an acute myocardial infarction (AMI) include hypotension, diaphoresis, and a new S3 gallop
- C) The absence of risk factors makes it unlikely that this patient has cardiac disease
- D) The fact that the pain is reproducible on palpation of the chest wall effectively rules out cardiac disease
- E) Based on the information available, further cardiac evaluation is unnecessary

Answer 2.1.1 The correct answer is "B." The findings that are most likely to be associated with an AMI are hypotension, diaphoresis, and a new S3 gallop. "A" is not true because pain radiating

to both arms can still be associated with cardiac disease. In fact, compared with left arm radiation, right arm radiation or bilateral arm radiation doubles the likelihood of the pain being cardiac (LR 2.3 for radiation to the left arm vs. LR 4.1–4.7 for radiation to the right or bilateral arms [JAMA 2005;294(20):2623–2629]). Women with AMI often present atypically and may experience more chest pain radiating to the right arm/shoulder and the anterior neck or with abdominal pain, as compared to men. “C” is incorrect. The absence of risk factors is only one consideration in the evaluation of this patient. Smoking, hypertension, family history, etc., **do not** change the prior probability of cardiac disease enough to allow them to be used to rule out or rule in cardiac disease. Of note, male gender and diabetes **do** increase the pretest probability of coronary artery disease (CAD). But luckily our patient is female! Evaluation of pretest probability is important in the diagnostic algorithm, but should be **used in addition to, not in exclusion of**, clinical judgment and findings. “D” is incorrect. It is true that chest pain reproduced by palpation of the chest wall makes cardiac disease less likely. However, 15% of patients with cardiac disease and 17% of patients with a pulmonary embolism (PE) will have their pain reproduced by chest wall pressure (BMJ 2005;330:452–453). This does not mean that you are making their cardiac pain worse. It is likely because of the patient’s inability to discriminate between the types of pain (cardiac vs. chest wall).

You decide that further testing is warranted, including an ECG and cardiac enzymes.

Question 2.1.2 Which of the following statements is TRUE?

- A) A normal initial ECG in the emergency department (ED) effectively rules out cardiac disease
- B) Creatine phosphokinase MB fraction (CPK-MB) is more sensitive but less specific than troponin
- C) Serum troponin is an unreliable marker of cardiac ischemia in patients with renal failure
- D) The serum troponin is 100% specific for myocardial infarction
- E) A normal high sensitivity troponin and ECG in the ED 3 hours after the pain began can be used to make decisions about who to admit

Answer 2.1.2 The correct answer is “E.” Newer “rule out” protocols allow ED physicians to categorize chest pain patients into a low-risk pool within 3 hours after pain onset. If the patient is found to be at low risk using a validated risk assessment tool (see “HEART” calculator at: <https://www.mdcalc.com/heart-score-major-cardiac-events>) **and** has a normal ECG **and** has a negative *high-sensitivity* troponin at 3 hours after presentation, one can rule out myocardial infarction without an admission. Remember, these are low-risk patients to begin with, not the 70-year-old with a history of CAD who is puffing like chimney. Note that the HEART score incorporates the ECG and troponin. There is a 16% discordance in how physicians score the same low-risk patients vis-à-vis HEART (Acad Emerg Med. 2018 Nov 14). “A” is incorrect since 9% of patients with AMI will have a normal initial ECG in the ED. In fact, only about 50% of those with AMI have a diagnostic ECG in the ED. **Even a normal ECG**

obtained during chest pain does not reliably rule out AMI (Acad Emerg Med. 2009;16:495). “B” is incorrect since the CPK-MB is overall less sensitive and may have a later rise than a high-sensitivity troponin. CPK-MB and myoglobin add little, if anything, to the troponin. Eighty percent of AMIs will have one positive marker within the first 3 hours of ED arrival (but 20% will not). “C” is incorrect. Patients with renal disease may have a mildly elevated troponin at baseline due to poor clearance, but troponin can still be useful in these patients if it continues to rise. It helps to know the patient’s baseline troponin in renal failure, but this is **NOT** an indication to start drawing a baseline troponin on all of your patients with renal failure. “D” is incorrect because we now know that other processes, such as PE, can elevate the serum troponin.

HELPFUL TIP:

Elevated troponin levels may be due to conditions other than AMI, including heart failure, PE, burns, sepsis or other critical illness, stroke, and more. In “atypical” patients (younger, female patients, like this one), also consider spontaneous coronary artery dissection (SCAD). Although uncommon, SCAD is more likely in women, especially those who have recently been pregnant or undergone highly aerobic activity, like running a marathon. SCAD should be considered in patients who present with symptoms of ischemia or infarct but who do not possess traditional cardiovascular risk factors.

HELPFUL TIP:

The new ultra-sensitive troponin may be positive within 3 hours. *You need to know what test your hospital is doing.* Troponin levels peak in about 36 hours after an infarct and may stay elevated for 7 to 10 days, so the infarct may have occurred anywhere within this time frame. Follow the trend of the troponin to help determine when the infarct occurred.

Question 2.1.3 All of the following statements are true EXCEPT:

- A) All myocardial infarctions present with chest pain
- B) Dyspnea may be the only presenting symptom of myocardial infarction
- C) Patients with myocardial infarction can present with syncope
- D) Females, the elderly, and diabetic patients are more likely to present with atypical symptoms of myocardial infarction

Answer 2.1.3 The correct answer is “A.” As the saying goes, “Never say never, and never say always.” Many elderly and diabetic patients (“D”) will present with atypical symptoms or painless, “silent” myocardial infarctions. In fact, up to 30% of myocardial infarctions are pain free. “B” is a correct statement because, especially in the elderly, dyspnea may be the only presenting symptom due to left ventricular failure secondary to ischemia. “C” is a correct statement because syncope (as well as

lightheadedness and fatigue) can be presenting symptoms of a myocardial infarction.

Her ECG shows nonspecific ST-T changes.

Question 2.1.4 Which of the following drug(s) is/are indicated in the initial management of this patient?

- A) Aspirin
- B) Thrombolytic such as tPA or streptokinase
- C) Heparin
- D) Glycoprotein IIb/IIIa inhibitor (e.g., abciximab [ReoPro])
- E) All of the above

Answer 2.1.4 The correct answer is “A.” Immediate therapy in the ED requires ASA 325 mg orally (chewed). Since we are not sure that this patient has AMI or unstable angina, there is no indication for thrombolytic therapy (“B”), heparin (“C”), or glycoprotein IIb/IIIa inhibitor (“D”). Since she is currently pain free, heparin carries more of a risk than a benefit at this juncture and is not recommended. However, all patients with possible angina or an AMI should have aspirin unless they are truly allergic (e.g., hives, anaphylaxis). “B” is incorrect because thrombolytics are indicated for acute ST elevation myocardial infarctions (STEMI), not for a simple chest pain evaluation.

HELPFUL TIP:

In med school, we learned “MONA (morphine, oxygen, nitroglycerin, aspirin) greets all patients.” Snappy mnemonic, but is it right? Recent data suggests that there is no need for oxygen if the oxygen saturation is 94% or above. In fact, it might be harmful. Hyperoxia is clearly detrimental in the ICU setting. So, withhold oxygen unless the oxygen saturation is <94%. Morphine should be used only after a patient fails specific therapy, such as aspirin and nitroglycerin. And, nitroglycerin does not change infarct size, but it does improve chest pain.

HELPFUL TIP:

Current use of anticoagulants or aspirin should **not** preclude the administration of aspirin in the ED for a patient with chest pain that may be cardiac in origin. You never know whether the patient is actually taking it or not. So, unless there is a real allergy to aspirin, it must be given to chest pain patients with a possible cardiac etiology—even if they tell you that they took an aspirin that morning already.

HELPFUL TIP:

Why do we always say to chew the aspirin? Does it really make a difference? Yes. In a small study of healthy volunteers, chewed aspirin started to work in 5 minutes, as opposed to 12 minutes for regular swallowed aspirin. It also reached its peak effect quicker, too.

The patient tells you that she is allergic to aspirin, which causes hives and bronchospasm. She can, however, take other nonsteroidal anti-inflammatory drugs (NSAIDs) without difficulty. Oh, great. Now you need to go to plan B (no, not the “morning after pill”).

Question 2.1.5 Which of the following is an acceptable substitute for aspirin in this situation?

- A) Dipyridamole
- B) Ticagrelor (Brillinta)
- C) Ibuprofen or naproxen
- D) Celecoxib (Celebrex)
- E) Salsalate

Answer 2.1.5 The correct answer is “B.” Ticagrelor (Brillinta) 180 mg as a loading dose is the correct choice. Alternatively, clopidogrel (Plavix) in a loading dose of 600 mg can be used as a substitute for aspirin in the setting of unstable angina or AMI. The other options are incorrect. “A” is incorrect because dipyridamole (in combination with aspirin) is indicated only for stroke prevention. Dipyridamole itself is a relatively weak platelet inhibitor. “C” is incorrect because ibuprofen and naproxen are reversible platelet inhibitors that do not give adequate platelet inhibition and have **NOT** been shown to be of benefit in angina/AMI. In addition, both ibuprofen and naproxen can block the effect of aspirin by making its binding sites on platelets unavailable. **In fact, stopping NSAIDs in any patient being admitted for possible CAD is considered good practice since they are known to increase the risk of a cardiac event.** “D” and “E” are both incorrect because celecoxib and salsalate have not been shown to inhibit platelets to a significant degree and thus would be of no use in this situation.

HELPFUL TIP:

Why not prasugrel (Effient) for AMI? While it is an option, it cannot be used in those over age 75 or in patients with a history of stroke or TIA. And the dose must be reduced in those weighing <60 kg. It also loses potency when stored. Don’t even consider Zonivity (vorapaxar) ... it has a 4-week washout period and no benefits over the other agents. Plus it must be used *with* aspirin.

HELPFUL TIP:

It is unclear which, if any, of the NSAIDs (except aspirin) is the safest in the setting of a history of CAD. Some data support the use of naproxen if an NSAID is required. Other data do not show any difference between the NSAIDs. Guidelines suggest stopping all NSAIDs (except aspirin) upon admitting a patient for an acute coronary syndrome (ACS) or a question of ACS. Do not use ketorolac to treat chest pain which is potentially ACS as this is also an NSAID (*BMJ* 2017;357:j190).

Well, not all chest pain is cardiac, and this patient may have another cause for hers.

Question 2.1.6 Which of the following is TRUE?

- A) Giving a “GI cocktail” (e.g., combination of Maalox and viscous lidocaine) can reliably differentiate cardiac from esophageal/GI causes of chest pain
- B) A normal chest radiograph and symmetrical pulses in the upper extremities reliably rules out a thoracic aortic dissection
- C) Most patients with a spontaneous pneumothorax should be treated with a chest tube
- D) If nitroglycerin relieves the chest pain, then the pain is certainly cardiac
- E) Pain is a finding in only about 60% of patients with a PE

Answer 2.1.6 The correct answer is “E.” Only a small majority (59%) of patients with pulmonary emboli have pain as a feature. “A” is incorrect because about 20% of patients with cardiac pain will have their pain relieved by a GI cocktail. Conversely, “D” is incorrect because nitroglycerin can relieve pain from esophageal spasm as it is a nonselective smooth muscle relaxer. “B” is incorrect because only 50% of patients with an aortic dissection will have unequal pulses and blood pressures, and only 75% will have an abnormal chest x-ray. The consideration of an aortic dissection mandates a chest CT scan with contrast, transesophageal echo, or angiogram. Remember that about 20% of the population will have unequal blood pressures in the upper extremities at baseline. “C” is incorrect because most patients with spontaneous pneumothorax can be treated with a “pigtail” catheter with a Heimlich valve. This type of treatment reduces the morbidity associated with a chest tube.

HELPFUL TIP:

Non-ionic CT contrast is safe even in those with an elevated creatinine (<4 mg/dL). Don’t go hog wild (a real “thing” in Iowa). But if you really need that CT in a patient with a creatinine of 2 mg/dL (such as for dissection of PE) go for it (*Ann Emerg Med.* 2017;69:577 and others).

HELPFUL TIP:

Chest x-ray findings in patients with thoracic aortic dissection may include widened mediastinum, obliterated aortic knob, pleural “capping,” tracheal deviation, depression of left main stem bronchus, esophageal deviation, and loss of the paratracheal stripe. But just do the contrast CT...you will sleep better.

The patient’s pain recurs in the ED. You suspect that she is having a myocardial infarction, but do not yet have unequivocal proof, such as ECG changes or elevated cardiac enzymes. The patient becomes markedly hypotensive in response to another dose of sublingual nitroglycerin.

Question 2.1.7 Which of the following is TRUE?

- A) Intravenous nitroglycerin is contraindicated in this patient
- B) Hypotension caused by nitroglycerin is usually unresponsive to IV saline
- C) Hypotension caused by nitroglycerin may be indicative of a right ventricular infarction, which is most commonly associated with an inferior wall myocardial infarction (IAMI)
- D) Hypotension caused by nitroglycerin is diagnostic of cardiogenic shock, suggesting that this patient will have a poor outcome

Answer 2.1.7 The correct answer is “C.” Hypotension in response to nitroglycerin may be indicative of a right ventricular infarct, which is most commonly associated with an inferior wall acute MI (IAMI). Since the right ventricle is dependent on filling pressure (preload), nitroglycerin, which drops the preload, will frequently result in hypotension in those with a right ventricular infarct. “A” is incorrect because hypotension from sublingual nitroglycerin is not a contraindication to additional nitrates *once the patient’s blood pressure is stable*. A typical sublingual dose is 400 µg (0.4 mg). A typical IV dose starts at 20 µg/min. Thus, the sublingual dose is quite a bit larger than the IV dose. In such a situation, you could consider starting IV nitroglycerin at 10 to 20 µg/min and titrating up as the blood pressure allows. “B” is incorrect because hypotension from nitroglycerin will generally respond to a saline bolus. “D” is incorrect. Certainly, patients with cardiogenic shock will be hypotensive, but hypotension with nitroglycerin is a common result of the drug itself and does not define cardiogenic shock.

HELPFUL TIP:

Oral beta-blockers (metoprolol succinate, carvedilol (Coreg), bisoprolol) should be initiated in most patients with an AMI—generally within 24 hours of the infarct. Hold beta-blockers in those with hypotension, heart block, or heart failure (HF). Beta-blockers are still important in these patients but should not be started until the patient is hemodynamically stable and asymptomatic in terms of HF. Remember that beta-blockers will reduce cardiac output.

Consider holding beta-blockers in IAMI, as these patients often have bradycardia and heart block. Also, beware of atypical presentations of IAMI such as nausea, vomiting, and other GI symptoms.

Question 2.1.8 Which of the following is TRUE of patients with an IAMI?

- A) They will likely continue to have problems with right ventricular functioning in the future
- B) They will need to increase their salt intake in order to increase preload and right ventricular filling pressure
- C) Their right ventricular function should return to normal or close to normal following their infarction
- D) A and B

Answer 2.1.8 The correct answer is “C.” Most patients will have return of right ventricular functioning following a myocardial infarction. “B” is incorrect because there will be no need to increase right ventricular filling pressure (which is what IV saline does acutely) once right ventricular function returns to normal.

The patient’s pain continues despite treatment with nitroglycerin, and you obtain another ECG (Fig. 2-1).

Question 2.1.9 Which of the following is TRUE regarding this ECG?

- A) This injury pattern on ECG is most consistent with an anterior wall MI
- B) In this situation, percutaneous transluminal coronary angioplasty (PTCA) and stent placement is superior to tPA or other thrombolytic
- C) This injury pattern on ECG is most consistent with pericarditis
- D) This injury pattern on ECG proves that this patient does not have an aortic dissection
- E) This pattern on ECG is totally fine. What, me worry?

Answer 2.1.9 The correct answer is “B.” Intervention in the cath lab with PTCA and/or stent placement is superior to thrombolytic therapy in the treatment of AMI, provided

that the “door to balloon” time is 90 minutes or less. In cases where the patient is located in a facility without a cardiac catheterization laboratory, the patient may receive thrombolytic therapy. “A” is incorrect because this pattern is indicative of an **inferior wall**, not an anterior wall, MI. You will note that this ECG shows ST elevations in leads II, III, and aVF (inferior leads) along with reciprocal ST-segment depression in leads V1 and V2. An anterior wall MI is defined by ST elevations in leads V3, V4, and V5, and an anteroseptal MI shows ST elevations in leads V1, V2, and V3. For IAMI concerning for RV infarction, consider “right-sided chest leads.” “D” is incorrect because patients with pericarditis should have ST elevations in all leads (although an ECG is only 80% sensitive for pericarditis). “D” is incorrect because patients with an aortic dissection can present with an abnormal ECG that looks similar to an infarct pattern. So, ECG changes do not prove that the patient does not have an aortic dissection. “E” is just plain wrong and you **should be worried** if you see this pattern!

You now have all the evidence that you need to show that this patient is indeed having an ongoing myocardial infarction. Since your rural hospital is “just around the corner from nowhere,” stenting is not going to happen within 90 minutes. You decide to initiate thrombolytic therapy.

FIGURE 2-1. ECG for patient in question 2.1.9.

Question 2.1.10 All of the following are true statements EXCEPT:

- A) Patients who are candidates for thrombolytics must have at least 1 mm of ST-segment elevation in at least 2 contiguous limb leads or at least 1 to 2 mm of ST-segment elevation in at least 2 contiguous precordial leads
- B) Patients who are candidates for thrombolytics must have an absence of prior history of hemorrhagic stroke
- C) Patients who are candidates for thrombolytics should have no active bleeding, including menstrual bleeding
- D) Patients who are candidates for thrombolytics should have no history of recent head trauma
- E) Patients who are candidates for thrombolytics should not be pregnant

Answer 2.1.10 The correct answer is “C.” While active internal bleeding is a contraindication to the use of thrombolytics (or fibrinolytics, as these terms are used interchangeably), menstrual bleeding is not. While there are no controlled trials, anecdotal evidence suggests that thrombolytics are safe with menstrual bleeding. “A” is true. See Table 2-1A for more clarity on the definition of STEMI as the ST-segment definition depends on the sex of the patient, to some degree. For thrombolytics, patients with only ST-segment **depression** or a normal ECG, even with symptoms, do **not** benefit. “B,” “D,” and “E” are all true statements. Patients are not candidates for thrombolytics if they have recent head trauma, are pregnant, or have had a hemorrhagic stroke **ever**. See Table 2-1B for a more comprehensive list of contraindications.

**HELPFUL TIP:**

“Facilitated PCI,” that is, administration of thrombolytics with the intent to perform PCI within 2 or more hours of giving thrombolytics has very mixed (and mostly negative) data. Outcomes are worse (and not just because PCI is a “rescue” technique at this point). It certainly is **NOT** the standard of care and, in fact, is no longer considered as part of the treatment algorithm. If thrombolytics versus primary PCI is being considered, it is valuable to contact the cardiologist at the cath center to determine whether he/she would like thrombolytics before transfer—timing (both from symptom onset and for transfer) is central to the decision-making process. “Rescue PCI” for failed reperfusion after thrombolytic therapy should be performed as soon as logistically possible, ideally within the first 24 hours, but **NOT** within the first 2 to 3 hours post thrombolytic therapy.

**HELPFUL TIP:**

Remember to repeat the ECG **after** thrombolytics to prove that ST elevations have resolved. Evidence of successful reperfusion after thrombolytics is suggested by: nearly sudden and complete relief of chest pain, >70% ST elevation resolution in the index lead showing the greatest degree of elevation, plus or minus the presence of reperfusion arrhythmia.

TABLE 2-1A ACC/AHA GUIDELINES FOR THE USE OF FIBRINOLYTIC THERAPY IN PATIENTS WITH ST-ELEVATION MYOCARDIAL INFARCTION: INDICATIONS

Definition of ST-segment elevation myocardial infarction is any ONE of the following ECG findings in a patient with a history suggestive of myocardial ischemia:

- ≥ 1 mm of ST-segment elevation in at least 2 contiguous limb leads
- In men, ≥ 2 mm of ST-segment elevation in at least 2 contiguous precordial leads
- In women, ≥ 1.5 mm of ST-segment depression in V2-3 or ≥ 1 mm of ST-segment depression in any other contiguous precordial leads
- **New** complete bundle branch block that obscures the ST-segment analysis

Class 1 recommendation for fibrinolytic therapy:

- In the absence of contraindications and when PCI cannot be performed within 120 minutes of first medical contact, fibrinolytic therapy should be given to patients presenting with STEMI and having onset of symptoms within prior 12 hours.

Class 2a recommendation for fibrinolytic therapy:

- In the absence of contraindications and when PCI is not available, it is reasonable to give fibrinolytic therapy in STEMI if there is clinical and/or ECG evidence of ongoing ischemia 12–24 hours after symptom onset, a large area of myocardium is at risk, or hemodynamic instability is found.

PCI, percutaneous coronary intervention.

Adapted from O’Gara PT, et al. 2013 ACC/AHA Guideline for the management of ST-segment elevation myocardial infarction. *J Am Coll Cardiol.* 2013;61(4):e78–140.

TABLE 2-1B ACC/AHA GUIDELINES FOR THE USE OF FIBRINOLYTIC THERAPY IN PATIENTS WITH ST-ELEVATION MYOCARDIAL INFARCTION: CONTRAINDICATIONS
Class 3 “Absolute” contraindications

Any prior intracranial hemorrhage

- Known structural cerebral vascular lesion
- Known intracranial neoplasm
- Ischemic stroke within 3 months (except acute stroke within 4.5 hours)
- Suspected aortic dissection
- Active internal bleeding (except menstrual bleeding)
- Significant closed-head or facial trauma within 3 months
- Intracranial or intraspinal surgery within 2 months
- Severe uncontrolled hypertension (unresponsive to emergency treatment)
- For streptokinase, prior treatment within the previous 6 months

Relative contraindications

- History of chronic, severe, poorly controlled hypertension
- Significant hypertension on presentation ($> 180/110$ mm Hg)
- History of prior ischemic stroke > 3 months
- Dementia
- Known intracranial pathology not covered in absolute contraindications
- Traumatic or prolonged CPR (> 10 min)
- Major surgery in prior 3 weeks
- Recent internal bleeding (prior 2–4 weeks)
- Noncompressible vascular punctures (e.g., subclavian line)
- Pregnancy
- Active peptic ulcer
- Oral anticoagulant therapy

Adapted from O’Gara PT, et al. 2013 ACC/AHA Guideline for the management of ST-segment elevation myocardial infarction. *J Am Coll Cardiol.* 2013;61(4):e78–140.

After conferring with your closest cath center, you give a thrombolytic—and cross your fingers. Unfortunately, the patient develops a new LBBB. In addition, the ECG shows evidence of a first-degree heart block (a prolonged PR interval), although the heart rate remains normal at 80 bpm.

Question 2.1.11 The proper response to this is to:

- A) Insert a Swan–Ganz catheter to monitor central pressures
- B) Insert a temporary pacemaker regardless of the heart rate
- C) Administer atropine to this patient
- D) Administer isoproterenol to this patient
- E) Do nothing, other than observe this patient

Answer 2.1.11 The correct answer is “B.” For patients with an AMI, a transvenous pacemaker should be inserted if the patient develops (1) complete heart block, (2) second-degree heart block type II (Mobitz II), or (3) new LBBB with first-degree AV block. See Tables 2-2 and 2-3 for more on arrhythmia and pacemakers in the setting of AMI. “A” is incorrect because a Swan–Ganz catheter will be of no help in arrhythmias. “C” is incorrect because atropine is indicated for symptomatic bradycardia and not for a bundle branch block. “D” is incorrect for the same reason as “C.” In addition, isoproterenol is arrhythmogenic and is no longer recommended. “E” is incorrect because the patient may rapidly progress into a complete heart block. Of note and importantly, the placement of a transvenous pacemaker should not delay transfer for catheterization since a pacemaker may also be placed in the cath lab. However, apply an external pacemaker as required.

The patient requires heparin with the thrombolytic that you choose (and is indicated, by guidelines, for a minimum of 48 hours and preferably for the duration of the index hospitalization, up to 8 days or until revascularization is performed).

TABLE 2-2 TYPE OF HEART BLOCK ASSOCIATED WITH INFARCTION

Anterior myocardial infarction	Bundle branch blocks Mobitz type II second-degree heart block
Inferior myocardial infarction	Bradycardia from: <ul style="list-style-type: none"> • Mobitz type I second-degree heart block • Third-degree heart block

TABLE 2-3 CLASS I INDICATIONS FOR PACEMAKER IN PATIENTS WITH AN ACUTE MYOCARDIAL INFARCTION

New left bundle branch block + first-degree AV block
New right bundle branch block + left anterior or posterior fascicular block + first-degree AV block
Mobitz type II heart block
Third-degree heart block
Symptomatic bradycardia unresponsive to atropine.

Question 2.1.12 Which of the following dosing regimens is the best accepted for use in AMIs?

- A) Enoxaparin 30 mg subcutaneously (SC) every 12 hours
- B) Enoxaparin 1 mg/kg SC every 12 hours
- C) Heparin 5,000 units bolus and a drip at 1,000 units per hour
- D) Heparin 100 unit/kg bolus with a drip at 25 units/kg/hr
- E) None of the above represents the best dosing option in this situation

Answer 2.1.12 The correct answer is “B.” For anticoagulation in AMI, the dose of enoxaparin is 1 mg/kg SC every 12 hours. “A” is incorrect since 30 mg SC every 12 hours is the dose for DVT prophylaxis in post-op joint replacement patients, not for anticoagulation. “C” is incorrect. This is the classic way that heparin has been dosed but it is **not** the best option listed. “D” is incorrect as well. The **correct** dose for heparin **when given with a thrombolytic** is 60 units/kg bolus (maximum of 4,000 units) with a drip of 15 units/kg/hr (maximum dose of 1,000 units/hr), with rate adjusted to achieve an activated partial thromboplastin time (aPTT) of 1.5 to 2 times control (for 48 hours or until revascularization). The bottom line here is that either enoxaparin or heparin can be used in this setting, and they are more or less equivalent. If you choose to use heparin, **do not use fixed dose heparin but rather weight-based dosing. One advantage to unfractionated heparin** is that the half-life is 30 minutes, so it is rapidly cleared. Additionally, it can be reversed with protamine zinc. (Did you know that protamine was originally extracted from fish sperm? Who came up with that idea? It is now produced by recombinant technology.)

HELPFUL TIP:

Did you know that for ST-elevation MI, an initial dose of 30 mg of **IV enoxaparin** (that’s right—intravenous) should be given with the **first (and only the first)** dose for those age <75 years. The IV dose should be given at the same time as the first 1 mg/kg subcutaneous dose. Do it!

The patient receives her thrombolytic, enoxaparin, and transvenous pacing, and she is admitted to the hospital to a monitored bed. You get a call from the nursing staff 5 hours later. The rhythm strip shows 3 PVCs per minute. Your patient remains pain free and is hemodynamically stable.

Question 2.1.13 The nurse (who has more than a few gray hairs) would like an order for lidocaine. Your response is:

- A) “Do it. Give the lidocaine”
- B) “Give amiodarone—it works better than lidocaine”
- C) “Give no antiarrhythmic at this point in time”
- D) “Check labs including potassium and magnesium”
- E) C and D

Answer 2.1.13 The correct answer is “E.” The use of lidocaine in this setting incurs no benefit and is proarrhythmic. The same is true for prophylactic amiodarone, which can cause

torsades de pointes, albeit at a lower frequency than other antiarrhythmics (such as quinidine, procainamide, sotalol, and newer Class III antiarrhythmic agents). In the setting of AMI, antiarrhythmics may be indicated only for complex arrhythmias (PVC couplets, triplets, nonsustained ventricular tachycardia [<30 seconds], or >10 PVCs per minute). More than 90% of patients will have isolated PVCs in the peri-infarct period, and there is no association with increased mortality. Correcting hypokalemia and hypomagnesemia can help to reduce arrhythmias, and checking these labs is prudent.

The patient remains pain free while in the hospital. She is ready to be discharged 4 days later—but she's still getting enoxaparin for a total of 8 days, as recommended in the guidelines.

Question 2.1.14 Which of the following tests is the most appropriate for this patient prior to discharge?

- A) Coronary angiography
- B) Submaximal stress test plus echocardiography
- C) Full Bruce protocol, symptom limited, stress test
- D) Spiral CT to assess for coronary artery calcification
- E) Ping test

Answer 2.1.14 The correct answer is “B.” Submaximal stress testing is considered the standard of care; a noninvasive evaluation of left ventricular ejection fraction (e.g., echocardiogram or radionuclide study) is also indicated. Patients with a positive submaximal stress test should be referred for catheterization. Patients with a borderline stress test can be sent for a radionuclide study. Coronary angiography is **not** routinely recommended for all patients who have had a myocardial infarction unless they are considered to be at high risk (continued symptoms, positive screening test such as submaximal stress test, heart failure, cardiogenic shock, etc.). “C” is incorrect because a symptom-limited, full-protocol stress test should be done only 14 to 21 days after an infarction. Finally, spiral CT (“D”) to assess for coronary artery calcification has no role in risk stratification after a myocardial infarction ... their risk is 100%! Also, keep in mind that the weight of the clinical evidence **favours transfer for early catheterization**, especially for higher risk patients. “E,” a ping test, is a test to see if your internet service is working.

Question 2.1.15 The patient passes her stress test with flying colors (and you pass your Board Examination). Patients after a myocardial infarction should be routinely discharged on all of the following medications EXCEPT:

- A) Aspirin
- B) Beta-blocker
- C) Continuous nitroglycerin (e.g., patch or isosorbide)
- D) HMG-CoA reductase inhibitor (“statin”)
- E) Sublingual nitroglycerin for PRN use

Answer 2.1.15 The correct answer is “C.” There is no benefit to scheduled nitrates unless needed for a specific indication

(e.g., recurrent angina). All post-myocardial infarction patients should be discharged on aspirin, a beta-blocker, a statin, nitroglycerin PRN, and an angiotensin-converting enzyme (ACE) inhibitor—if they are tolerated, of course. A P2Y₁₂ inhibitor should be continued for up to 12 months in those with no stent (options include clopidogrel 75 mg daily, ticagrelor 90 mg BID). See “helpful tip” for treatment of those with a stent (after question 2.2.9).

HELPFUL TIP:

All patients with an ST-elevation MI **or** non-STEMI/unstable angina should be discharged on an intensive lipid-lowering regimen with an HMG-CoA reductase inhibitor (“statin”), such as atorvastatin 40 to 80 mg per day, including those with a baseline LDL <70 mg/dL. Keep reading for more on statins below.

While this patient had a STEMI (or “Q-wave” MI), it is also important to recognize some of the differences between STEMI and non-STEMI.

Question 2.1.16 Regarding non-STEMI, which of the following statements is TRUE?

- A) Patients with a non-STEMI have the same, or perhaps a bit worse, outcomes long term than do patients with a STEMI
- B) Patients with a non-STEMI have worse in-hospital outcomes when compared with patients with a STEMI
- C) Unstable angina and non-STEMI can be readily differentiated from one another on presentation
- D) None of the above is true

Answer 2.1.16 The correct answer is “A.” Patients with a non-STEMI actually have the same, or perhaps even slightly worse, outcomes long term when compared to patients with a STEMI. This makes sense; there is still myocardium left to infarct after a non-STEMI. As to the other answers, patients with a STEMI do have worse in-hospital outcomes, and unstable angina and non-STEMI look similar on ECG with T-wave inversion, etc., but without the ST elevations that are classically seen in a transmural infarction.

► Objectives: Did you learn to ...

- Define the accuracy of the initial history, ECG, and labs in the diagnosis of cardiac disease in the ED or office?
- Recognize the role and significance (or lack thereof) of risk factors, such as diabetes, family history, smoking, and hypertension, in the decision of whether or not to admit a patient to the hospital for chest pain?
- Generate a differential diagnosis of chest pain?
- Identify the roles of various diagnostic tests in the evaluation of chest pain?
- Treat a patient with an AMI?

**QUICK QUIZ: CORONARY CALCIUM**

You are seeing a 42-year-old male patient. He is asymptomatic and presenting for a routine annual exam. The patient looks well-conditioned and admits (well, beams...the jerk) that he exercises daily without any chest pain. He smokes one pack of cigarettes per day and has a blood pressure of 135/87 mm Hg, total cholesterol of 179 mg/dL, and HDL of 30 mg/dL. He takes no medication. In order to better stratify his risk for atherosclerotic cardiovascular disease (ASCVD), he is wondering if he should get one of those fancy CT scans he's seen advertised on billboards in your town.

Which of the following is true regarding the role of a coronary calcium score in this patient?

- A) A coronary calcium score may be a helpful tool in the evaluation of this patient if used in combination with an ASCVD risk score
- B) A coronary calcium score is a helpful tool in the evaluation of this patient independent of his calculated ASCVD risk score and will help decide statin treatment for primary prevention
- C) A coronary calcium score is only useful in evaluating this patient once he has had an echocardiogram
- D) A coronary calcium score is only useful in the evaluation of ongoing anginal chest pain

The correct answer is "A." The patient presents with an ACC/AHA ASCVD risk score of 7.7% which places him in the 10-year intermediate-risk category (find calculator at <https://www.mdcalc.com/ascvd-atherosclerotic-cardiovascular-disease-2013-risk-calculator-aha-acc>). What to do in that category is in itself controversial, with ACC/AHA recommending statin therapy to all patients in that risk category and the USPSTF giving statins a "C" rating for individualizing the decision. In this circumstance, more information via a CT coronary calcium score **may** be useful. However, there is significant controversy over the utility of the calcium score with some evidence favoring its use, while the USPSTF states that the evidence is insufficient (JAMA 2018;320(3):271–280). Independently ("B"), a coronary calcium score is not helpful, as you would need to know other patient characteristics and risk factors in order to make a decision on primary prevention. "C" and "D" are incorrect because a coronary calcium score does not require an echocardiogram and it can be used to help stratify risk.

**QUICK QUIZ: GLYCOPROTEIN IIB/IIIA INHIBITORS**

You are seeing a patient in the ED with chest pain. The ECG shows elevated ST segments in leads V1, V2, and V3 with reciprocal changes inferiorly. You have run through the "standard" medications, but the patient continues to have pain. You consult a cardiologist who suggests the use of a glycoprotein IIb/IIIa inhibitor.

Which of the following is true about the glycoprotein IIb/IIIa inhibitors?

- A) They are best used in patients who are not candidates for PTCA and stenting
- B) They cause no increase in the rate of intracranial bleeding
- C) They are useful in all groups of patients with ACS
- D) They are most effective in patients going to PTCA and/or stenting

The correct answer is "D." The glycoprotein IIb/IIIa inhibitors are most effective in patients who are undergoing PTCA or stenting. The GUSTO V trial showed **NO** difference in 30-day mortality in patients **who were not** scheduled for catheterization. Thus, "A" is incorrect. "B" is incorrect because glycoprotein IIb/IIIa inhibitors do increase rates of intracranial and other bleeding. "C" is incorrect because patients who have an ACS that is well-controlled with other drugs (e.g., heparin, metoprolol, and ASA) are not likely to benefit from glycoprotein IIb/IIIa inhibitors.

**HELPFUL TIP:**

Since the arrival of potent P2Y₁₂ inhibitors (e.g., ticagrelor, prasugrel), which inhibit platelet degranulation upstream from the IIb/IIIa receptor, glycoprotein IIb/IIIa inhibitors are now only used in special circumstances for patients undergoing PTCA/stenting.

CASE 2.2

A 53-year-old male with a history of hypertension and smoking, but no family history of cardiac disease, presents to your office complaining of a chest pain. The pain is substernal, radiates to his left arm, and is associated with exertion. The patient notes that this same pain has been going on for the last 6 months and has not changed at all in duration, intensity, or characteristic. It generally lasts 5 minutes or so and resolves with rest.

Question 2.2.1 You tell the patient that:

- A) Without doing any test, you know that the probability that this pain is cardiac is greater than 85%
- B) If his ECG in the office is normal, his pain is unlikely to represent cardiac disease
- C) Even with risk factors, his probability of having CAD with "typical angina" is about 50%
- D) The only interventions indicated at this point are lifestyle modifications (e.g., stop smoking) and addressing his cholesterol and hypertension
- E) It is likely that he has unstable angina

Answer 2.2.1 The correct answer is "A." A 50-year-old male with "classic" angina symptoms has **greater than a 90%** probability of having CAD. "B" is incorrect because patients with angina who are pain free may have a normal electrocardiogram (as will many patients with active angina or even a myocardial infarction). Thus, his pain could still be cardiac in origin. "C" is incorrect because, based on demographic data, his risk of CAD is much

higher than 50%. “D” is incorrect because he needs a further evaluation and treatment of his chest pain. “E” is incorrect since this pain represents “stable angina.” There has been no change in quality, duration, amount of exertion required to bring on symptoms, etc., eliminating unstable angina as a diagnosis. Use of tools such as the TIMI Risk Score (<https://www.mdcalc.com/timi-risk-score-stemi>) and/or Grace Risk Model (<https://www.mdcalc.com/grace-acs-risk-mortality-calculator>) can assist in estimation of the level of risk and to help guide management decisions.

HELPFUL TIP:

Know your pretest probability of cardiac disease before embarking upon testing for chest pain. This varies by age and type of chest pain. An approximation of the probability of cardiac disease is as follows:

Male, **atypical angina**: age 30 to 39 = 34%, age 40 to 49 = 51%, age 50 to 59 = 65%, age 60 to 69 = 72%.

Male, **typical angina**: age 30 to 39 = 76%, age 40 to 49 = 87%, age 50 to 59 = 93%, age 60 to 69 = 94%.

Female, **atypical angina**: age 30 to 39 = 12%, age 40 to 49 = 22%, age 50 to 59 = 31%, age 60 to 69 = 52%.

Female, **typical angina**: age 30 to 39 = 26%, age 40 to 49 = 55%, age 50 to 59 = 73%, age 60 to 69 = 86%.

You send the patient home on aspirin with a prescription for sublingual nitroglycerin for PRN use and arrange for a stress test.

Question 2.2.2 All of the following are considered absolute contraindications to exercise stress testing EXCEPT:

- A) Left bundle branch block (LBBB)
- B) Presence of severe heart failure
- C) Critical aortic stenosis
- D) Myocarditis
- E) Unstable angina

Answer 2.2.2 The correct answer is “A.” An LBBB is a relative—not absolute—contraindication to stress testing. In the setting of LBBB, there are already repolarization abnormalities that limit the usefulness of the ECG component of a stress test. One should add an imaging modality, such as myocardial perfusion scanning or echocardiography, in cases of LBBB. The same holds for any baseline ECG pattern that would interfere with ST-segment interpretation (baseline ST changes, LVH with repolarization changes involving the ST-T wave, intraventricular conduction delay, paced rhythm, preexcitation, or ST-T changes due to digoxin therapy). The rest are all “absolute” contraindications to exercise stress testing. See Table 2-4 for a list of contraindications to stress testing.

Question 2.2.3 Exercise stress testing is best suited to which group of individuals?

- A) Men with an intermediate probability of cardiac disease
- B) Women with a high risk of cardiac disease
- C) Men at a high risk of cardiac disease
- D) Men at a low risk of cardiac disease
- E) Women with a low risk of cardiac disease

TABLE 2-4 CONTRAINDICATIONS TO EXERCISE STRESS TESTING

Absolute contraindications	<ul style="list-style-type: none"> • Acute myocardial infarction within 2 days • Dissecting aneurysm • Recent pulmonary embolism • Active thrombophlebitis • BP > 200/120 mm Hg • Hemodynamically significant arrhythmias • Severe heart failure • Severe aortic stenosis • Active myocarditis, pericarditis, or endocarditis • Inability to complete test (e.g., severe knee arthritis) • Unstable angina
Relative contraindications	<ul style="list-style-type: none"> • Left bundle branch block • Moderate aortic stenosis • Hypertrophic cardiomyopathy • Electrolyte disturbance • High-grade AV block • Tachyarrhythmias or bradyarrhythmias including uncontrolled atrial fibrillation

Answer 2.2.3 The correct answer is “A.” Stress testing is best suited to patients with an intermediate pretest probability of cardiac disease (between 25% and 75%). “B” and “C” are incorrect since patients with a high risk of cardiac disease should go directly to another study, such as nuclear myocardial perfusion imaging study (MPI, also sometimes termed “thallium stress testing”) or stress echocardiography. “D” and “E” are incorrect since these are not the best groups in whom to use exercise stress testing; there will be a greater proportion of false-positive results in these low-risk patients. Exercise stress testing in these groups is best used to allay patient fears that they do not have cardiac disease, not to prove they do have cardiac disease. However, a false-positive stress test may lead to other unnecessary invasive testing!

You decide to do an exercise stress test on this patient. It turns out to be negative.

Question 2.2.4 Your next step is to:

- A) Reassure the patient that he does not have cardiac disease
- B) Suggest a chest CT scan to rule out possible aortic aneurysm
- C) Schedule the patient for another cardiac test such as stress echocardiogram, exercise myocardial perfusion test, or angiography
- D) Schedule the patient for endoscopy to rule out gastroesophageal disease as a cause of these symptoms
- E) Start an anxiolytic to treat the panic disorder, which is the underlying cause of his chest pain

Answer 2.2.4 The correct answer is “C.” This patient who is in his 50s and who has a “classic” history for angina has greater than a 90% pretest probability of cardiac disease. Thus, it is likely that the negative stress test is a **false** negative. What was the point of that stress test anyway? It probably should not have been done in this patient since a negative test just leads to further testing

(as would have a positive test, probably resulting in angiography). For this reason, “A” is incorrect. “B,” “D,” and “E” are also incorrect because you have not yet eliminated a cardiac cause.

You are considering whether to order an MPI or a stress echocardiogram.

Question 2.2.5 Which of the following is true?

- A) Stress echocardiography is more sensitive for cardiac disease than is an MPI
- B) Stress echocardiography is more specific than is a stress MPI
- C) MPI is more specific for cardiac disease than is stress echocardiography
- D) None of the above is true

Answer 2.2.5 The correct answer is “B.” Stress echocardiography is more specific for cardiac disease than is MPI. Alternatively, MPI is more sensitive. Table 2-5 summarizes this data. Remember that positive and negative predictive values of these tests will vary depending on the pretest probability of disease in the patient **and** severity of disease. Numbers given above are overall.

You decide to send the patient for an MPI. However, since you last saw him, he fell and sprained his ankle...just to help us write this case (taking one for the team). So, you decide to stress him chemically. The patient is taking theophylline (really—in the 21st century!) for chronic obstructive pulmonary disease (COPD).

Question 2.2.6 The LEAST desirable pharmacologic agent to administer for stressing this patient is:

- A) Adenosine
- B) Dobutamine
- C) Dipyridamole
- D) All of the above are equally acceptable methods of chemically stressing this patient
- E) Neither A nor C is desirable

Answer 2.2.6 The correct answer is “E.” Theophylline (and caffeine) interact with both adenosine and dipyridamole, attenuating their effect. Additionally, adenosine may precipitate

bronchospasm and should be avoided in patients with COPD or asthma. Thus, neither drug is a good choice for stressing this patient. Dobutamine is an acceptable method of chemically stressing those on theophylline or caffeine (like us), but it would only be used with an echocardiogram—not an MPI. On the other hand, COPD patients often have poor echocardiographic windows. Is this patient headed to a cath? We’ll see...

You do your patient a big favor by tapering him off theophylline and getting him on a more modern inhaled COPD regimen. Good thing he came to see you. Indeed, his echocardiogram windows are suboptimal. Several studies have shown that regadenoson (Lexiscan®) appears safe in COPD (e.g., *J Nucl Cardiol.* 2008;15:319). So, finally, you order a regadenoson-based MPI (after completing a prior authorization, calling his insurance company, etc., etc.).

Question 2.2.7 The patient’s MPI shows an antero-apical nonreversible (“fixed”) defect. The best interpretation of this is that it indicates:

- A) Attenuation artifact from breast tissue
- B) Prior myocardial infarction
- C) Angina
- D) Anomalous cardiac circulation
- E) It is not significant and therefore adds no value to this test

Answer 2.2.7 The correct answer is “B.” A nonreversible (“fixed”) defect suggests prior myocardial infarction. A reversible defect suggests inducible ischemia. “A” is incorrect since breast attenuation occurs mostly in women (but can also be seen in obese males, which is part of the rationale for performing PET imaging in patients with BMI > 35 kg/m² since PET uses a higher-energy isotope to mitigate soft tissue attenuation). Another advantage of a PET scan is that it can detect both cardiac perfusion *and* myocardium viability. “C” is incorrect since angina would likely be manifested by a reversible deficit.

Since a reversible defect was not found on the stress test, you conclude that there is no myocardium currently at risk. However, the patient continues to have chest pain and now at an increasing frequency with less exertion. He is asymptomatic when he presents to your office. He was noted at the last visit to have an elevated glucose at 350 mg/dL.

Question 2.2.8 What is the next step in the evaluation or treatment of this patient?

- A) Stress echocardiogram to document what segments are involved
- B) Start the patient on insulin to control his blood sugars
- C) Proceed directly to cardiac catheterization
- D) Since there were no reversible deficits on stress testing, schedule the patient to see a gastroenterologist
- E) Give a trial of NSAIDs to help differentiate chest wall pain from other causes

TABLE 2-5 OVERALL SENSITIVITY AND SPECIFICITY OF NONINVASIVE CARDIAC TESTING

	Sensitivity (%)	Specificity (%)
Exercise stress testing	45–68	77
Myocardial perfusion imaging (thallium or SPECT)	88	77
Stress echocardiography	76	88
Cardiac CT	88–99%	64–83%

Answer 2.2.8 The correct answer is “C.” Given that this high-risk patient has worsening angina and now is even at higher risk since he probably has diabetes, he should have the definitive test done. “A” is incorrect since we already have done a noninvasive test. We already know what segment was previously infarcted, as noted on the MPI. “B” is incorrect for two reasons. First, addressing his diabetes will not address the immediate problem of what you must presume is unstable angina. Second, insulin is not necessarily the first drug to use in this patient who presumably has type 2 diabetes. Certainly, the blood glucose needs to be addressed but so does the chest pain. Which is going to kill him first? “D” is incorrect. The sensitivity of MPI is in the 88% range (see Table 2-5), so it will miss 12% of disease. Thus, we still have not proven in this high-risk patient that he does not have treatable cardiac disease causing his chest pain. “E” is incorrect for the same reason.

The patient has a catheterization done that shows three-vessel disease including left main CAD. The cardiologist calls you with the report the next day and suggests PTCA with stenting, since, in his opinion, “This is the best modality for diabetics and diabetics are high-risk candidates when it comes to surgery.”

Question 2.2.9 Your opinion is that:

- A) Patients with stents generally have better outcomes in terms of control of angina with stenting when compared with coronary artery bypass grafting (CABG)
- B) Diabetic patients do particularly well with stenting when compared with CABG
- C) Medical control of symptoms is indicated as the best management in this diabetic patient with three-vessel disease
- D) Diabetic patients do better with CABG when compared with stenting
- E) You don't have an opinion. You just do what the nice cardiologist says

Answer 2.2.9 The correct answer is “D.” This patient should probably have surgery for his three-vessel disease because diabetic patients generally have **worse** outcomes with stenting than do nondiabetic patients in terms of angina relief and need for repeat revascularization. “A” is incorrect because a proportion of patients with stents have to go on to have an open CABG due to in-stent restenosis or incomplete revascularization with percutaneous revascularization. “B” is incorrect. Diabetic patients have a much higher rate of in-stent restenosis or secondary occlusion (meaning a narrowing/stenosis somewhere else in the diseased vessel). “C” is incorrect. The indications for CABG are significant left main CAD (>50%), three-vessel disease with evidence of LV dysfunction (ejection fraction <50%), or origin/proximal LAD/LCX disease (left main equivalent). This patient has left main vessel disease and thus medical control is **NOT** the best option for this patient. He is also young and, from the available data, appears to be a good surgical candidate. Therefore, CABG is the guideline-recommended option for this patient. “E” is incorrect because you went to medical school and have a brain.

HELPFUL TIP:

Drug-eluting stents (DES) decrease overall re-occlusion rates in comparison to bare metal stents (BMS). Women who have multiple stents and multi-vessel disease are at a higher risk of restenosis, as are patients with a small post-stenting lumen size. Early re-occlusion secondary to thrombosis is higher with DES versus BMS, and the mortality risk due to stent thrombosis when it occurs is high (range 20–45%). This is because it takes the body longer to cover these stents with intima (i.e., re-endothelialization). Thus, clopidogrel, ticagrelor or prasugrel (not our favorite) for 1 year **PLUS** aspirin for life should be used in patients who have a DES inserted. For BMS, the recommendation is to use one of the antiplatelet agents for **3 to 6 months PLUS** aspirin for life. (Note: the risk of stent thrombosis with a bare metal stent is highest in the first 14–30 days.) Eighty-one milligrams of aspirin to Aspirin 81 mg seems to be the Goldilocks spot: not too much bleeding, adequate antiplatelet effect.

HELPFUL TIP:

A plea from your editors. Don't continue clopidogrel, etc., outside of the time frame in which they have been shown to be useful (3–6 months for a BMS, 1 year for a DES) unless there is ongoing ACS. The bleeding risk is increased for no or minimal benefit. Continue aspirin indefinitely, of course (*N Engl J Med.* 2014;371:2225–2226). For patients on warfarin or another oral anticoagulant, consideration should be given to reducing the duration of triple therapy (oral anticoagulant + ASA + clopidogrel, for example) due to bleeding risk without significant benefit. Drop one of the antiplatelet drugs. However, the optimum duration of therapy has not been established. It may be safe to stop triple therapy as early as 4 to 6 weeks after a DES (*J Am Coll Cardiol.* 2015;65:1619).

HELPFUL TIP:

The treatment of **stable** angina is somewhat controversial. Most data shows that conservative *optimized* medical treatment is just as good as stenting for both cardiovascular disease outcomes and symptom relief (*N Engl J Med.* 2015;373:1937; *Lancet* 2018;391(10115):31–40).

For those with unstable angina/MI/multivessel disease, CABG leads to overall better outcomes when compared to stenting. This is especially true in diabetics (*Lancet* 2018;391:939). However, with isolated **stable** left main CAD, stenting seems as good as CABG in **nondiabetics**.

Your patient has a CABG and comes into your office complaining of chest pain and fever 3 weeks after the surgery. He has had the pain and fever for 4 days and does not seem to be getting any better. He has no cough, no sputum production,

FIGURE 2-2. Electrical alternans. Note alternating voltages on ECG.

and the pain seems to be worse when he breathes or lies down. He reports no dyspnea and has 97% oxygen saturation on room air. The wound from the surgery is well healed, and a chest radiograph shows no evidence of abnormalities.

Question 2.2.10 Which of these studies is LEAST likely to be abnormal in this patient?

- A) ECG
- B) Ventilation/perfusion (V/Q) scan
- C) Echocardiogram
- D) Sedimentation rate (ESR)

Answer 2.2.10 The correct answer is “B.” A V/Q scan is not likely to be positive in this patient. This patient is unlikely to have a pulmonary embolism (PE), given the duration of symptoms, the fact that the patient has chest pain that worsens with inspiration (found in only 59% of those with PE), fever, absence of dyspnea, and has normal oxygen saturation. Certainly, this **could** still be a PE, but it would be less likely than other, more plausible, explanations. The most likely diagnosis in this patient, given the lack of other symptoms, is post-pericardiotomy syndrome. This is similar to Dressler syndrome, which occurs after a myocardial infarction and presents with fever and chest pain several days to weeks after the inciting event. The white blood count is often elevated, as is the ESR. The ECG can be helpful as can an echocardiogram.

You obtain an ECG on this patient that shows a pattern consistent with pericarditis.

Question 2.2.11 Which of the following patterns can be seen in a patient with pericarditis?

- A) Diffuse ST-segment elevation
- B) Normal ECG
- C) LBBB
- D) A and B
- E) All of the above

Answer 2.2.11 The answer is “D.” Both diffuse ST-segment elevations and a normal ECG can be seen with pericarditis, as can electrical alternans (Fig. 2-2). A PR depression (Fig. 2-3) can also be seen in pericarditis and is almost pathognomonic. There is one caveat: If there are **only inferior wall ST elevations, isolated PR depression in aVL may be associated with an inferior wall MI**. The initial ECG is only 80% sensitive for pericarditis. Small (low voltage) QRS complexes or electrical

FIGURE 2-3. PR depression.

alternans can also be seen if there is a pericardial effusion. “C” is incorrect since bundle branch blocks have nothing to do with pericarditis.

After a complete history, physical examination, ECG, and echocardiogram, you determine that he has pericarditis.

Question 2.2.12 Which of the following drugs might be helpful in this patient?

- A) Heparin
- B) Warfarin
- C) Furosemide
- D) Colchicine

Answer 2.2.12 The correct answer is “D.” Colchicine is the only drug in the list that is a treatment for pericarditis. It can be used first line with an NSAID such as aspirin, indomethacin, or naproxen (*Lancet* 2014;383(9936):2232–2237). Steroids are reserved for those who fail NSAIDs and colchicine. Do not use anticoagulation, either heparin or warfarin, in patients with pericarditis. This can cause bleeding into the pericardial space and tamponade. Thus, “A” and “B” are incorrect. “C” is incorrect because furosemide will likely make this patient worse. Patients with increased pericardial pressures are dependent on circulating preload volume in order to fill the right heart. Decreasing the preload may cause dyspnea in this patient.

The patient returns the next day and is now feeling short of breath. On examination, you notice JVD and peripheral edema. His blood pressure is 90/50 mm Hg with a pulse of 130 bpm. You rightly call an ambulance.

Question 2.2.13 The best initial treatment of this patient is:

- A) Furosemide
- B) Nitroglycerin
- C) IV saline
- D) Morphine

Answer 2.2.13 The correct answer is “C.” This patient is in “pure” right heart failure secondary to possible cardiac tamponade. He is preload dependent. The treatment is to **increase** his preload by using IV saline. All the other options reduce the preload and will worsen this patient’s symptoms.

He gets admitted to a cardiac inpatient bed and you give a bolus of 1 liter 0.9% saline IV on the way to the hospital. Despite this, he remains dyspneic with elevated neck veins and has a pulsus paradoxus of 14 mm Hg (normal <10 mm Hg).

Question 2.2.14 The next step for this patient is:

- A) Change the patient to steroids from indomethacin
- B) Perform a pericardiocentesis
- C) Start a positive inotrope (e.g., dopamine) to improve right heart function
- D) Start an afterload reducer to reduce cardiac demand

Answer 2.2.14 The correct answer is “B.” The patient is clearly not doing well if he is getting more dyspneic and not responding to your treatment. The pulsus paradoxus is 14 mm Hg. This is indicative of possible cardiac tamponade, but it may be seen in constrictive pericarditis, severe asthma, or anything else that reduces right heart filling (e.g., tension pneumothorax). This patient’s clinical picture is consistent with decompensated cardiac tamponade, and drastic action is indicated to relieve the symptoms of right heart failure. The definitive treatment is pericardiocentesis. “A” is incorrect because more drastic action is required. You would be correct to change the patient to prednisone or to add colchicine if not done already. “C” is incorrect since an inotrope will do little to help this problem. “D” is incorrect for two reasons: the first is that this is a right heart problem and reducing afterload (systemic vascular resistance) will not help the right heart, which pumps against pulmonary resistance; second, most drugs that reduce systemic vascular resistance will also decrease preload to some degree, worsening the symptoms of tamponade.

HELPFUL TIP:

Be aware that up to 25% of patients with cardiac tamponade will **NOT** demonstrate an elevated pulsus paradoxus. So, a normal pulsus paradoxus does not rule out cardiac tamponade.

HELPFUL TIP:

Measuring pulsus paradoxus: Pump up the BP cuff to greater than the systolic BP. Deflate the BP cuff slowly and listen for the first Korotkoff sound heard **only** during expiration; continue slowly deflating until you hear the Korotkoff sounds with inspiration as well. The difference is the pulsus paradoxus.

You perform a pericardiocentesis and the patient gets better. Of course, a good outcome never protected anyone from a lawsuit ...

► Objectives: Did you learn to ...

- Evaluate a patient with typical anginal chest pain?
- Describe the test characteristics of various types of noninvasive cardiac testing?
- Become familiar with the interpretation of noninvasive cardiac testing?
- Recognize various indications for PTCA with stent placement versus CABG?
- Understand the physiology, presentation, and treatment of post-pericardiotomy syndrome?
- Treat pericarditis and cardiac tamponade?

QUICK QUIZ: CARDIAC CT SCAN

When planning treatment or diagnosing (i.e., “ruling out” ACS) based on a cardiac CT angiogram (CCTA), which of the following is TRUE?

- A) In patients with stable CAD, CCTA is associated with reduced CAD mortality and overall mortality compared to other noninvasive tests (MPI, exercise testing, etc.)
- B) The radiation exposure for CCTA is less than that of MPI
- C) The downstream radiation exposure after MPI is less than that of CCTA
- D) CCTA images are of best quality in patients with a pulse of 80 to 100 bpm
- E) A creatinine of 1.6 mg/dL is a contraindication to the use of CCTA because of the contrast load

The correct answer is “B.” The radiation exposure of CCTA is less than that of MPI, both initially and downstream (thus, “C” is wrong). More patients who have MPI go on to angiogram and additional radiation exposure. “D” is incorrect. The slower the heart rate, the better the images (within reasonable limits, of course, as pulse of 12 bpm isn’t so good). So, patients are often pretreated with metoprolol to slow the heart rate before CCTA. “E” is also incorrect. It turns out that IV contrast is less of a factor in renal failure than we have thought (*Radiology* 2014;273(3):714; *Ann Emerg Med.* 2017 Aug 12). If you feel the patient really needs the CT and has a creatinine of 1.7 mg/dL or less, go ahead with the CT. What about option “A”? It turns out that even though CCTA is better at identifying cardiac disease (Table 2-5) and leads to more interventions than MPI and echo, its use is not associated with a reduction in cardiovascular or all-cause mortality. CCTA does reduce non-fatal MIs. Most of the benefit was from more aggressive medical management (e.g., statins, BP control) and not revascularization (*N Engl J Med.* 2018;379:924–933). So, treat your patients appropriately and you can bypass the CCTA in patients with stable CAD.

QUICK QUIZ: HYPERTENSION

According to the Eighth Joint National Committee (JNC 8), the blood pressure goal in a patient with diabetes is:

- A) <100/50 mm Hg
- B) <110/70 mm Hg
- C) <130/80 mm Hg
- D) <140/90 mm Hg
- E) None of the above

The correct answer is “D.” According to JNC 8, the goal for a diabetic patient (or any patient age 30–59 years, including those with chronic kidney disease) is <140/90 mm Hg. Tighter control does not seem to confer any benefit. The BP goal in those over age 60 is <150/90 mm Hg. These goals are consistent with the best current evidence at the time JNC 8 was published. In fact, tight blood pressure control in diabetics increases mortality (*JAMA* 2010;304(1):61–68). However, the American Diabetes Association continues to recommend more aggressive targets (e.g., <140/90 mm Hg in the 2018 *Standards* update, with the caveat that treatment should be individualized).

HELPFUL TIP:

Recommendations for treating hypertension in the elderly vary a little based on the organization publishing the goals. For patients over age 80 years, there is universal agreement (ACC/AHA, JNC 8, ASH, ESH/ESC,

ACP, AAFP) that <150/90 mm Hg should be the goal. For patients age 60 to 79 years, JNC 8, ACP, and AAFP recommend a goal of <150/90 mm Hg while the other organizations recommend a goal of <140/90 mm Hg—but with a systolic pressure remaining greater than 115 mm Hg. Most of these guidelines also specifically state that standing blood pressure and/or 24-hour ambulatory blood pressures should be measured in older adults and considered in individualized blood pressure targets.

CASE 2.3

A 24-year-old male presents to your clinic with a 50-hour history of an irregular heart rate. He is generally well but has a history of hypertension (too many super-jumbo burgers ... with bacon ... he’s been “supersized”), which he has been trying to control with exercise and diet (he switched to tofu burgers yesterday). There is no prior history of cardiac disease or palpitations. He did “have a bit to drink” celebrating ... well, whatever, just celebrating ... who needs a reason! He was embarrassed about his drinking and thus waited 2 days to seek care. There is no family history of heart disease and the patient does not smoke. Vital signs reveal an irregular pulse of 130 bpm and a blood pressure of 160/100 mm Hg. The patient is afebrile and has normal respirations. He has no heart murmur. The ECG is shown below (Fig. 2-4).

FIGURE 2-4. ECG for patient in question 2.3.1.

Question 2.3.1 The most appropriate diagnosis is:

- A) Multifocal atrial tachycardia (MAT)
- B) Wandering atrial pacemaker
- C) Atrial fibrillation
- D) Ventricular tachycardia
- E) Accelerated junctional rhythm

Answer 2.3.1 The correct answer is "C," atrial fibrillation.

This is characterized by the lack of P waves and an irregularly irregular rhythm. "A" and "B" are incorrect. While both MAT and a wandering atrial pacemaker are irregularly irregular, both have P waves. "D" is incorrect. Ventricular tachycardia is a wide complex tachycardia and is regular. "E" is incorrect. While there are no P waves, an accelerated junctional rhythm should be a regular, organized rhythm.

Question 2.3.2 What is the most likely cause of this patient's dysrhythmia?

- A) Congenital prolonged QT syndrome
- B) Hypertrophic cardiomyopathy
- C) Alcohol use
- D) Marijuana use
- E) Ischemic cardiac disease

Answer 2.3.2 The correct answer is "C." The most likely cause of atrial fibrillation in this 24-year-old is alcohol. This is also known by the moniker "holiday heart." It occurs after episodes of significant alcohol intake. The underlying mechanism is not known, but alcohol is known to be cardiotoxic at higher doses which varies by individual. "A" is incorrect because prolonged QT typically causes polymorphic ventricular tachycardia (torsades de pointes). "B," hypertrophic cardiomyopathy, is unlikely since the patient has never had a murmur, and hypertrophic cardiomyopathy generally presents with signs of aortic outlet obstruction (syncope or angina with exercise) although a subset of patients do not have obstructive physiology. "D" is incorrect because marijuana is not implicated in causing atrial fibrillation, and "E" is incorrect because a patient who is 24 years old is unlikely to have ischemic cardiac disease.

Question 2.3.3 Other states that can cause atrial fibrillation include all of the following EXCEPT:

- A) Valvular disease, especially mitral disease
- B) Hyperthyroidism
- C) Stroke
- D) Heart failure
- E) Pulmonary embolism (PE)

Answer 2.3.3 The correct answer is "C." Stroke does not generally cause atrial fibrillation but can be a result of atrial fibrillation. Certainly, stroke and other intracranial injuries can be associated with arrhythmias. However, these are generally isolated PVCs. Stroke may also be associated with heart failure and ischemic changes on the ECG (the etiology is unknown...call it "neurohumeral" and you will sound smart), but it is rarely an isolated cause of atrial fibrillation. Valvular heart disease, hyperthyroidism, heart failure, and PE have all been demonstrated to

be causes of atrial fibrillation. Valvular heart disease, heart failure, and PE have a similar mechanism: stretching of the atrium leading to atrial irritability. Atrial fibrillation is found in 10% to 20% of those with hyperthyroidism, especially in the elderly.

The patient confides that he was indeed at a bachelor party several days ago (so that was what he was celebrating) and had a bit too much to drink. This is quite unusual for the patient. He generally drinks 2 to 3 beers per week, but on this particular night had 12 or more (hmm ... now we're wondering). The patient's pulse increases to 160 bpm, but he remains asymptomatic.

Question 2.3.4 The INITIAL goal for this patient, suspected of having 50 hours of atrial fibrillation, is:

- A) Anticoagulation
- B) Immediate cardioversion (DCCV)
- C) Rate control
- D) Blood pressure lowering
- E) Treatment of alcohol withdrawal

Answer 2.3.4 The correct answer is "C." Since this patient has had > 48 hours of atrial fibrillation, rate control is the goal. One should consider anticoagulation ("A"), but rate control is the most immediate concern. In real life, one would simultaneously address the patient's rate and anticoagulation needs, but—hey—a test isn't real life! If the onset of atrial fibrillation is indeterminate or >48 hours, one should withhold cardioversion due to the risk of thrombus formation in the atria and subsequent embolization; therefore, "B" is incorrect. "D" is incorrect because control of blood pressure is a secondary goal in this situation, and "E" is incorrect as this patient's tachycardia is not due to alcohol withdrawal.

The patient's heart rate remains elevated at 160 bpm with occasional forays into the 170 bpm range.

Question 2.3.5 Which of the following is the best drug to administer to this patient?

- A) Digoxin
- B) Lidocaine
- C) Amiodarone
- D) Adenosine
- E) Diltiazem

Answer 2.3.5 The correct answer is "E." Of the options listed, diltiazem should be the first choice for rate control. "A" is incorrect. Digoxin will be of limited use since it takes at least 30 minutes to have an effect. As an aside, digoxin is associated with higher mortality rates in those with atrial fibrillation. Don't use it; we have better drugs. Digoxin can be used in those with atrial fibrillation secondary to heart failure but will still not significantly help with rate control—especially in younger patients with robust sympathetic tone. "B" is incorrect because lidocaine is indicated for a wide complex tachycardia. "C" is incorrect. Amiodarone will work as a treatment of atrial fibrillation but

is a second-line drug because it can cause torsades de pointes. It can be used in patients with atrial fibrillation and congestive failure, where verapamil or diltiazem might be contraindicated. Amiodarone is considered to be advantageous in maintaining sinus rhythm, especially when given as pretreatment prior to cardioversion, but is not as efficacious in prompt heart rate control due to longer onset of action. Be aware that amiodarone can lead to “chemical cardioversion” with the attendant stroke risk. “D” is incorrect. Adenosine is ultra-short-acting, blocks the AV node, and can be used to convert a paroxysmal supraventricular tachycardia (PSVT) or slow down the rate of the arrhythmia temporarily if you are not sure what the diagnosis is (e.g., a rapid atrial flutter vs. PSVT). However, adenosine will not reduce the ventricular rate in atrial fibrillation since atrial fibrillation does not require the AV node to propagate. A beta-blocker could also be used in this situation.

Being the astute clinician that you are, you realize that 50% of atrial fibrillation will spontaneously convert to normal sinus rhythm, especially if present <72 hours. A transthoracic echocardiogram was performed and did not demonstrate any structural heart disease or vegetations. Thus, you choose to give verapamil and monitor the patient. At 24 hours, he still is in atrial fibrillation, although the rate is controlled well (90–110 bpm) with verapamil and he is normotensive. You discuss his case with your friendly neighborhood cardiologist who suggests that you plan cardioversion in 3 to 4 weeks.

Question 2.3.6 How would you anticoagulate this patient should you choose anticoagulation?

- A) Start warfarin alone
- B) Start heparin and rivaroxaban at the same time
- C) Start heparin alone
- D) Start aspirin alone

Answer 2.3.6 The correct answer is “A.” If the onset of atrial fibrillation is indeterminate or >48 hours (as with this patient), one should withhold cardioversion and anticoagulate the patient for 3 weeks before cardioversion. A second strategy is to anticoagulate the patient and arrange for a trans-esophageal echocardiogram. If the trans-esophageal echocardiogram shows no vegetations, you can proceed with cardioversion. For those with <48 hours of atrial fibrillation, immediate cardioversion is a viable option. Since we now are planning to cardiovert this patient in the future, “A” is the most reasonable option provided. Some physicians will start heparin or low-molecular-weight heparin at the initiation of warfarin; however, the combination is not necessary in patients with nonvalvular atrial fibrillation. This scenario is much different than when patients have a PE/DVT. **For nonvalvular atrial fibrillation, starting warfarin (or a DOAC) alone is sufficient.** “B” is incorrect. There is no need to bridge patients starting rivaroxaban or apixaban with heparin; the anticoagulant effect is “immediate” and there is no transient hypercoagulable state. Dabigatran still requires 5 to 10 days of heparin, enoxaparin, etc. Heparin (“C”) or aspirin (“D”) alone would not be the best choices in this case.

HELPFUL TIP:

Note that the *Chest* guidelines, updated in 2018 (*Chest* 2018;154(5):1121), recommend a direct oral anticoagulant over warfarin for anticoagulation in atrial fibrillation. Rivaroxaban, apixaban (factor Xa inhibitors), and dabigatran (a direct fibrin inhibitor) are all approved for use in nonvalvular atrial fibrillation (although warfarin is less expensive, even when checking INRs). There may be some clinical advantages to apixaban, including fewer embolic phenomenon and less bleeding. But, there is no compelling evidence to favor one over the other. We now have reversal agents for dabigatran and the factor Xa inhibitors. In general, avoid edoxaban (Savaysa). The outcome data isn’t as good as with other factor Xa inhibitors.

Question 2.3.7 All of the following can be used to cardiovert atrial fibrillation EXCEPT:

- A) Ibutilide
- B) Electrical cardioversion
- C) Quinidine
- D) Digoxin
- E) Procainamide

Answer 2.3.7 The correct answer is “D.” Digoxin does not work to cardiovert atrial fibrillation. Digoxin may facilitate cardioversion in patients with heart failure by reducing atrial stretching. However, it does not convert atrial fibrillation. All of the other answers are correct. Because of potential induction of arrhythmias with the other agents, electrical cardioversion is becoming the preferred method of restoring normal sinus rhythm.

► Objectives: Did you learn to ...

- Recognize the clinical and ECG presentation of atrial fibrillation?
- Use rate-controlling drugs to treat a patient with atrial fibrillation?
- Appropriately employ anticoagulation in atrial fibrillation for a patient undergoing cardioversion?
- Identify appropriate situations for cardioversion of atrial fibrillation?

QUIZ: ANTIHYPERTENSIVE AGENTS

A 70-year-old male complains of erectile dysfunction (ED) and requests medical treatment. You begin to discuss sildenafil (Viagra®—or whatever your phosphodiesterase-5 [PDE5] inhibitor of choice is). You believe his ED is secondary to vascular disease and that he is healthy enough to engage in sexual activity.

Which of the following antihypertensive drug classes can cause prolonged hypotension when used with PDE5 inhibitors?

- A) Peripheral alpha-blockers
- B) Calcium channel blockers (CCBs)

- C) ACE inhibitors
- D) Thiazide diuretics
- E) Beta-blockers

The correct answer is “A.” The peripheral alpha-blockers (doxazosin, prazosin, and tamsulosin) can cause symptomatic hypotension when combined with sildenafil or other drugs of this class (Cialis [tadalafil], Levitra [vardenafil]). This hypotensive effect is more severe when these drugs are combined with a nitrate. Nitrates should **not** be administered within 24 hours (or longer in patients with renal or hepatic dysfunction) of these drugs, as the combination has reportedly resulted in prolonged hypotension and strokes. None of the other drugs (“B”–“E”) cause this hypotensive effect when combined with a PDE5 inhibitor.

► CASE 2.4

A 55-year-old male with a history of newly identified atrial fibrillation is referred to you for “medical clearance” for surgery. He has a history of hypertension and hypercholesterolemia (to calculate his CHA₂-DS₂-VASC score, see Table 2-6A). He has normal cardiac function otherwise with a normal ejection fraction and no valvular disease on echocardiogram. His atrial fibrillation has not been addressed since it was discovered by the surgeon at a pre-op visit. His heart rate is 80 bpm when you see him, his rhythm is irregularly irregular, and he has no signs of heart failure.

Question 2.4.1 Which of the following options would be appropriate for this patient?

- A) Anticoagulate the patient with warfarin or a direct oral anti-coagulant (DOAC) and allow him to stay in atrial fibrillation
- B) Place the patient on aspirin and allow him to stay in atrial fibrillation
- C) Give digoxin to cardiovert the patient
- D) Recommend DC cardioversion immediately since sustained normal sinus rhythm yields the best long-term outcomes
- E) A and B

Answer 2.4.1 The correct answer is “E.” This patient’s CHA₂-DS₂-VASC (see Table 2-6A) score is “1” allowing him to take aspirin *or* be anticoagulated with either a DOAC or warfarin. For a CHA₂-DS₂-VASC score of 1, it is still a matter of clinical judgment based on patient-specific risk factors (see Table 2-6B). Prior to deciding on an approach to anticoagulation in a particular patient, calculate a HAS-BLED score (<https://www.mdcalc.com/has-bleed-score-major-bleeding-risk>) to determine risk of bleeding. Balance stroke and bleeding risk when making a decision. A CHA₂-DS₂-VASC score of “0” corresponds to what we used to call “lone atrial fibrillation” and does not necessitate anticoagulation. In a 2019 update to the ACC/AHA Guidelines for the Management of Patients with Atrial Fibrillation, it was recommended to initiate anticoagulation with a DOAC (preferred) over warfarin for nonvalvular atrial fibrillation in men with a CHA₂-DS₂-VASC score of ≥ 2 and for women with a score ≥ 3 . Please see Table 2-6B for anticoagulation recommendations

TABLE 2-6A CALCULATING THE CHA₂DS₂-VASC SCORE

Criteria	Points	Score and Risk of CVA (in %/yr)
Congestive heart failure	1	
Hypertension (treated or above 140/90 mm Hg)	1	0 = 0.2–0.6%
Age >75	2	1 = 0.6–1.3%/yr
Diabetes	1	2 = 2.2%/yr
Stroke, TIA or thromboembolic disease	2	3 = 3.2%/yr
		4 = 4%/yr
		5 = 7%/yr
		6 = 10%/yr
Vascular disease (CAD, PAD, aortic plaque)	1	
Age 65–74	1	
Sex Category Female ^a	1	

^aNew guidelines *do not* include female gender as a risk factor *unless* there is another risk factor present. So, women cannot have a score of “1.” If they have *only* female gender, the score is zero. If they have another risk factor, they get +1 for gender + the points for the additional risk factor.

based on CHA₂-DS₂-VASC score Renal and hepatic function should be evaluated at initiation of anticoagulation and at least annually. “C” is incorrect since this patient does not require rate control and digoxin is not effective for cardioversion. “D” is wrong. Long term, it is reasonable to allow most patients to remain in atrial fibrillation as long as they are properly anticoagulated based on the CHA₂-DS₂-VASC score. Outcomes of patients who stay in atrial fibrillation and are given appropriate therapy are the same (or a bit better) than in patients in whom one tries to maintain sinus rhythm with drugs such as amiodarone, etc.

HELPFUL TIP:

Other options for atrial fibrillation include ablation and closure of the left atrial appendage (LAA). Compared with anticoagulation, LAA closure reduces the stroke risk as much as anticoagulation but entails the risk of surgery (about 1:25 will have some significant complication).

The patient returns at age 75. He is 20 years older. You, however, have not aged a day because doctors are immortal, right? He is now hypertensive, and diabetic, and he requires a cholecystectomy. Apparently, he only sees you for pre-op exams. His CHA₂-DS₂-VASC score is now 4 and he has been on warfarin for the past 5 years.

TABLE 2-6B TREATMENT OF NONVALVULAR ATRIAL FIBRILLATION BASED ON THE CHA₂DS₂-VASc SCORE

CHA ₂ DS ₂ -VASc Score	Recommended Treatment ^a
0	No anticoagulation indicated but use clinical judgment (0.5–0.7% stroke risk/yr)
1	Consider anticoagulation with a DOAC (preferred) or warfarin (0.6–1.3% stroke risk/yr). Use clinical judgment
2 or greater	Anticoagulation with a DOAC (preferred) ^b or warfarin (2.2% or > stroke risk/yr)

^aAspirin is no longer recommended for A-fib. The data does not support its use.

^bDOAC, direct acting oral anticoagulant: Xarelto (rivaroxaban), Eliquis (apixaban) and Pradaxa (dabigatran), Savaysa (edoxaban). Apixaban has the best profile for bleeding versus prevention of stroke.

Question 2.4.2 Which of the following approaches is the best for controlling his anticoagulation, given that he needs surgery?

- A) Stop the warfarin several days before surgery to allow his INR to normalize. Restart the warfarin after surgery
- B) Hospitalize the patient a couple of days ahead of time and start heparin. Then stop his warfarin. Restart the warfarin after surgery
- C) Use low-molecular-weight heparin at home and stop the warfarin once this is started. Restart the warfarin after surgery
- D) Stop the warfarin several days before surgery to allow his INR to normalize. Start heparin after surgery and simultaneously restart warfarin

Answer 2.4.2 The correct answer is “A.” For patients with nonvalvular atrial fibrillation who are undergoing surgery or invasive diagnostic procedures, it is reasonable to interrupt anticoagulation for up to 1 week without substituting heparin (assuming they haven’t had a recent stroke or other thromboembolic event). “Bridge” therapy with IV heparin or low-molecular-weight heparin confers no benefit (*Circulation* 2015;131(5):488). The risk of perioperative bleeding with heparin is actually greater than the risk of thromboembolism from atrial fibrillation. “B,” “C,” and “D” are incorrect because the patient does not need heparin. Bridging therapy is typically indicated for patients at higher risk for thromboembolic events such as those with mechanical heart valves, prior stroke, or CHA₂DS₂-VASc score >5.

The 75-year-old patient has his surgery and returns to your clinic for a postoperative check-up 1 month after his surgery. You check his INR and it is noted to be 5.2. There is no active bleeding.

Question 2.4.3 The most appropriate action at this point is to:

- A) Hospitalize the patient for observation since he is at a high risk of bleeding
- B) Give the patient 5 mg of vitamin K orally
- C) Give the patient 2 units of fresh frozen plasma to reverse his anticoagulation
- D) Hold the next warfarin dose and reduce the maintenance dose
- E) A, B, and C

Answer 2.4.3 The correct answer is “D.” The risk of bleeding in a relatively healthy patient with an INR of 5.2 is very low. Thus, simply holding the next one to two doses of warfarin and reducing the maintenance dose of warfarin is appropriate. “A” is incorrect because the patient does not need hospitalization. “B” is incorrect because it will be difficult to anticoagulate the patient after vitamin K is administered. “C” is incorrect because there is no active bleeding.

The patient misunderstands your instructions and takes an extra dose of warfarin that evening and for the next 2 days. He returns to your clinic and his INR is now 13.

Question 2.4.4 What is the best option for therapy at this point?

- A) Vitamin K 5 mg IV × 1
- B) Fresh frozen plasma
- C) Vitamin K 5 mg PO × 1
- D) Vitamin K 10 mg IV × 1

Answer 2.4.4 The correct answer is “C.” Giving this patient 5 mg of PO vitamin K is the best solution. This has been found to reduce the INR while still allowing the patient to be anticoagulated relatively easily after treatment. “B” is incorrect because there is no call for FFP in this asymptomatic patient. The other answers are incorrect because there is no advantage to higher doses or IV doses of vitamin K in this patient, and the higher doses will make continued anticoagulation more difficult.

HELPFUL TIP: REVERSING WARFARIN

In patients who are not bleeding:

- If the INR is <4.5 simply reduce the dose of warfarin or hold the next dose of warfarin.
- If the INR is 4.5 to 10 you have several options. If there is no bleeding: hold one or two doses of warfarin. **Routine vitamin K is not recommended.** If the patient will require surgery or is at high bleeding risk, administer vitamin K ≤ 5 mg with another 1 to 1.5 mg in 24 hours.
- If the INR is >10 administer 2.5 to 5 mg of vitamin K even if there is no bleeding.

In patients who are bleeding:

- Administer prothrombin complex concentrate (e.g., Kcentra® ... should they buy a vowel? They can afford it!). This is preferred over fresh frozen plasma (FFP), which is second line. In addition, administer 5 to 10 mg of vitamin K. The INR of FFP is approximately 1.5. You won't get it lower no matter how much FFP you give. Tell your surgeon to chill.

► Objectives: Did you learn to ...

- Weigh the advantages and disadvantages of rate control versus rhythm control strategies for atrial fibrillation?
- Manage anticoagulation and atrial fibrillation vis-à-vis surgery?
- Manage the over-anticoagulated patient?

► CASE 2.5

A 62-year-old female presents to your office with a history of occasional palpitations that are of great concern to her. She notes that she feels a racing heart that lasts for a matter of seconds and occurs every 7 days or so. However, when she has the symptoms, she will generally get four to five episodes during that day. She denies any chest pain, dyspnea, light-headedness, or other associated symptoms. You order an event monitor and it shows that the patient is having non-sustained episodes of monomorphic ventricular tachycardia lasting 4 beats or less each. She is asymptomatic except for the palpitations.

Question 2.5.1 The best approach at this point is to:

- Start an antiarrhythmic such as quinidine or mexiletine to control the heart rhythm
- Refer the patient to a cardiologist for an electrophysiologic (EP) study to determine the best drug to control this rhythm
- Implant an automatic defibrillator to prevent sudden death
- Implant a pacemaker
- Check serum potassium, magnesium, TSH, glucose, CBC

Answer 2.5.1 The correct answer is "E." The first step in determining the treatment of this patient is to make sure that there is not an underlying metabolic abnormality that could predispose to this rhythm abnormality.

You check a panel of laboratory studies including thyroid function tests, electrolytes, magnesium, glucose, and CBC. They are all within normal limits. You suggest that the patient avoid potential triggers such as caffeine and sympathomimetics. "Darn," she sighs. "I have to quit my crystal meth?"

Question 2.5.2 The next step for this patient is to:

- Start an antiarrhythmic such as quinidine or mexiletine to control the heart rhythm
- Refer the patient to a cardiologist for an EP study to determine the best drug to control this rhythm

- Implant an automatic defibrillator to prevent sudden death
- Start a beta-blocker
- Order transthoracic echocardiogram to rule out structural heart disease

Answer 2.5.2 The correct answer is "E." Nonsustained ventricular tachycardia is associated with sudden cardiac death in the presence of structural heart disease such as hypertrophic cardiomyopathy or ischemic heart disease. An echocardiogram as well as stress test will be helpful in evaluating for these underlying conditions. There is no evidence that nonsustained, asymptomatic ventricular tachycardia worsens outcomes **as long as the patient has no underlying cardiac disease**. In an otherwise healthy, asymptomatic patient, the risk of using antiarrhythmic drugs to suppress ventricular ectopy leads to worse outcomes than doing nothing. Quinidine, mexiletine, amiodarone, and other antiarrhythmics all have proarrhythmic effects. In general, there is more sudden death in these patients if they are treated with antiarrhythmic drugs than if they are watched. Therefore, "A" is incorrect because these drugs will actually increase mortality. "B" is incorrect since the patient has asymptomatic, self-limited episodes. The reason to do an EP study is to determine if there is an inducible arrhythmia and to determine treatment. This patient does not (yet) need treatment. "C" is incorrect because this patient has asymptomatic nonsustained ventricular tachycardia. Thus, an implantable defibrillator is not indicated. *After your evaluation is complete*, you may prescribe a beta-blocker ("D") for relief from palpitations. A beta-blocker (metoprolol or carvedilol) is considered the first-line drug in this type of patient. You can add diltiazem or verapamil to this should she still feel palpitations. Amiodarone would be third line should she continue to be bothered by the palpitations after trying beta-blockers and calcium channel blockers.

The echocardiogram and stress test are normal, and the patient does well for the next 3 months but then becomes symptomatic with prolonged episodes of ventricular tachycardia. While all of the episodes are self-limited, the patient has had two episodes of syncope.

Question 2.5.3 Which of the following is the best next step in treating this patient?

- Sotalol
- Implantable defibrillator
- Amiodarone
- Electrophysiologic study
- Tocainide (an oral lidocaine equivalent)

Answer 2.5.3 The correct answer is "D." An electrophysiologic study is indicated to induce and characterize the ventricular tachycardia. Certain types of ventricular tachycardia respond very well to radiofrequency ablation so this should be the next step. **Some of you may have answered "B." This is true in patients with ischemic heart disease, left ventricular dysfunction, and symptomatic ventricular tachycardia. These patients should get an implantable defibrillator as should**

“all” heart failure patients with an ejection fraction of <30% to 35% (there are literally over 200 variations of this recommendation based on heart failure class, QRS duration, etc., but this is the basic idea). Our patient may yet get an implantable defibrillator since she is now symptomatic (syncope), but do the EP study first.

► **Objectives: Did you learn to ...**

- Evaluate a patient with palpitations?
- Manage nonsustained, asymptomatic, ventricular tachycardia?

► CASE 2.6

A 22-year-old female presents to your office with a history of palpitations. You are able to capture the arrhythmia on the monitor in your office: the rhythm strip shows evidence of isolated premature atrial contractions (PACs). She is otherwise healthy and taking no medications, and there is no family history of heart disease.

Question 2.6.1 All of the following are salient points of the history with regard to PACs EXCEPT:

- A) Aged cheese consumption
- B) Caffeine use
- C) Tobacco use
- D) Alcohol use
- E) COPD

Answer 2.6.1 The correct answer is “A.” Aged cheese can cause problems in combination with monoamine oxidase inhibitors (MAOIs). In combination with an MAOI, aged cheese and other sources of tyramine can cause a hypertensive emergency. However, this patient is not taking any medications. All of the other conditions and drugs listed can cause PACs. While there are conflicting data about the strength of the association caffeine, it is clear that COPD, tobacco, and alcohol can all cause an increase in sympathetic tone, leading to PACs. Neurologic abnormalities (e.g., stroke) can also be associated with PACs, as can some drugs (e.g., theophylline).

HELPFUL TIP:

You have to eat 2 pounds of cheddar cheese in half an hour in order to develop a hypertensive crisis with an MAOI. In studies where there was free access to cheese, the maximum anyone was able to eat was 1.9 pounds in 2 hours. Believe it or not, someone studied this (probably somewhere in Wisconsin). And, banana peels (but not the fruit of the banana) are contraindicated with MAOIs...really (who eats the peel anyway?).

Question 2.6.2 Which of the following statements about PACs is true?

- A) Mitral valve prolapse is associated with PACs
- B) Mitral valve stenosis is associated with PACs

- C) Bicuspid aortic valve is associated with PACs
- D) None of the above is true

Answer 2.6.2 The correct answer is “B.” Anything that can cause an increase in left atrial pressures (and therefore atrial wall stretching) is associated with an increase in the number of PACs. Mitral stenosis causes increased pressures in the left atrium, wall stretching, and enlargement and thus predisposes to PACs. “A” is incorrect. Even though multiple problems have been blamed on mitral valve prolapse, a study done as part of the Framingham study showed that the symptoms blamed on mitral valve prolapse (anxiety, PACs, tachycardia, etc.) are no more prevalent in those with mitral valve prolapse than in those without it. “C” is incorrect. A bicuspid aortic valve may cause PACs as a result of heart failure when the patient decompensates and has increased left-sided heart pressures. However, a bicuspid aortic valve itself is not a source of PACs. Similarly, hypertrophic cardiomyopathy, other causes of heart failure, drugs (e.g., theophylline and digoxin), and neurologic diseases can be associated with PACs.

This patient is bothered by her PACs. She is rather aware of them and finds them disconcerting.

Question 2.6.3 What is the best pharmacologic therapy to consider at this point?

- A) Sotalol
- B) Metoprolol
- C) Trasyolol
- D) Amiodarone
- E) Mountain Dew—lots of it

Answer 2.6.3 The correct answer is “B.” A beta-blocker may help to reduce this patient’s PACs. “A” is incorrect because, while sotalol can be used for both atrial and ventricular arrhythmias, it is proarrhythmic and can cause torsades de pointes. Thus, it should be initiated in the hospital with monitoring and reserved for those with severe arrhythmias. “C” is incorrect because Trasyolol is the trade name for aprotinin, an enzyme that was used to reduce bleeding during surgical procedures. “D” is incorrect because, like sotalol, amiodarone is proarrhythmic, and its use should be limited to those with significant arrhythmias.

► **Objectives: Did you learn to ...**

- Recognize causes of PACs?
- Treat a patient with bothersome PACs?

QUICK QUIZ: VALVULAR DISEASE

Surgery is indicated in which of these patients with valvular disease?

- A) An asymptomatic patient with severe mitral regurgitation and a left ventricular ejection fraction (LVEF) of less than 60%
- B) An asymptomatic patient with a bicuspid aortic valve

- C) Asymptomatic aortic regurgitation with an LVEF of less than 50% on echocardiogram
- D) Only symptomatic valvular lesions should be approached surgically
- E) A and C

The correct answer is “E.” Once patients with mitral regurgitation and aortic regurgitation become symptomatic, the morbidity and mortality increases significantly. Thus, these patients should be operated on **before** they become symptomatic. Patients should have routine echocardiography yearly if they have severe valvular disease. In addition to evaluating the valve, echocardiography allows you to evaluate ventricular size and function. Importantly, proper management of patients with valvular heart disease depends on accurate diagnosis of the cause as well as proper staging of the disease process, which is based on valvular anatomy, valvular hemodynamics, severity of left ventricular dilation and systolic function, and patient symptoms. (NOTE: left ventricular systolic function and patient symptoms are only part of the decision-making process regarding management and timing of referral to surgery.)

QUICK QUIZ: MINIMALLY INVASIVE VALVE REPLACEMENT

A 78-year-old female with syncope was found to have severe aortic stenosis on echocardiogram. She’s worried about open-heart surgery and has heard about something called a “Transcatheter Aortic Valve Replacement” (TAVR). You counsel her on the risks, benefits, and alternatives. Which of the following is true?

- A) TVAR is especially useful in those who are likely to be the most active after surgery since it is less invasive
- B) A small leak at the side of TAVR is common and associated with a poor outcome
- C) Stroke risk in 30 days is 8% to 10%
- D) No anticoagulation is needed since it is a bioprosthetic valve
- E) Mitral valve injury is a well-recognized complication of TAVR

The correct answer is “E.” Mitral valve injury has been associated with TAVR procedures. “A” is wrong since TAVR is most useful in those who are not likely to be extremely active, such as elderly patients and/or those with multiple comorbidities. “B” is also incorrect. Small leaks are common *but are not associated with a worse outcome*. On the other hand, moderate or severe leaks do worsen outcome. Stroke risk is 2% to 5% and peri-procedure mortality is 1% to 4%. Bleeding is not uncommon at the site of vascular access. Finally, patients should be anticoagulated for at three (or more) months after TAVR and 6 months after an open bioprosthetic aortic valve replacement.

HELPFUL TIP: TRANSCATHETER VALVE REPLACEMENT

Transcatheter mitral valve replacement for mitral regurgitation is not quite ready for prime time. Outcomes after the procedure are not different than the outcomes in those treated medically (*N Engl J Med*. 2018;379:2297–2306). For *mitral stenosis* transcatheter or open repair are both options depending on the valve anatomy. For aortic regurgitation (AR), TAVR has not been as successful or as widely used as it has been for aortic stenosis (AS); this may be due to the widely heterogeneous etiologies of AR as compared to AS, which occurs along a more predictable pathophysiologic pathway.

CASE 2.7

A 74-year-old male presents to your office with a chief complaint of a “long cold” with an intermittent cough for 5 months. He has also noticed that he gets up to urinate twice a night although he has no trouble with his urine stream, starting urination, or dribbling afterward. He has been a bit more tired lately and notices that his exercise tolerance has decreased to several blocks, limited mainly by shortness of breath. He has not had any chest pain. He has no history of asthma or COPD and has not had any exposures to drugs or chemicals. He has a history of hypertension and noncompliance with medical recommendations. In fact, he is taking no medications except for an aspirin a day. His pulse is 100 bpm with a blood pressure of 160/95 mm Hg. He looks comfortable. On examination, you find only trace pitting edema of the lower extremities.

Question 2.7.1 Which of the following is NOT a possible cause of cough in this patient?

- A) Heart failure
- B) Asthma
- C) Deconditioning
- D) COPD
- E) GERD

Answer 2.7.1 The correct answer is “C.” Deconditioning may cause dyspnea on exertion but should not cause a cough. The purpose of this question is to point out the fact that a “chronic cold” or “chronic cough” in an elderly person can be due to a myriad of causes, including “occult” heart failure (systolic dysfunction (HFrEF) or diastolic dysfunction (HFpEF)). Do not make the assumption that the patient’s diagnosis (e.g., a “chronic cold”) is necessarily the correct diagnosis.

HELPFUL TIP:

Systolic heart failure (secondary to infarction, etc.) is now termed “Heart Failure with a reduced Ejection Fraction” (HFrEF). Diastolic heart failure is now termed “Heart Failure with a preserved Ejection Fraction” (HFpEF). In this book we use both the “old” and new notations.

You decide that this patient may have heart failure. An ECG shows no evidence of prior or ongoing ischemia. There are no signs of atrial enlargement or ventricular hypertrophy on the ECG.

Question 2.7.2 The proper conclusion from this is:

- A) The patient does not have cardiac chamber enlargement or hypertrophy and therefore is unlikely to have heart failure
- B) The absence of evidence for prior infarct makes heart failure unlikely
- C) Regardless of the ECG results, clinical judgment alone is sufficient to make the diagnosis of heart failure, being correct 85% of the time
- D) The patient's edema is likely from venous insufficiency
- E) Despite a normal ECG, further testing is needed in this patient to evaluate for heart failure

Answer 2.7.2 The correct answer is “E.” “A” is not correct because only 30% to 60% of moderate-to-severe left ventricular hypertrophy (LVH) is detectible on ECG. “B” is incorrect because patients with HFpEF (discussed later) may not have any evidence of prior ischemia or infarct. “C” is incorrect. The clinical diagnosis of heart failure is incorrect up to 50% of the time. For this reason, confirmation is required *before* embarking upon a therapeutic adventure for heart failure. “D” is unlikely, since the patient has other symptoms of heart failure (exertional dyspnea, cough, etc.) that make simple venous insufficiency unlikely. Plus, have you ever known “get further information” to be the wrong answer?

Question 2.7.3 You decide on further testing. Assuming every test is easily available to you (which might not be the case depending on the setting in which you work), what is the one best test that you would use to determine if this patient has heart failure?

- A) Echocardiography
- B) Brain natriuretic peptide (BNP) level
- C) Chest radiograph looking for evidence of pulmonary edema (Kerley B lines, etc.)
- D) SPECT myocardial perfusion imaging (MPI)
- E) Positron emission tomography (PET) testing

Answer 2.7.3 The correct answer is “A.” Echocardiography is the procedure of choice for the diagnosis of heart failure. This is for two reasons. First, you can assess left ventricular systolic function as well as look for diastolic dysfunction to determine if this is HFrEF or HFpEF. Second, you can evaluate the potential causes of heart failure including valvular heart disease, ischemic heart disease, pericardial disease, deposition disease (amyloidosis, hemochromatosis), etc. “B” is incorrect because the BNP will give you less concrete information about the patient compared to echocardiography. In this patient, with a high pretest probability of heart failure, BNP will most likely be elevated (though not always). “D” and “E” are incorrect because MPI and PET testing are best used to diagnose ischemia due to CAD.

HELPFUL TIP:

In a low-risk patient, a BNP of <100 pg/mL effectively rules out heart failure. A BNP of 100 to 500 pg/mL is indeterminate and may not be related to cardiac disease. A BNP of >500 pg/mL is relatively specific for heart failure (if other cardiac and noncardiac causes are excluded). Alternate cardiac causes of an elevated BNP include acute coronary syndromes, heart muscle disease, valvular heart disease, pericardial disease, atrial fibrillation, myocarditis, cardiac surgery, and status-post DC cardioversion.

(LESS) HELPFUL TIP:

Noncardiac causes of an elevated BNP include renal failure, anemia, advanced age, sepsis, pulmonary (obstructive sleep apnea, pulmonary hypertension, severe pneumonia), critical illness, severe burns, toxic/metabolic events (cancer, chemotherapy, envenomation). Obesity can cause a falsely low BNP.

BNP-directed therapy for heart failure does not seem to be any better than symptom directed therapy (*Eur Heart J.* 2014;35(1):16–24) (*JAMA* 2017;318:713). An elevated BNP *in the absence of heart failure* is still a marker for a worse outcome when compared to those with a normal BNP (*J Am Coll Cardiol.* 2018;71(19)).

The patient has an echocardiogram that shows a left ventricular ejection fraction (LVEF) of 35% and a regional wall motion abnormality (RWMA).

Question 2.7.4 This is the most consistent with a diagnosis of:

- A) HFrEF secondary to myocarditis
- B) HFrEF secondary to CAD
- C) HFpEF secondary to hypertension
- D) HFrEF secondary to constrictive pericarditis
- E) Age-related changes; therefore, a normal variant

Answer 2.7.4 The correct answer is “B.” A regional wall motion abnormality (RWMA) suggests that this patient has ischemic or infarcted myocardium. “A” is not the best choice since those with myocarditis (fulminant or acute) typically have global hypokinesis (although RWMA has been reported) and the patient would typically appear more clinically ill. “C” is incorrect by definition. HFpEF requires an LVEF of at least 50%, recognizing that this group may not have an entirely normal LVEF, but the major abnormality is not a reduction in LV systolic function. HFpEF is associated with a hypertrophied left ventricle and a **preserved** LVEF. HFrEF is defined by an LVEF of <40%. The echocardiogram in constrictive pericarditis (“D”) generally shows normal left ventricular systolic function. It may reveal pericardial thickening, dilated inferior vena cava or hepatic veins, and abnormal mitral and tricuspid in-flow Doppler.

**HELPFUL TIP:**

Toxins such as methamphetamine, cocaine, alcohol, and antineoplastic chemotherapeutic drugs can cause a cardiomyopathy and should be considered as a possible etiology of heart failure in the appropriate patient.

Question 2.7.5 Which of the following is the most appropriate next strategy to work up this patient's HFrEF?

- A) Cardiac MRI to assess myocardial viability
- B) Coronary angiogram
- C) Measure serial troponins to rule out acute coronary syndrome (ACS)
- D) Electrophysiologic study to assess for inducible ventricular arrhythmia
- E) CT to assess calcium scores

Answer 2.7.5 The correct answer is "B." Ischemic heart disease causes most HFrEF. If you can reverse the ischemia, mortality is decreased from 16% annually to 3.2% annually. Of all the options listed above, coronary angiography remains the gold standard to evaluate for CAD in this setting. Coronary angiograms provide information about anatomy and feasibility of revascularization but do not predict recovery of function after revascularization. This patient does not have chest pain or ECG changes to suggest ACS; therefore, "C" is incorrect. "D" is incorrect, as there is no indication for an electrophysiologic study in the absence of any arrhythmia. "E" is incorrect, because, as noted, the presence or absence of coronary calcification would not change the overall management plan for this patient. CT calcium scoring may be used as an additional risk stratification tool in intermediate-risk patients (similar to CRP, in addition to traditional risk factors such as hypertension, dyslipidemia, vascular or renal disease, etc.) but **not** in high-risk, symptomatic patients.

The coronary angiogram shows diffuse CAD; no coronary lesions are considered to be amenable to angioplasty and there are no vessels considered to be viable targets for bypass surgery. You decide to initiate medical therapy in this patient. In addition, you advise the patient regarding the nonpharmacologic therapies for heart failure treatment.

Question 2.7.6 Possible nonpharmacologic therapies for HFrEF include all of the following EXCEPT:

- A) Fluid restriction of <2 L/day
- B) Sodium restriction of <3 g/day
- C) Dietary consultation
- D) Cardiac risk factor modification
- E) Monthly weight monitoring.

Answer 2.7.6 The correct answer is "E." The keystone of an effective heart failure treatment regimen is sodium and fluid balance as well as management of comorbidities ("A" and "B"). Cardiac risk factors, including hypertension, diabetes, hyperlipidemia, sleep apnea, obesity, sedentary lifestyle, smoking/

alcohol/drug use, etc. need to be treated with the same aggressiveness as in a patient with an ACS. Patients should be advised about **daily** weight monitoring rather than monthly monitoring ("E"). A weight gain of more than 3 to 5 lb may necessitate additional doses of a diuretic. **Note that significant fluid restriction to 1.5 to 2 L/day is typically, though not exclusively, reserved for Stage D advanced heart failure patients who are hyponatremic or diuretic resistant.** Conversion of patients in atrial fibrillation *via ablation (but not drugs)* to normal sinus rhythm is also of benefit and reduces mortality, hospitalizations, and improves left ventricular function (*N Engl J Med.* 2018;378(5):417–427).

**HELPFUL TIP: PLEASE PASS THE SALT**

Even though it is traditional, there is only weak evidence to suggest that salt restriction in CHF makes any real difference (*JAMA Intern Med.* 2018;178(12):1693–1700). European guidelines suggest limiting to no more than 6 grams of sodium per day (*Eur Heart J.* 2016;37(27):2129). We suspect the answer on the test will still be to restrict salt. But for your "real-life" patients, 1.5 to 2 gram sodium restriction per day may be excessive.

You wish to start an appropriate drug regimen for this patient's heart failure.

Question 2.7.7 All of the drugs below have been shown to reduce mortality in patients with HFrEF EXCEPT:

- A) Digoxin
- B) Metoprolol succinate
- C) ACE inhibitors
- D) Hydralazine and long-acting nitrates used in combination in patients intolerant of ACE inhibitors
- E) Spironolactone

Answer 2.7.7 The correct answer is "A." Digoxin is an inotropic agent, and as such, would intuitively make sense as an effective drug for HFrEF. However, digoxin has **not** been shown to increase survival and in fact may worsen outcomes, especially in women and those with atrial fibrillation (*J Am Coll Cardiol.* 2018;71(10)). Its use is primarily for symptomatic relief. If using digoxin in HFrEF, the therapeutic target is a dose that achieves a plasma concentration of drug in the range of 0.5 to 0.9 ng/mL. The common daily dosage to achieve that target is typically 0.125 to 0.25 mg/day in patients <70 years of age with normal renal function and body mass. For patients with abnormal renal function, low body mass, or age >70, low doses (0.125 mg daily or every other day) are recommended initially with the dose titrated to the target therapeutic range. Digoxin **does** reduce hospitalizations and improve symptoms in those with HFrEF who are symptomatic despite use of maximal guideline-directed therapy. As noted above, digoxin *seems to worsen mortality* in those with atrial fibrillation, however. Avoid digoxin in patients with atrial fibrillation and significant sinus or AV nodal block unless they have a pacemaker. NOTE: Other cardiac

medications such as amiodarone, dronedarone, verapamil, propafenone, and quinidine as well as noncardiac meds such as clarithromycin, erythromycin, itraconazole, and cyclosporine can increase the serum digoxin concentrations and may precipitate digoxin toxicity.

All of the other options, including the combination of isosorbide dinitrate and hydralazine, have been shown to reduce mortality. However, hydralazine and isosorbide dinitrate are generally reserved for those patients who are unable to tolerate ACE inhibitors or angiotensin receptor blockers (ARBs) or remain symptomatic despite maximal medical therapy with the other medications. This combination seems particularly effective in African Americans. However, enalapril reduces mortality by 28% when compared with hydralazine and nitrates. Thus, hydralazine and nitrates are second line. None of the “traditional” loop diuretics such as furosemide, bumetanide, etc., have been shown to positively affect mortality.

You start this patient on furosemide for diuresis and lisinopril for HFrEF. You also decide to initiate metoprolol succinate for its survival benefits. However, the patient’s symptoms worsen.

Question 2.7.8 Which of these is true about the use of metoprolol succinate in HFrEF?

- A) Metoprolol succinate is the only beta-blocker indicated for use in HFrEF
- B) Metoprolol succinate is best used in those patients who are still symptomatic since it will help to control symptoms
- C) Metoprolol succinate should only be initiated in patients with well-controlled HFrEF who are not currently having significant symptoms
- D) Metoprolol succinate can lead to significant hypokalemia when combined with diuretics, so potassium levels should be monitored closely
- E) Metoprolol succinate is contraindicated in patients who have both COPD and HFrEF

Answer 2.7.8 The correct answer is “C.” Beta-blockers should **not** be initiated in patients who are significantly symptomatic or decompensated. While beta-blockers do reduce mortality, they can increase symptoms and further exacerbate heart failure. Therefore, they are best initiated in the stable patient (as an outpatient or 24 to 48 hours prior to hospital discharge and on a stable drug regimen). Even then some patients cannot tolerate the introduction of beta-blockers without worsening of symptoms, which may require additional diuresis, discontinuation of the beta-blocker, a reduction in dose, or other measures. “A” is incorrect. Long-acting metoprolol **succinate**, bisoprolol, and carvedilol all have a benefit in HFrEF. Specifically avoid atenolol which does not seem to improve outcomes. “B” is incorrect because beta-blockers may actually worsen heart failure symptoms. “D” is incorrect since beta-blockers do not cause hypokalemia. “E” is incorrect. Beta-blockers can be used in patients with COPD with the same caveats that apply to any other patient: if the patient is becoming more symptomatic on the

beta-blocker, reduce the dose, or discontinue the drug. In fact, beta-blockers may improve survival in COPD.

HELPFUL TIP:

When starting a beta-blocker for HFrEF, start low and go slow! When starting digoxin for HFrEF, monitor for hypokalemia, hypomagnesemia, or hypothyroidism to avoid digoxin toxicity, even with low doses.

You reduce the dose of metoprolol succinate and consider starting this patient on another medication.

Question 2.7.9 Which of the following patients is/are good candidates for spironolactone?

- A) A patient with NYHA Class I and Class II heart failure
- B) A patient with NYHA Class III and Class IV heart failure
- C) Both A and B
- D) Neither A nor B

Answer 2.7.9 The correct answer is “B.” Spironolactone has been shown to reduce mortality in patients with New York Heart Association (NYHA) Class III and Class IV heart failure. It has not been studied in Class I (thus “A” is wrong). However, it may be useful in symptomatic patients with Class II with an EF of <30%. Serum potassium needs to be monitored closely after initiation of spironolactone, especially since it will generally be used with an ACE inhibitor or ARB, both of which can increase the serum potassium. This drug should be avoided in patients with renal insufficiency or patients with serum potassium >5 mEq/L. Spironolactone is indicated for patients with NYHA Classes II–IV and who have LVEF ≤35% and a creatinine of <2.5 mg/dL in males or <2 mg/dL in females (or estimated GFR >30 mL/min/1.73 m²). Eplerenone is another aldosterone inhibitor but is much more expensive with little, if any, advantage. *Remember that trimethoprim–sulfamethoxazole can lead to fatal hyperkalemia in those on an ACE/ARB/spironolactone and other potassium sparing drugs with even a couple of doses.*

HELPFUL TIP:

Aliskiren (Tekturna), a renin inhibitor, **is contraindicated** with an ARB or ACE inhibitor. It worsens outcomes and causes hyperkalemia. It also worsens outcomes in patients with diabetes. Another “don’t use it” drug.

You treat this patient with metoprolol succinate, lisinopril, furosemide, atorvastatin, and aspirin. This regimen seems to help, and the patient’s symptoms improve. However, a few weeks later, he presents to the ED with increased dyspnea. There have been no changes in his medications, and he assures you that he is taking his medications as directed. His examination reveals that he has elevated JVD, rales over the lower half of his lung fields bilaterally, and pedal edema.

Question 2.7.10 Common causes of decompensation in patients with otherwise stable heart failure include all of the following EXCEPT:

- A) Inactivity
- B) Fever
- C) Arrhythmia
- D) Dietary indiscretion
- E) Ischemia

Answer 2.7.10 The correct answer is "A." Inactivity will not generally cause an exacerbation of heart failure (though may have been an underlying cause!). The major causes of acute exacerbations of chronic heart failure include dietary indiscretion (increased salt and fluid consumption), increased metabolic demand (e.g., from infection), anemia, medication noncompliance, arrhythmia, and ischemia. The inappropriate use of medications, such as some calcium channel blockers and the institution of beta-blockers when heart failure is decompensated, is also a common cause of exacerbations of HF.

The patient notes that he did have some chest pain earlier in the day. You want to initiate therapy. You take his vitals, and his pulse is 100 bpm, blood pressure 140/95 mm Hg, oxygen saturation 89% on room air, and respiratory rate 32.

Question 2.7.11 Besides oxygen, the one best drug to initiate first in the ED to treat this patient with an acute exacerbation of his chronic HFrEF is:

- A) Furosemide
- B) Digoxin
- C) A positive inotrope, such as dobutamine
- D) Nitroglycerin
- E) An ACE inhibitor

Answer 2.7.11 The correct answer is "D." This patient will benefit from nitroglycerin for several reasons. First, the patient has told you that he had chest pain earlier today. Thus, it is possible that this patient's heart failure exacerbation is due to ischemic disease. Nitroglycerin will help this via vasodilation. The second reason is that the goal here is to restore normal cardiac function by causing vasodilation and decreasing preload and afterload. Nitroglycerin will do both of these. "A," furosemide, is also a good choice but not the one best choice. By inducing diuresis, furosemide will also significantly decrease preload and provide symptomatic relief. But remember not all heart failure patients are fluid-overloaded (such as with flash edema from ischemia). "B" is incorrect because it will take some time for digoxin to have a significant impact on this patient's symptoms. "C" is incorrect because dobutamine is a second-line drug reserved for those not responding to more conservative therapy for "cardiogenic shock," and it would not be indicated in active ischemia due to increasing myocardial oxygen demand. Norepinephrine would generally be the preferred alternative

if a positive inotrope is needed in cardiogenic shock. "E" is technically not incorrect, but it is not the best answer. There is ample evidence that ACE inhibitors, which work as after-load reducers, can be used in acute HF exacerbations either IV (e.g., enalapril) or sublingual (e.g., captopril). However, these drugs should be reserved as second-line therapy for patients who do not respond to more appropriate initial measures, and they would not be the first-line to address ischemia among choices listed.

You treat the patient with nitroglycerin, he improves, and you admit him to the floor. While in the hospital, the patient develops some additional chest pain that lasts for 10 minutes and responds to additional sublingual nitroglycerin. His BNP is noted to be elevated. His hemoglobin (Hb) is 7.2 g/dL and hematocrit (HCT) is 22%. He is still in congestive failure. The pathologist tells you that there is blood available in the blood bank to transfuse this gentleman if you so choose. There is a problem, of course: he is in heart failure, appearing fluid-overloaded, and now is somewhat tachycardic at 110 bpm.

Question 2.7.12 You tell the pathologist that:

- A) Hb of 7.2 g/dL is not an indication for transfusion
- B) Transfusing this gentleman is inappropriate since he is already in heart failure and may become more fluid-overloaded with a blood transfusion
- C) You would like to go ahead with transfusing this patient
- D) Making this patient's blood more viscous with a transfusion will increase the stress on his heart
- E) Erythropoiesis-stimulating agents (ESAs), such as darbepoetin (Aranesp®) and erythropoietin, are safer and more effective than blood transfusions for patients with HF

Answer 2.7.12 The correct answer is "C." This patient should be transfused. Guidelines suggest triggering transfusion in heart disease when the Hb is <8 to 10g/dL and if the patient is symptomatic (i.e., tachycardic, chest pain). There is no benefit to transfusing patient with a higher Hb (*Ann Intern Med.* 2013;159:770). Use clinical judgment, of course, as there are no guidelines for transfusion in an individual with ACS. ESAs ("E") seems to increase thromboembolic events without providing any benefit in those with stable HF and mild-to-moderate anemia. They should generally be avoided in this population.

Regarding non-STEMI, there are no official ACC/AHA recommendations regarding transfusion. However, the mortality at 30 days is increased if the Hb is <11 mg/dL in a patient with a non-STEMI. Whether or not transfusion will help this is not known: it may just be that patients with anemia are sicker at baseline. Patients with an HCT of <20% to 24% likely benefit from a transfusion while those with an HCT >27% to 30% do not. For 25% to 26% use your judgment. HF is different. Blood transfusion should be reserved for patients with heart failure that are severely anemic and

the transfusion be undertaken **slowly** and with the concurrent use of diuretics to avoid volume overload (*Am Heart J.* 2009;158:653–658). “A” and “B” are incorrect because this patient should be transfused carefully as noted above. “D” is incorrect since transfusing this patient to a normal Hb and HCT will not cause excess blood viscosity.

HELPFUL TIP:

Nesiritide (Natrecor), a BNP analog, can be used for HFrEF but is expensive, contributes to renal failure, and likely increases mortality. Nesiritide can produce prolonged hypotension, which limits the dose that can be used. This is a therapy of last resort ... and that may be too charitable. Just don't use it.

► Objectives: Did you learn to ...

- Recognize atypical presentations of heart failure with reduced ejection fraction in the elderly?
- Describe the sensitivity and specificity of an ECG for LVH?
- Evaluate a patient with heart failure with reduced ejection fraction?
- Manage a patient with heart failure with reduced ejection fraction and understand the role of beta-blockers, ACE inhibitors, ARBs, digoxin, and spironolactone in the treatment of HFrEF?
- Describe the role of BNP measurement in the evaluation of heart failure with reduced ejection fraction and of nesiritide in the treatment of heart failure?

QUICK QUIZ: HEART FAILURE CLASSIFICATION

A 72-year-old male with a history of myocardial infarction, PTCA, and stenting is known to have heart failure with an EF of 35% per recent echocardiogram. He presents with shortness of breath with light activities for the last 2 weeks. The appropriate classification of his heart failure by ACC/AHA stage and NYHA class is, respectively:

- A) A and II
- B) B and II
- C) C and II
- D) C and IV
- E) D and IV

The correct answer is “C.” The NYHA classification system has been around for a long time and is based on heart failure symptoms and has some fluidity to it. Patients can move from one class to another and then back again. On the other hand, the ACC/AHA staging system is progressive. We might joke that “everyone has ACC/AHA stage A heart failure,” since anyone at risk for heart failure is, by definition, stage A. Both the NYHA and ACC/AHA systems can and should be used together to categorize patients with heart failure. See the following table to review the classes/stages.

NYHA Heart Failure Classification System

- I. Cardiac disease but no symptoms and no limitation with ordinary physical activity.
- II. Mild symptoms and slight limitation with ordinary activity.
- III. Significant limitation in activity due to symptoms. Comfortable at rest.
- IV. Severe limitations. Symptoms even while at rest.

ACC/AHA Heart Failure Staging System

- A. Patients at risk for heart failure who have not yet developed structural changes or symptoms (e.g., patients with diabetes, hypertension).
- B. Patients with structural heart disease who have not yet developed symptoms.
- C. Patients who have developed clinical heart failure.
- D. Patients with refractory heart failure requiring advanced therapies.

► CASE 2.8

Your patient with heart failure does well and is discharged from the hospital after a couple of days. You are just beginning to think that the authors are tired of writing questions about heart failure ... but you are wrong. The patient's 70-year-old wife shows up with shortness of breath. Her physical examination is consistent with heart failure. Since you have learned so much from the previous case already, you send her to get an echocardiogram. You also order the recommended tests: CBC, electrolytes, ECG, thyroid functions, etc.

Question 2.8.1 The results of the echocardiogram show a **concentric thickening of the left ventricle with an ejection fraction of 75%. This is most consistent with:**

- A) Ischemic cardiomyopathy
- B) HFpEF
- C) Viral cardiomyopathy
- D) Hypertrophic cardiomyopathy
- E) None of the above

Answer 2.8.1 The correct answer is “B.” “A” is incorrect since there would likely be evidence of RWMA if there had been an old myocardial infarction. Also, this patient has a preserved ejection fraction, which is consistent with HFpEF rather than the decreased ejection fraction associated with ischemic cardiomyopathy. “C” is incorrect. Viral cardiomyopathy is associated with a dilated ventricle rather than a hypertrophic one, and there would be global dyskinesia with decreased ejection fraction. “D” is incorrect; hypertrophic cardiomyopathy is usually associated with asymmetric hypertrophy, often septal, rather than concentric hypertrophy of the left ventricle. Hypertrophic cardiomyopathy *may* lead to HFpEF in addition to left ventricular outflow tract obstruction.

Question 2.8.2 HFpEF is associated with which of the following?

- A) A prolonged history of untreated hypertension
- B) Poor relaxation of the ventricular wall
- C) Thyroid disease
- D) A and B
- E) B and C

Answer 2.8.2 The correct answer is “D.” HFpEF is often associated with long-standing hypertension as well as a stiff ventricular wall that does not relax to allow good filling during diastole (therefore “diastolic dysfunction”). *For these reasons (and others), HFpEF is more common in the elderly.* “C” is not correct because hyper- and hypothyroidism are usually associated with a dilated cardiomyopathy.

Question 2.8.3 HFpEF represents approximately what percentage of HF?

- A) <5%
- B) Approximately 10%
- C) Approximately 25%
- D) Approximately 50%
- E) >75%

Answer 2.8.3 The correct answer is “D.” HFpEF represents between 40% and 60% of cases of HF when looking at the population as a whole. The other answers are incorrect. The point here is that, as discussed earlier, patients with HF need an echocardiogram to determine what type of heart failure they have.

Question 2.8.4 Which of the following drugs is the LEAST desirable in patients with HFpEF?

- A) Diuretics
- B) ACE inhibitors
- C) Nitrates
- D) Digoxin
- E) Negative inotropes such as beta-blockers and CCBs

Answer 2.8.4 The correct answer is “D.” Poor digoxin. It is not good for almost anything. Nesiritide, digoxin, and other positive inotropes (e.g., milrinone) are not very useful in HFpEF. This makes sense. The problem here is not a lack of contractility but alternatively a lack of muscle relaxation. While there has not been a superior therapeutic regimen identified by randomized control trials, the goals of therapy are blood pressure control, the use of diuretics to relieve congestion and edema, treatment of ischemia if present, and control of the heart rate to avoid tachycardia.

Question 2.8.5 Which of the following drugs or drug classes is theoretically the best choice for the treatment of HFpEF?

- A) ACE inhibitors
- B) Beta-blockers
- C) Diuretics
- D) Hydralazine
- E) ARBs

Answer 2.8.5 The correct answer is “B.” Beta-blockers, especially metoprolol succinate, are useful as initial therapy in HFpEF. Beta-blockers (1) slow down the heart to permit longer LV filling duration during diastole and (2) help to relax the myocardium to promote a less restrictive filling pattern. If a patient fails beta-blockers, try a CCB (e.g., verapamil, diltiazem). Unlike HFrEF, the treatments of HFpEF are not well established, and there is no convincing evidence that beta-blockers or ACE inhibitors reduce mortality.

HELPFUL TIP:

Heart failure is a terminal illness with a 5-year survival of only 50%. This is worse than many cancers.

► Objectives: Did you learn to ...

- Understand the pathophysiology of HFpEF?
- Treat a patient with HFpEF?

► CASE 2.9

Your “congestive heart failure couple,” as they now call themselves, are doing so well that the wife refers her cousin to you (... and we still aren’t tired of writing heart failure questions). Her cousin, a 65-year-old male, arrives at your office and you immediately notice the smell of tobacco leaching from his clothing. The small burns in his sleeves confirm to you that he smokes, and he informs you that he has smoked three packs per day “since birth.” He recently has noticed some swelling in his feet and increased shortness of breath. He denies a history of cardiac disease. An ECG performed in the office shows right-axis deviation and a right bundle branch block (RBBB). An echocardiogram shows that he has normal left ventricular function, but a hypertrophied right heart with paradoxical bulging of the ventricular septum into the left ventricle was noted.

Question 2.9.1 This clinical picture is most consistent with which of the following?

- A) Constrictive pericarditis
- B) Chronic mitral valve prolapse
- C) Cor pulmonale
- D) Old right ventricular infarction with subsequent dysfunction
- E) Chiari network

Answer 2.9.1 The correct answer is “C.” A typical picture of cor pulmonale is right ventricular hypertrophy (RVH) with paradoxical bulging of the septum into the left ventricle, right-axis deviation on ECG, and partial or complete RBBB. “A” is incorrect. Constrictive pericarditis is associated with pericardial thickening, dilated inferior vena cava or hepatic veins, and abnormal mitral and tricuspid flow. “B” is incorrect because mitral valve prolapse in the absence of severe mitral regurgitation is not likely to be hemodynamically significant. “D” is incorrect because with a right ventricular infarct, you would expect to see a poorly functioning right ventricle. “E” is incorrect because a Chiari network is normal vestigial variant in the right atrium and would not cause RVH.

Question 2.9.2 Cor pulmonale may result from all of these disease processes EXCEPT:

- A) Sickle cell anemia
- B) Left ventricular failure
- C) Pulmonary embolus (PE)
- D) Chronic obstructive lung disease
- E) Interstitial lung disease

Answer 2.9.2 The correct answer is “B.” Cor pulmonale is the term used for right heart failure caused by diseases primarily affecting the lungs and pulmonary vasculature. The chronic pressure overload of the right ventricle as it ejects into the high resistance pulmonary vasculature results initially in RVH with normal RV systolic function but over time, the RV contractility declines leading to RV dilation and right-sided heart failure with associated significant tricuspid regurgitation and right atrial dilation.

Question 2.9.3 A possible finding on the ECG of this patient would include:

- A) P-mitrale (an “m” shaped, notched P wave in lead II)
- B) P-pulmonale (an enlarged, peaked, P wave in lead II)
- C) Absent P waves
- D) Inverted P waves

Answer 2.9.3 The correct answer is “B.” Patients with cor pulmonale often have an enlarged and peaked P wave in lead II reflecting right atrial enlargement. “P-mitrale” is found in left atrial enlargement and is characterized by a prolonged and/or notched (“m-shaped”) p-wave in lead II.

Pulmonary function testing and chest radiography support an underlying diagnosis of COPD. You counsel the patient to quit smoking, prescribe pulmonary rehabilitation, and treat him with bronchodilator therapy.

Question 2.9.4 Besides stopping smoking, the best treatment of this patient’s cor pulmonale and pulmonary hypertension (PHTN) is:

- A) Continuous prostacyclin infusion
- B) Continuous, low-flow oxygen
- C) Calcium channel blockers (CCBs)
- D) Nitroglycerin
- E) Antibiotics to reduce pulmonary inflammation secondary to infection

Answer 2.9.4 The correct answer is “B.” In this patient who is a smoker with cor pulmonale, the best drug is continuous, low-flow oxygen. This will help to reverse the pulmonary vasoconstriction caused by chronic hypoxia. It should go without saying that you must do everything you can to get him to **stop smoking**. His disease process will progress much faster if he continues to smoke. “A” is incorrect because prostacyclin infusion is useful in primary pulmonary hypertension (PHTN), not this type of cor pulmonale. “C” is incorrect. In some cases of primary PHTN, CCBs, PDE5 inhibitors (e.g., sildenafil), and several other medications, which serve as direct vasodilators to dilate the pulmonary vascular bed, can be useful. However, this is not the best choice for this patient with COPD. “D” is incorrect because patients with cor pulmonale are dependent on high right heart-filling pressures to get blood through the pulmonary vasculature. Nitroglycerin will reduce preload, thereby lowering right ventricular pressure and resulting in worsening of his symptoms. “E” is also incorrect. Antibiotics might be needed in this patient for pneumonia, bronchiectasis, etc., but they are not going to help with the treatment of cor pulmonale.

HELPFUL TIP:

Remember sleep apnea as a cause of cor pulmonale. Nocturnal oxygen desaturation causes increased pulmonary vascular resistance causing elevated right ventricular pressure and possibly right-sided failure if severe and untreated.

HELPFUL TIP:

In a reversal of fortunes for home oxygen companies and fire fighters everywhere, oxygen for COPD-related mild hypoxia (baseline SpO₂ 89–93%) or desaturation with walking to SpO₂ <90% for ≥10 seconds, but ≥80% for ≥5 minutes, has not been shown to improve survival or rate of hospitalization (*N Engl J Med.* 2016;375:1617). Note that this study did not include patients with resting saturations below 88%, which is when we usually employ home oxygen. Nor did these subjects have cor pulmonale (for which oxygen is indicated). We don’t know what the right answer on the test will be, but keep this in mind.

► Objectives: Did you learn to ...

- Diagnose cor pulmonale?
- Describe causes of cor pulmonale?
- Treat a patient with cor pulmonale?

► CASE 2.10

A 65-year-old male presents to your clinic for a complete history and physical examination. You notice that his abdominal examination reveals a pulsatile mass, which you suspect may represent an aortic aneurysm (*now we are tired of writing heart failure questions*). This finding is confirmed by ultrasound. The radiologist reports that the patient has a 3.5-cm abdominal aortic aneurysm without evidence of dissection or thrombus formation.

Question 2.10.1 The best advice to this patient is:

- A) Have the aortic aneurysm fixed now while he is still healthy
- B) Have a follow-up ultrasound every 3 months
- C) Have a stent placed to prevent further aortic dilatation
- D) Have an angiogram in the next several days to rule out vascular disease below the aorta (femoral arteries, iliac arteries, etc.)
- E) Have a repeat ultrasound at 1 year

Answer 2.10.1 The correct answer is “E.” Patients with an abdominal aortic aneurysm less than 4 cm in diameter should have an ultrasound yearly to check progression. Those with an aneurysm 4 to 5 cm in diameter should have an ultrasound every 6 months. An ultrasound on an every 3 to 6 months basis is also indicated for aneurysms that are growing >0.5 cm per year. Bottom line: the larger the aneurysm, the more frequently one should do an ultrasound. “A” is incorrect (see next question for an explanation). “C” is incorrect since a stent is not indicated

at this point. “D” is incorrect. The only reason to do an angiogram at this point is if the patient is symptomatic or if you are planning surgical intervention.

Question 2.10.2 The patient is really worried that this aneurysm will rupture and kill him. You educate him that the benefit of having the aneurysm repaired is greater than the risk of the surgery when the aneurysm reaches:

- A) ≥ 4.5 cm
- B) 5 to 5.5 cm
- C) 5.5 to 6 cm
- D) > 6 cm
- E) No repair is indicated until the patient becomes symptomatic

Answer 2.10.2 The correct answer is “B.” The risk of the surgery outweighs the benefits until the aneurysm reaches somewhere between 5 and 5.5 cm. The rest are incorrect. It would be an especially bad idea to wait until an aneurysm is symptomatic, as a ruptured aortic aneurysm can be lethal in a matter of minutes.

HELPFUL TIP:

Percutaneous endovascular stent graft repair is becoming the procedure of choice as compared to open repair. But there are tradeoffs: 30 day mortality from an endovascular graft is 1.6% versus 3.2% for open repair, but at 8 years rupture rate was 5.4% versus 1.4%. Overall 8-year mortality is the same (*N Engl J Med.* 2015;373:328).

HELPFUL (-ISH) TIP:

The rate of AAA rupture is higher in women, and there is some debate as to what the threshold should be for elective surgical repair for women. Should it occur when the AAA diameter is 5 cm or less? Maybe. But women also have higher rates of complications post-repair.

The patient goes to Texas (or Arizona or Florida—somewhere warmer than Iowa) for the winter as part of the re-establishment of human annual migration. When he returns, he calls you complaining of back pain that is somewhat sharp and radiating into his legs. You meet him in the ED and suspect that he is having a dissection of his aneurysm.

Question 2.10.3 All of the following are true regarding aortic dissection EXCEPT:

- A) A substantial number of patients will have palpable pulses below the level of the dissection
- B) Patients may have an elevated LDH and microangiopathic findings on RBC examination
- C) Blood pressure should be kept on the high side to ensure perfusion below the area of the aneurysm
- D) The pain may migrate down from the chest to the lower abdominal area over time
- E) The pain may be episodic

Answer 2.10.3 The correct answer is “C.” One does not want to keep the blood pressure on the high side. In fact, reducing the blood pressure is the initial treatment of choice for a dissecting aneurysm. “A,” “B,” “D,” and “E” are all correct statements. Patients may have an elevated LDH and microangiopathic findings on RBC smear as a result of trauma and cell lysis. “D” is a correct statement, but patients often do not have this “classic” migrating pattern of pain. “E” is often true of pain in aortic dissection—it may be episodic.

The patient has a blood pressure of 160/105 mm Hg and a pulse of 115 bpm. Clearly, this is too high in a patient who has an ongoing dissection. You decide to treat this patient before transferring him to a tertiary care center where he can be surgically managed.

Question 2.10.4 The best medication(s) to use in this patient to control his blood pressure is/are:

- A) Sublingual nifedipine plus metoprolol
- B) Amlodipine
- C) Intravenous hydralazine
- D) Intravenous esmolol plus nitroprusside
- E) Intravenous nitroglycerin

Answer 2.10.4 The correct answer is “D.” The goal of therapy here is not only blood pressure reduction but also control of shear forces on the aorta, which requires the prevention of tachycardia. Intravenous beta-blockers such as labetalol, propranolol, metoprolol, or esmolol are the first-line agents. Esmolol is preferred because of the short half-life; you easily can turn it off if there is hypotension. Shoot for a pulse of 60 bpm. Nitroprusside (or our favorite, IV nitroglycerin) can be added if the blood pressure control remains suboptimal even after beta-blockade. In this scenario, nitroprusside should never be given without beta-blockade, as it may cause reflex tachycardia induced by vasodilation and thus further aortic shear stress. The same rationale is true for not using intravenous hydralazine without beta-blockers in this scenario. “A” is incorrect for two very good reasons. First, nifedipine should **never** be used sublingually. Syncope, heart block, MI, stroke, and other serious adverse consequences have been reported. Second, nifedipine increases heart rate causing an increase in shear forces on the aorta. “B” is incorrect since amlodipine does nothing to reduce heart rate, is not titratable to any useful degree, and the onset of action is too slow to be used when prompt blood pressure lowering is desired. “E” is incorrect because nitroglycerin alone causes reflex tachycardia.

HELPFUL TIP:

Screen for an aortic aneurysm **once** in men age 65 to 75 who have ever smoked 100 cigarettes or more (per USPSTF and ACC/AHA guidelines). Also, consider screening those *who have not smoked* age 65 to 75 based on comorbidities (e.g., DM, HTN, family history) and risk, realizing that guidelines in these groups vary considerably, and the best approach is an individualized one.

► **Objectives: Did you learn to ...**

- Identify the treatment options and timing of treatment of an abdominal aortic aneurysm?
- Manage a patient with a dissecting aneurysm?

► **CASE 2.11**

A 60-year-old male presents with dizziness and palpitations. The patient has a blood pressure of 100/60 mm Hg and a pulse of 160 bpm. His ECG is shown in Figure 2-5.

Question 2.11.1 Which of the following interventions are appropriate options in the treatment of this patient?

- A) Amiodarone, lidocaine, defibrillation, metoprolol
- B) Amiodarone, lidocaine, defibrillation, diltiazem
- C) Amiodarone, lidocaine, cardioversion, diltiazem
- D) Procainamide, lidocaine, adenosine, defibrillation
- E) Amiodarone, procainamide, lidocaine, cardioversion

Answer 2.11.1 The correct answer is “E.” The rhythm is stable ventricular tachycardia. Procainamide, lidocaine, amiodarone, and *synchronized* cardioversion can all be used for ventricular tachycardia. “A” is incorrect for two reasons. The rhythm is ventricular tachycardia and is stable, and neither metoprolol nor defibrillation is appropriate. Defibrillation could be appropriate if the patient was unstable, pulseless (including pulseless ventricular tachycardia), or had ventricular fibrillation. “B” is

incorrect because of the inclusion of diltiazem and defibrillation. “C” is incorrect because of the inclusion of diltiazem. “D” is incorrect because adenosine, which is used for atrial arrhythmias, is useless in ventricular arrhythmias and because, again, defibrillation is inappropriate.

HELPFUL TIP:

Procainamide is another option for ventricular tachycardia if you have time to load it.

The patient does not respond to IV amiodarone and you choose to cardiovert him.

Question 2.11.2 Which of the following is the recommended energy (in joules) for an initial attempt at synchronized cardioversion?

- A) 200 joules, monophasic
- B) 360 joules, monophasic
- C) 300 joules, biphasic
- D) 360 joules, biphasic
- E) None of the above

Answer 2.11.2 The correct answer is “A.” For cardioversion of stable ventricular tachycardia, start with 100 to 200 joules for monophasic waveforms and 100 to 200 joules for biphasic waveforms. The rest are incorrect.

FIGURE 2-5. ECG for patient in question 2.11.1.

FIGURE 2-6. ECG for patient in question 2.11.3.

HELPFUL TIP:

For **defibrillation**, escalating doses of electricity are out of the new protocols. Start with a single shock at 360 joules with a monophasic defibrillator or 150 to 200 joules if using a biphasic defibrillator, depending on the manufacturer. See Chapter 1 for a “practice code.”

HELPFUL (AND VERY IMPORTANT) TIP:

The 2010 and 2015 AHA guidelines for ACLS emphasize the importance of starting with chest compressions (Circulation–Airway–Breathing) and NEVER interrupting chest compressions during resuscitation (really that means minimizing interruptions—they feel that too often chest compressions are halted for less important interventions such as intubation, venous access, etc.).

You cardiovert the patient, and the rhythm in Figure 2-6 is on the monitor. Is it getting hot here, or is it just you?

Question 2.11.3 Of the following, what is the first step you will take (while maintaining good compressions and ventilations, of course)?

- A) Re-shock the patient at the same energy level
- B) Check another lead to assure the readout is accurate
- C) Give epinephrine, 1 mg IV
- D) Give atropine, 1 mg IV

Answer 2.11.3 The correct answer is “B.” This rhythm is asystole. It is important to quickly check another lead and make sure that all of the leads are connected properly. “A” is incorrect because cardioversion/defibrillation is not routinely indicated in the treatment of asystole. “C” and “D” are incorrect because it is important to ensure that the patient actually is in asystole prior to treating with any medications.

HELPFUL TIP:

With regard to ACLS, doing compressions and ventilations are particularly important. There is no need to intubate the patient if he/she can be easily bagged. The correct number of ventilations (10–12/min) and compressions (100 bpm with 2 inches of depth) in a ratio of 15 compressions: 2 breaths for two provider CPR or 30:1 for single provider is important. The Bee-Gees “Staying Alive” has the correct rate for compressions. Queen’s “Another One Bites the Dust” also has the correct rate but is considered less decorous in the code situation (of course, you don’t have to sing it out loud!).

Question 2.11.4 The new lead placement continues to show asystole. Which of the following drugs and doses are considered appropriate in asystole?

- A) Epinephrine 1 mg
- B) Atropine 0.5 mg
- C) Atropine 1 mg
- D) Epinephrine 10 mg
- E) A and C

Answer 2.11.4 The correct answer is “A.” Atropine is no longer in the ACLS guidelines for asystole. Older ACLS recommendations for asystole included both epinephrine and atropine.

► Objectives: Did you learn to ...

- Recognize and manage ventricular tachycardia and asystole?
- Apply the current American Heart Association’s ACLS guidelines to a patient in asystole?

► CASE 2.12

A 75-year-old female presents to your office complaining of episodic palpitations with episodes of lightheadedness that are *not* concurrent with the palpitations. You perform an electrocardiogram in your office, and the rhythm is shown in Figure 2-7.

Question 2.12.1 What rhythm does this represent?

- A) First-degree heart block
- B) Second-degree heart block type I (Wenckebach)
- C) Second-degree heart block type II
- D) Third-degree heart block
- E) Atrial flutter with variable block

FIGURE 2-7. ECG for patient in question 2.12.1.

Answer 2.12.1 The correct answer is “C.” Your patient’s ECG shows a second-degree heart block, type II (Mobitz II). This is characterized by a **fixed PR interval** with an intermittently non-conducting *P* wave and resultant dropped beats. “A” is incorrect. First-degree heart block is characterized by a prolonged PR interval without any blocked beats (meaning every QRS is preceded by a *P* wave conducted with a long PR interval). The upper limit of normal of the PR interval is 0.2 seconds (and we admit that this one is darn close, but Mobitz II is the issue here). A second-degree heart block, Mobitz type I (Wenckebach), is defined by a progressively prolonged PR interval ending with a non-conducted *P* wave and a dropped beat. A third-degree heart block is characterized by no consistent pattern between the *P* waves and the QRS complex. “E” is incorrect because, by definition, atrial flutter is represented by a rapid atrial rate. In this patient, the rate is slow.

By the time the patient arrives at the hospital, she is having a rapid, chaotic rhythm, which appears to be atrial fibrillation on the monitor. It seems as though there are also episodes of atrial flutter with 2:1 block.

Question 2.12.2 The most likely diagnosis in this patient with varying rate is:

- A) Sick sinus syndrome (bradycardia–tachycardia syndrome)
- B) Hypothyroidism
- C) Hyperthyroidism
- D) Hyperkalemia

Answer 2.12.2 The correct answer is “A.” The most likely diagnosis in this patient is “sick sinus syndrome,” also known as “tachy–brady” syndrome and “bradycardia–tachycardia” syndrome. This syndrome is most common in elderly individuals and reflects the replacement of the SA node with fibrous tissue. “B” is incorrect because hypothyroidism should cause bradycardia without intermittent tachycardia. “C” is incorrect because hyperthyroidism should cause tachycardia without bradycardia. “D” is incorrect because hyperkalemia generally causes a widened QRS complex on ECG and eventually ventricular tachycardia. Note: With Mobitz type II second degree heart block, the problem is infra-nodal, below the AV node, and can result in complete heart block. Sick sinus syndrome is due to disease of the SA node.

Question 2.12.3 Which of the following is the definitive treatment of sick sinus syndrome?

- A) Mexiletine
- B) Hydralazine
- C) Quinidine
- D) Pacemaker
- E) Implantable defibrillator

Answer 2.12.3 The correct answer is “D.” In general, patients with sick sinus syndrome become symptomatic because of the bradycardia episodes. Thus, pacing is necessary. Note: A pacemaker would also be indicated in patients with Mobitz type II second-degree heart block without tachy–brady

syndrome. “A” and “C” are incorrect because these two drugs are aimed primarily at ventricular arrhythmias; sick sinus syndrome is a problem with the SA node. “B” is incorrect because hydralazine is an afterload reducer with no direct effect on cardiac rhythm. “E” is incorrect because patients with sick sinus syndrome do not have ventricular fibrillation or ventricular tachycardia, and thus there is no need for a defibrillator.

HELPFUL TIP:

In sick sinus syndrome, in addition to the pacemaker, it is often necessary to add a beta-blocker or a CCB (diltiazem or verapamil) to address the tachycardia (e.g., PSVT or atrial fibrillation).

► Objectives: Did you learn to ...

- Identify and differentiate second-degree heart blocks?
- Diagnose and treat sick sinus syndrome?

► CASE 2.13

A 58-year-old male smoker with a history of type 2 diabetes mellitus presents with complaints of easy fatigability and pain in his thighs when exerting himself. The left leg is worse than the right. The pain resolves after resting and is no worse going downhill than uphill. He works as a carpenter, and the leg pain is now limiting his ability to work. He will not quit smoking (“It’s the only thing I truly love, Doc”). The patient states that his symptoms are better when he hangs his leg over the side of the bed at night.

Question 2.13.1 The etiology of this patient’s leg pain is most likely:

- A) Peripheral venous disease (e.g., venous insufficiency, varicose veins)
- B) Spinal stenosis
- C) Diabetic neuropathy
- D) Peripheral arterial disease (e.g., arterial stenosis)
- E) None of the above

Answer 2.13.1 The correct answer is “D.” Intermittent claudication is the classic presenting symptom of peripheral arterial disease. When rest pain is present, relief of symptoms occurs by making the affected area dependent (e.g., hanging the legs over the side of the bed), letting gravity help increase blood flow. The pain associated with diabetic neuropathy begins distally, has a burning quality, and is not typically relieved with rest. In fact, patients often notice it more at rest (e.g., during the night). Patients with peripheral venous disease will often have worsening of their symptoms when their legs are in a dependent position. Spinal stenosis is often made worse by walking downhill and better when walking uphill or leaning forward (a kyphotic/forward flexed position opens up the foramen, thereby decreasing nerve root compression).

His examination shows decreased pulses in the lower extremities bilaterally. You would like to confirm your suspicion that this patient has peripheral vascular disease.

Question 2.13.2 What is the first study you would order in this patient?

- A) Spiral CT to confirm vascular calcification
- B) Ankle-brachial index (ABI)
- C) Color Doppler to assess flow
- D) Catheterbased arteriography
- E) None of the above.

Answer 2.13.2 The correct answer is “B.” The ABI is sensitive and specific for peripheral arterial disease in the lower extremity. The pressure in the ankle should be higher than that in the brachial artery in a healthy person. The highest sensitivity is achieved by measuring pressures in both brachial arteries, both dorsalis pedis, and both posterior tibial arteries. Neither spiral CT or color Doppler are recommended as the initial screening test for the presence of peripheral vascular disease (although CT angiogram may be useful in the future to define the degree and location of narrowing in preparation for bypass or angioplasty). Catheter-based arteriography is an option but should be reserved for patients with known peripheral artery disease in whom intervention is being considered.

The ABI results are normal. However, you strongly suspect claudication.

Question 2.13.3 The next step should be:

- A) Catheter-based arteriography
- B) Repeat ABI after an exercise stress test
- C) Magnetic resonance arteriography
- D) CT arteriography
- E) None of the above

Answer 2.13.3 The correct answer is “B.” In patients in whom you strongly suspect peripheral vascular disease, ABIs after exercise can be positive when a resting test is negative. This would be the least invasive and most cost-effective test of the options given.

The post-exercise ankle-brachial indices are as follows: 0.9 in the right leg, 0.4 in the left leg.

Question 2.13.4 The proper interpretation of this information is:

- A) 95% probability of some degree of occlusive disease in the right leg, severe occlusive disease in the left
- B) No occlusive disease in the right leg, mild disease in the left
- C) Moderate occlusive disease on both legs
- D) No occlusive disease in either leg

Answer 2.13.4 The correct answer is “A.” A normal ABI should be 0.95 to 1.29. An ABI of 0.9 is 95% sensitive for

finding **some** degree of occlusive disease on arteriography (although it may not be hemodynamically significant). An ABI of 0.81 to 0.94 represents mild arterial disease that may or may not be associated with claudication. An ABI of 0.41 to 0.80 is classified as moderate arterial disease and is usually associated with some degree of claudication. An ABI of ≤ 0.4 represents severe disease and may be associated with rest pain. Paradoxically, an ABI > 1.30 represents noncompressible arteries and may be a marker for arterial calcification. In these cases, a toe-brachial index should be measured (really). (Don't ask us ... we don't know where to find a toe BP cuff either. Maybe you can use a full-sized gnome or pixie cuff. We'd love to sell you one.)

You decide to start the patient on a medication to help control his claudication.

Question 2.13.5 Which of the following statements is correct?

- A) Pentoxifylline is relatively contraindicated in heart failure
- B) Cilostazol is the best choice for claudication in patients with heart failure
- C) Beta-blockers are good arterial dilators and are thus useful in claudication
- D) The main mechanism of action of pentoxifylline and cilostazol is selective vasodilation
- E) Tobacco smoking paradoxically alleviates claudication

Answer 2.13.5 The correct answer is "A." Cilostazol (Pletal®) and pentoxifylline (Trental®) are phosphodiesterase inhibitors. Their mechanism of action in improving walking distance is poorly understood. Other phosphodiesterase inhibitors (such as milrinone) increase mortality in patients with heart failure. Thus, pentoxifylline and cilostazol ("B") should be used with *extreme caution*, if at all, in patients with heart failure. Selective beta-blockers actually cause peripheral arterial constriction, not arterial dilation; therefore, "C" is also incorrect. The purported benefit of pentoxifylline is to increase RBC malleability and thus reduce the viscosity of blood in the microcirculation. It has no vasodilative effects. However, cilostazol does have some vasodilative effects. Therapeutic benefit with these drugs may take several weeks. A dedicated and supervised walking program is of paramount importance and underutilized. Given the strong association between smoking and peripheral artery disease, smokers should be encouraged to quit, so "E" is incorrect. Statins should also be initiated and have been shown to have benefit (*Cochrane Database Syst Rev.* 2007 Oct 17;(4):CD000123). Therapy of PAD should include antiplatelet therapy and cardiovascular risk factor modification.

HELPFUL TIP:

Remember that peripheral artery disease is considered a CAD equivalent with the same 10-year attendant cardiac risk even in the absence of CAD.

Question 2.13.6 In and of themselves, indications for further intervention for peripheral artery disease (e.g., bypass, stenting) include all of the following EXCEPT:

- A) Rest pain
- B) Persistent pain that interferes with day-to-day functioning
- C) Tissue loss
- D) 80% occlusion of the femoral artery

Answer 2.13.6 The correct answer is "D." Classic indications for invasive treatment of lower extremity PAD are (1) salvage of a threatened limb (rest pain, nonhealing ulceration, or gangrene) and (2) improvement in functional capacity. An 80% occlusion of the femoral artery, in and of itself, is not an indication for percutaneous or surgical revascularization in a patient who is asymptomatic. Endovascular therapy is generally preferred. Note that claudication is a marker for a high risk of mortality (up to 31% over 10 years). There is also an increased risk of limb loss.

The patient sees the light, but does not go into it, and quits smoking. The case ends happily ...

HELPFUL TIP:

No anticoagulation regimen seems to prevent re-occlusion of lower extremity arteries after stenting. Patients should, however, continue on their current antithrombotic regimen as indicated for cardiovascular disease (ASA, warfarin, DOACs, etc.).

► **Objectives: Did you learn to ...**

- Recognize symptoms and signs of peripheral vascular disease?
- Order appropriate diagnostic tests for a patient suspected of having peripheral vascular disease?
- Develop an understanding of the agents used to treat peripheral vascular disease?

► **CASE 2.14**

A 75-year-old male presents to your office for a complete physical examination before prostate surgery. On examination, you notice a 3/6 harsh, mid-systolic ejection murmur heard best at the upper right sternal border and radiating to the neck. S1 and S2 are normal. An echocardiogram demonstrates mild aortic stenosis. Currently he is asymptomatic.

Question 2.14.1 The indications for valve replacement surgery include:

- A) Grade 4/6 murmur
- B) Requirement for major, semi-elective surgery such as prostatectomy
- C) Severe aortic stenosis without symptoms and normal LV function
- D) Severe aortic stenosis in a patient undergoing coronary bypass grafting
- E) All of the above

Answer 2.14.1 The correct answer is “D.” As a general rule, aortic stenosis is repaired when it becomes symptomatic. Repair of *asymptomatic*, severe aortic stenosis is indicated in the following scenarios: undergoing CABG or other valve or aorta surgery, LVEF < 50%, hypotension in response to exercise, or high likelihood of rapid progression. “A” is incorrect because the loudness of the murmur does not always correlate with its functional significance. “B” is incorrect as well. As long as the lesion is not hemodynamically significant, the patient should tolerate prostate surgery. “C” is incorrect because surgery is not usually necessary even in severe valvular disease **without** symptoms as long as the left ventricular function is normal. Note that it is not uncommon that patients with severe aortic stenosis report that they are asymptomatic, but they have modified their activity to avoid symptoms which may have occurred gradually so that they don’t recognize the decline.

HELPFUL TIP:

There is a move afoot to repair aortic stenosis before it becomes symptomatic. This is because the LV starts to fibrose prior to onset of symptoms, and the fibrosis is associated with worse long-term outcomes. This is not the standard yet, however (*Circulation* 2018;138:1935).

Question 2.14.2 The patient would like to know how often he should have a repeat echocardiogram given that he has mild disease. Your answer is:

- A) Every 3 to 5 years
- B) Every year
- C) Every 6 months
- D) When he develops symptoms
- E) None of the above

Answer 2.14.2 The correct answer is “A.” Patients with mild aortic stenosis who are asymptomatic can be followed by echocardiogram every 3 to 5 years. Patients with severe disease should have yearly echocardiography to evaluate for left ventricular dysfunction. See Table 2-7.

TABLE 2-7 RECOMMENDED INTERVALS FOR ECHOCARDIOGRAPHIC EVALUATION FOR VALVULAR DISEASE^a

Lesion	Mild Disease	Moderate Disease	Severe Disease
Aortic stenosis	Every 3–5 years	Every 2 years	Every 6–12 months
Mitral stenosis	Every 3–5 years	Every 1–2 years	Every 1–2 years
Aortic regurgitation	Every 3–5 years	Every 1–2 years	Every 6–12 months
Mitral regurgitation	Every 3–5 years	Every 1–2 years	Every 6–12 months

^aRecommendations vary.

Two years later, the patient returns for a checkup and states that he believes he has been having symptoms from his aortic stenosis.

Question 2.14.3 All of the following can occur with symptomatic aortic stenosis EXCEPT:

- A) Left-to-right intracardiac shunt
- B) Exertional dyspnea
- C) Syncope
- D) Angina
- E) Lightheadedness

Answer 2.14.3 The correct answer is “A.” Intracardiac shunts don’t occur with aortic stenosis. If you got this one wrong, back to anatomy for you! An isolated, fixed valvular lesion as an adult cannot cause intracardiac shunting. Exertional dyspnea, lightheadedness (presyncope), syncope, and chest pain are common symptoms in severe aortic stenosis.

Question 2.14.4 Which of the following statements about aortic valve disease is INCORRECT?

- A) Aortic stenosis can be treated quite effectively with balloon valvulotomy with good long-term outcomes
- B) There are no known medical treatments that reduce the need for aortic valve replacement
- C) Risk factors for the development of aortic stenosis are similar to CAD
- D) Valve replacement surgery is the preferred treatment of symptomatic aortic stenosis

Answer 2.14.4 The correct answer is “A.” Valvulotomy (balloon aortic valvuloplasty) is not a long-term solution for the management of severe symptomatic aortic stenosis. While it may be indicated as a “bridge” to definitive treatment (surgery or transcatheter aortic valve replacement [TAVR]), durability of the valvulotomy results are poor, only lasting 3 to 6 months. The procedure carries the attendant risk of cerebral embolism causing stroke, aortic rupture, or acute severe aortic insufficiency. The epidemiological risk factors for aortic stenosis and CAD are similar (as is the pathophysiology). Unfortunately, there are no drugs that are effective at reducing the need for valve replacement. You can provide symptomatic relief but that is all.

► Objectives: Did you learn to ...

- Recognize symptoms of aortic stenosis?
- Manage a patient with aortic stenosis?
- Evaluate aortic valve disease and determine long-term follow-up vis-à-vis periodic echocardiograms?

► CASE 2.15

A 35-year-old male presents to the office with upper respiratory symptoms. He is taking no medications except for a bit of pseudoephedrine for his cold. You notice when looking at his vital signs that his blood pressure is 180/106 mm Hg. Repeat measurement confirms that the blood pressure is elevated at 175/105 mm Hg.

Question 2.15.1 What is your initial approach to this patient?

- A) Start a chronic antihypertensive since he is at risk for a stroke within the next couple of days with a blood pressure at this level
- B) Administer clonidine in the office to reduce the blood pressure to a safe level of about 150/100 mm Hg
- C) Watch the patient over the next 2 weeks and get additional blood pressure readings before deciding what to do and instruct him to discontinue pseudoephedrine
- D) Schedule the patient for outpatient labs and electrocardiogram
- E) Fire the patient from your practice. He's messing up your quality measures

Answer 2.15.1 The correct answer is "C." The diagnosis of hypertension requires two elevated blood pressures on two different occasions. This patient's elevated blood pressure could be situational, related to decongestants and current illness (though decongestants only increase systolic blood pressure by 2–3 mm Hg if at all). Neither "A" nor "B" is correct because a blood pressure of 175/105 mm Hg does not pose a risk of acute stroke, and the pressure need not be lowered acutely *unless there is evidence of end-organ injury* (e.g., angina, heart failure, hypertensive encephalopathy). "D" is incorrect because you cannot definitively establish that this patient has hypertension based on only one in office blood pressure measurement. As for "E"...really? Is this why we went into medicine?

The patient returns to your office with blood pressures measured six times over a period of 2 weeks at a local pharmacy. Only three of the six readings suggest that the patient is hypertensive. The patient states that the elevated blood pressures were while he was under stress at work.

Question 2.15.2 Your best response at this point is to:

- A) Start an antihypertensive
- B) Send the patient for a 24-hour ambulatory blood pressure measurement
- C) Don't worry about the blood pressure since half of the readings were within a normal range
- D) Get a nephrology consult to help in decision making
- E) Make another office visit so you can buy that Porsche

Answer 2.15.2 The correct answer is "B." One way to determine if a patient with contradictory readings is hypertensive is to perform 24-hour ambulatory blood pressure monitoring. This can be useful in patients who have elevated blood pressures in the office but not at home or vice versa. It can also be used if you do not trust the blood pressure readings taken outside of your office. "A" is incorrect since we have not yet established that this patient is hypertensive. "C" is incorrect since we have not yet established that this patient is not hypertensive. "D" is incorrect because you are smarter than that and should be able to work through this kind of case yourself! As to "E," whoops, we forgot. We're family physicians, not radiologists. No Porsche for us!

Question 2.15.3 The following are all well-accepted indications for 24-hour ambulatory blood pressure monitoring EXCEPT:

- A) Suspected white coat hypertension
- B) Patients with difficult-to-control hypertension
- C) Patients having hypotensive symptoms on their antihypertensive treatment
- D) Follow-up after initiating antihypertensive treatment
- E) Evaluation of patient for autonomic dysfunction

Answer 2.15.3 The correct answer is "D." One need not do 24-hour ambulatory blood pressure monitoring to document response to antihypertensive therapy in patients in whom most or all measurements post-treatment are normal. All of the other answer choices are considered reasonable indications for 24-hour ambulatory blood pressure monitoring.

Elevated blood pressure in response to stress (especially in the doctor's office) is called "white coat hypertension."

Question 2.15.4 Which of the following statements is true about white coat hypertension?

- A) As long as the majority of blood pressure readings are normal, the patient does not require treatment because there is no increased risk of adverse cardiac outcomes
- B) Patients with white coat hypertension have an intermediate risk for adverse outcomes when compared with patients with normal blood pressure and those with chronically elevated blood pressure
- C) White coat hypertension is more common in young patients
- D) Patients with white coat hypertension have an elevated left ventricular mass when compared to patients with normal blood pressures
- E) B and D

Answer 2.15.4 The correct answer is "E." Patients with white coat hypertension have outcomes that are intermediate between normotensive and hypertensive patients. In addition, they have an elevated left ventricular mass. Surprisingly, white coat hypertension is more common in the elderly.

Question 2.15.5 Hypertension is defined as an ambulatory 24-hour monitor average blood pressure of:

- A) 135/85 mm Hg during the day and 125/75 mm Hg at night
- B) 140/90 mm Hg during the day and 130/85 mm Hg at night
- C) 130/85 mm Hg over 24 hours
- D) 140/90 mm Hg over 24 hours

Answer 2.15.5 The correct answer is "A." Hypertension is diagnosed via ambulatory monitoring when patients have an average blood pressure of >135/85 mm Hg during the day and >125/75 mm Hg at night, as defined by JNC 8. Another published criterion is a blood pressure of >140/90 mm Hg more than 40% of the time. The ACC/AHA would like to make things more difficult. Their criteria are 24-hour mean of 125/75 mm Hg, daytime average of \geq 130/80 mm Hg or nighttime average of \geq 110/65 mm Hg.

The ambulatory blood pressure monitor reveals that the patient's blood pressure is >140/90 mm Hg more than 40% of the time, indicating that he is indeed hypertensive.

Question 2.15.6 The initial evaluation of the hypertension includes the following:

- A) History, physical, CBC, urinalysis, glucose, BUN, creatinine, electrolytes, ECG, and lipids
- B) History, physical, CBC, uric acid, glucose, BUN, creatinine, electrolytes, and lipids
- C) History, physical, CBC, urinalysis, glucose, BUN, creatinine, electrolytes, ECG, lipids, and echocardiography
- D) History, physical, and labs only as indicated by history and physical

Answer 2.15.6 The correct answer is "A." History, physical, CBC, urinalysis, glucose, BUN, creatinine, electrolytes, ECG, and lipids are the generally agreed-upon initial workup of the hypertensive patient. "C" includes echocardiography, which is not recommended as part of the routine evaluation but may be indicated if signs of cardiac disease are present.

The patient's ECG comes back showing evidence of LVH.

Question 2.15.7 This finding suggests that:

- A) You should initiate this patient's therapy with an ACE inhibitor since ACE inhibitors prevent disadvantageous cardiac remodeling
- B) The patient has heart failure
- C) You should recommend an echocardiogram for this patient
- D) You should order a BNP level to screen for LVH and early heart failure

Answer 2.15.7 The correct answer is "C." The sensitivity of ECG for LVH is only in the 30% to 60% range with a specificity of 80%. Thus, a "positive" ECG is not a strong enough indication to initiate therapy for LVH. For this reason, an echocardiogram should be done to confirm the diagnosis of LVH. "A" is incorrect since an ACE inhibitor is not necessarily the first drug one would start. In addition, we really don't know if this patient has LVH yet, though ACE inhibitors do prevent harmful cardiac remodeling. "B" is incorrect. Certainly, long-standing hypertension and significant LVH can cause heart failure. However, we cannot conclude that this patient has heart failure on the basis of an ECG, especially in the absence of symptoms. "D" is incorrect since the sensitivity of the BNP as a screening tool in an asymptomatic population is poor.

The echocardiogram is normal. You have decided to start this patient on treatment for his hypertension.

Question 2.15.8 Based on outcome data, which of the following is the LEAST effective drug to start on this patient?

- A) An Angiotensin Converting Enzyme inhibitor (ACEI), such as lisinopril
- B) An Angiotensin Receptor Blocker (ARB), such as losartan

- C) An alpha-blocker, such as doxazosin
- D) A thiazide diuretic, such as chlorthalidone
- E) A Calcium Channel Blocker (CCB), such as amlodipine

Answer 2.15.8 The correct answer is "C." Alpha-blockers have worse outcomes in hypertension when compared to other antihypertensives. The JNC 8 recommendations suggest that the first-line agent, in the general non-Black population including those with diabetes, could appropriately be a thiazide-type diuretic, CCB, ACEI, or ARB. Notice that beta-blockers do not make the list of first-line antihypertensives. For the Black population (in general), including those with diabetes, the initial antihypertensive treatment should include a thiazide-type diuretic or a CCB.

Question 2.15.9 Time to digress a bit. Which of the following drugs is the *best* choice as your initial agent for the treatment of hypertension in a patient with diabetes and known microalbuminuria?

- A) Lisinopril
- B) Metoprolol
- C) Losartan
- D) Verapamil
- E) Amlodipine

Answer 2.15.9 The correct answer is "A." In a diabetic patient who has proteinuria, an ACE inhibitor is indicated to slow down the progression of renal disease. An ARB or non-dihydropyridine CCB (verapamil, diltiazem) is a viable alternative for those who cannot tolerate an ACE inhibitor. (Note: Some patients may not tolerate verapamil or diltiazem due to bradycardia or may not be candidates due to LV systolic dysfunction). However, ACE inhibitors are still first-line. These recommendations stem from the renal and cardiac benefits of ACE inhibitors.

HELPFUL TIP:

Although thiazide diuretics decrease the left ventricular diameter (due to diuresis), beta-blockers, CCBs, and ACE inhibitors **all** reverse LVH.

HELPFUL TIP:

Experts (and the literature) go back and forth between choosing the old standby, hydrochlorothiazide (HCTZ), and the even older drug, chlorthalidone. Hypokalemia is more frequently seen with chlorthalidone than with HCTZ. Potassium should be monitored periodically with diuretics anyway, and hypokalemia often complicates hypertension.

Question 2.15.10 Digressing a bit further ... Which of the following drugs might you want to use as your initial agent for the treatment of hypertension in a 72-year-old male who you also diagnosed with symptomatic benign prostatic hypertrophy (BPH)?

- A) Amlodipine

- B) Doxazosin
- C) Captopril
- D) Losartan
- E) Verapamil

Answer 2.15.10 The correct answer is “B.” Doxazosin is an alpha-blocker that is useful in the treatment of symptomatic BPH. None of the other choices can be used for this indication. Of course, alpha-blockers are also antihypertensives, and thus serve a useful purpose by killing two birds with one stone (Why would you want to kill two birds? And why with stones? Isn’t there a better way?). As noted above, alpha-blockers do not confer as much benefit for the hypertensive patient as other classes of drugs. Thus, alpha-blockers are not the best choice in general but could be used as the initial agent if you have a compelling reason.

The point of these digressions is that you should look at the patient’s other underlying conditions when deciding what to recommend at initial therapy. Another example would be a patient with CAD and angina starting on a beta-blocker as initial treatment rather than a thiazide (since the beta-blocker may improve angina symptoms and is indicated for CAD). Recall that not all beta-blockers are created equal. Atenolol is least preferred and metoprolol succinate is among the best. If the patient has renal disease, consider an ACE inhibitor or ARB as first-line treatment for hypertension.

Remember the 35-year-old guy? You start him on chlorthalidone, but his blood pressure does not respond at a dose of 12.5 mg/day (have your patients cut the 25-mg tabs in half). His blood pressure on follow-up is 148/96 mm Hg.

Question 2.15.11 The best approach for such a patient is to:

- A) Push his chlorthalidone to 25 mg daily before starting another medication
- B) Stop the chlorthalidone and start another medication
- C) Rely on exercise and diet to normalize the blood pressure
- D) Start a second drug **before** you have maximized the dose of the first drug
- E) Start a workup for secondary causes of hypertension
- F) A or D

Answer 2.15.11 The correct answer is “F.” Per the JNC 8 guidelines, both “A” and “D” are acceptable strategies; you could push up the dose of a first drug or add a second drug. There is a lack of randomized controlled trials to guide these recommendations. JNC 8 urges us to tailor therapy based on individual circumstances, clinician and patient preference, and drug tolerability. Low-dose chlorthalidone (12.5 mg) provides the greatest blood pressure reduction per mg of drug, and there is little clinical benefit of utilizing >25 mg daily of HCTZ or chlorthalidone. Higher doses are associated with increased adverse effects with minimal clinical gain in hypertension management. “B” is incorrect because a patient with this level of blood pressure elevation will generally require more than one drug to achieve a normalized blood pressure. “C” is

incorrect because the majority of patients are unable to maintain an adequate diet or exercise regimen to effectively treat blood pressure. Exercise and dietary change are certainly laudable goals and should be encouraged in all patients. However, they are not likely to normalize blood pressure in most hypertensive patients. “D” is also correct as it represents one of the acceptable JNC 8 guideline strategies to dose antihypertensive drugs. “E” is incorrect since this patient has not yet proven to be resistant to treatment.

HELPFUL TIP:

Another strategy for the *initial* treatment of hypertension, depending on the patient’s blood pressure, is to start therapy with two drugs at submaximal doses (e.g., lisinopril 10 mg and HCTZ 12.5 mg), recognizing that most patients will eventually need two drugs.

You decide to start this patient on diltiazem as a second agent.

Question 2.15.12 Which of the following side effects is most characteristic of diltiazem and other CCBs?

- A) Dehydration
- B) Cough
- C) Dependent edema
- D) Hypokalemia
- E) Elevated cholesterol

Answer 2.15.12 The correct answer is “C.” As a class, CCBs tend to cause peripheral edema. Dehydration and hypokalemia can be caused by diuretics. Cough and hyperkalemia are characteristic of ACE inhibitors and ARBs (though cough is less common with ARBs). Diuretics can increase cholesterol, while beta-blockers can increase triglycerides.

Despite the fact that the patient is on two medications, he remains hypertensive. In fact, the blood pressure has barely moved. With your thorough history taking, you have ruled out excess alcohol intake (often an “occult” cause of hypertension). The patient is compliant with his medications.

Question 2.15.13 Further investigations that might be helpful in determining the cause of hypertension in this patient include all of the following EXCEPT:

- A) Checking the potassium level *while the patient is taking his current medications* to rule out hyperaldosteronism
- B) Assessing for renal artery stenosis (RAS)
- C) Checking a 24-hour urine for glucocorticoids
- D) Checking a 24-hour urine for catecholamines
- E) Screening for obstructive sleep apnea

Answer 2.15.13 The correct answer is “A.” Hypertension is secondary to another cause in about 1% of patients with mild hypertension but in 10% to 45% of those with severe, difficult to control hypertension. Secondary causes of hypertension

include hyperaldosteronism, RAS, pheochromocytoma, Cushing disease, untreated obstructive sleep apnea, primary hyperparathyroidism, medications (e.g., oral contraceptives), and others. “A” is the thing to avoid because when checking the serum potassium level for hyperaldosteronism, the patient must be off all diuretic medications and have an unrestricted salt intake. All of the other choices *can* be a part of a workup for secondary hypertension caused by RAS (“B”), Cushing disease (“C”), and pheochromocytoma (“D”), respectively (see Table 2-8).

Question 2.15.14 You decide to check this patient for RAS. The best choice for a screening test for RAS is:

- A) Doppler ultrasound
- B) Captopril renal scan
- C) Serum renin level
- D) MR or CT angiography
- E) Both A and D

Answer 2.15.14 The correct answer is “E.” Per the ACC/AHA guideline for diagnosing RAS, duplex ultrasonography, CTA in patients with normal renal function, and MRA are the recommended screening tools for diagnosis of RAS (Class I Level of Evidence B). The captopril renal scintigraphy (“B”), selective renal vein renin measurements (“C”), plasma renin activity, and the captopril test (which includes measurement of plasma renin levels at baseline and after captopril administration) are considered Class III for screening tests for establishing the diagnosis of RAS.

HELPFUL TIP:

Consider an evaluation for RAS in a patient who has a “positive” clinical (inadvertent) “captopril challenge.” If you start an ACE inhibitor and see a dramatic decline in renal function in a few days, RAS, especially bilateral RAS, may be the culprit.

Your patient does not have any identifiable cause for secondary hypertension. You add a third agent, and his blood pressure comes under control. Sometimes, you just have to be persistent!

TABLE 2-8 CAUSES OF SECONDARY HYPERTENSION

Drugs, including over-the-counter medications
Sleep apnea
Endocrine:
• Hyperaldosteronism
• Pheochromocytoma
• Thyroid disease
• Cushing syndrome (innate or iatrogenic)
Vascular:
• Renal artery stenosis
• Coarctation of the aorta
• Intrinsic renal disease

HELPFUL TIP:

Adding spironolactone to the regimen of a patient with difficult to control blood pressure can often be helpful even in the presence of another diuretic. It should be a part of any antihypertensive regimen which includes 4 drugs. The 4 drugs should include a diuretic, an ACE or an ARB, a CCB, and spironolactone. Watch for hyperkalemia when spironolactone is used with ACE inhibitors. Eplerenone is an acceptable alternative but is more expensive.

► Objectives: Did you learn to ...

- Evaluate a patient with initial high blood pressure readings?
- Select initial antihypertensive therapy?
- Appropriately tailor the treatment of hypertension, based on patient-specific characteristics?
- Use and interpret 24-hour ambulatory blood pressure monitoring?
- Understand the concept of white coat hypertension?
- Generate a differential diagnosis and an appropriate evaluation of secondary hypertension?

► CASE 2.16

You have a patient who is mildly hypertensive and decide to check baseline labs. On no medications whatsoever, the patient’s potassium is low at 3 mEq/L. You re-check the potassium before getting too excited. It is 2.9 mEq/L.

Question 2.16.1 Of the following, the MOST LIKELY cause of low potassium in this hypertensive patient is:

- A) Hyperaldosteronism
- B) Hypoaldosteronism
- C) Spuriously low potassium because of an elevated glucose
- D) Metabolic acidosis

Answer 2.16.1 The correct answer is “A.” Hyperaldosteronism can cause hypokalemia and hypertension. Aldosterone increases the secretion of potassium, which leads to hypokalemia. “B” is incorrect because hypoaldosteronism, such as that seen with adrenal failure secondary to adrenal destruction, causes hyperkalemia and hypotension. “C” is incorrect because elevated glucose does not result in a spuriously low potassium; if you answered “C,” maybe you were thinking of sodium (the sodium goes down by approximately 1.6 to 2 mEq/L for every 100 mg/dL increase in the glucose). Finally, “D” is incorrect because a metabolic acidosis should cause an elevated potassium rather than a low one.

HELPFUL TIP:

The serum potassium goes up by *approximately* 1 mEq/L for every 0.1 decrease in the pH from 7.4. Thus, the potassium would go from 4 to 6 mEq/L if the pH changes from 7.4 to 7.2.

You suspect that the patient has hyperaldosteronism.

Question 2.16.2 Which of the following is true?

- A) Many patients with hyperaldosteronism have normal serum potassium
- B) In hyperaldosteronism, the plasma aldosterone-to-renin ratio is usually high
- C) All antihypertensives should be stopped before checking a plasma renin level
- D) If a confirmatory 24-hour urine is done, the urine potassium should be low to confirm the diagnosis of hyperaldosteronism
- E) A and B

Answer 2.16.2 The correct answer is “E.” Many patients with hyperaldosteronism will have normal serum potassium levels. In addition, the plasma aldosterone-to-renin level is usually high. “C” is incorrect because, although ACE inhibitors and spironolactone (and perhaps all diuretics) should be stopped before renin and aldosterone levels are drawn, other antihypertensives (e.g., CCBs) will have little effect on plasma renin levels. “D” is incorrect because hyperaldosteronism causes potassium wasting, so the urine potassium should be elevated.

You diagnose this patient with hyperaldosteronism.

Question 2.16.3 The most common cause of hyperaldosteronism is:

- A) Adrenal adenoma
- B) Idiopathic
- C) Pituitary adenoma
- D) Aldosterone-secreting tumor such as small-cell carcinoma
- E) Renal artery stenosis

Answer 2.16.3 The correct answer is “A.” Adrenal adenomas are the most common cause of hyperaldosteronism. The second leading cause is idiopathic (“B”).

Question 2.16.4 Accepted approaches to the treatment of hypertension caused by hyperaldosteronism include all of the following EXCEPT:

- A) Unilateral adrenalectomy in the case of adrenal adenoma
- B) Liberalized sodium intake
- C) Use of a potassium-sparing diuretic
- D) Use of a combination of amiloride and HCTZ

Answer 2.16.4 The correct answer is “B.” Liberalizing sodium intake will actually cause volume expansion, which is counterproductive and can lead to further hypokalemia. Once the patient is hypervolemic, there will be a spontaneous diuresis (the so-called “aldosterone escape”) leading to increased hypokalemia. The exact mechanism of aldosterone escape is not known, but it occurs after a weight gain of approximately 3 kg from fluid retention. If you want to seem smart, just say it is “neurohumeral.” You will probably be right and it makes you sound cool.

► **Objectives: Did you learn to ...**

- Identify laboratory abnormalities that occur in hyperaldosteronism?
- Evaluate a patient suspected of having hyperaldosteronism?
- Initiate treatment of hyperaldosteronism?

QUICK QUIZ: ACE INHIBITORS

Which of the following side effects is/are associated with the use of ACE inhibitors?

- A) Cough
- B) Dependent edema
- C) Hypokalemia
- D) Angioedema
- E) A and D

The correct answer is “E.” Both chronic dry cough and angioedema (more common in African-American patients or those with hereditary angioedema) are side effects of ACE inhibitors. Hyperkalemia is another potential concern. These side effects may not occur immediately. Hence, you should be wary of these symptoms in *any* patient on an ACE inhibitor for *any* period of time.

► CASE 2.17: RHYTHM STRIPS

Question 2.17.1 What is the rhythm on the rhythm strip shown in Figure 2-8?

- A) Second-degree heart block, type I
- B) Second-degree heart block, type II
- C) Third-degree heart block with junctional escape rhythm
- D) Sinus rhythm with non-conducted PACs

Answer 2.17.1 The correct answer is “A.” This is a Wenckebach block, also known as second-degree heart block type I or Mobitz type I AV block. Note the progressive prolongation of the PR interval before a non-conducted P wave on the rhythm strip in Figure 2-9 (arrows indicate P waves).

Question 2.17.2 The proper treatment of an asymptomatic patient with this rhythm is:

- A) Treat any underlying causes identified and observe
- B) Place temporary pacemaker followed by permanent pacemaker
- C) Give atropine followed by permanent pacemaker
- D) Refer for an electrophysiologic study

Answer 2.17.2 The correct answer is “A.” Wenckebach/second-degree heart block type I can be treated with observation as long as any underlying cardiac disease is treated. You should also stop any medications that might be contributing to this rhythm disturbance, such as digoxin, beta-blockers and other AV node blocking agents. Pacemaker is appropriate for a few select patients, usually those with symptoms. Atropine is used in the emergent setting for treatment of bradycardia.

FIGURE 2-8. Rhythm strip for patient in question 2.17.1.

FIGURE 2-9. Arrows show P waves with progressively longer PR interval.

FIGURE 2-10. ECG for patient in question 2.17.3.

Question 2.17.3 What is the proper diagnosis of the ECG shown in Figure 2-10?

- A) Anterior wall myocardial infarction
- B) Posterior wall myocardial infarction
- C) Pericarditis
- D) Hyperkalemia
- E) Inferior wall myocardial infarction (IMI)

Answer 2.17.3 The correct answer is "E." This is an IMI. Note the ST elevations in leads II and III, and aVF with reciprocal ST-segment depression in leads V2 to V5 (see indicator arrows in Fig. 2-11).

A patient presents with a history of lightheadedness when he stands and has the ECG shown in Figure 2-12.

Question 2.17.4 What is the rhythm?

- A) Atrial flutter with 4:1 block
- B) Atrial fibrillation with slow ventricular response
- C) Atrial tachycardia with third-degree heart block
- D) Mobitz type I (Wenckebach)

Answer 2.17.4 The correct answer is "C." This is an atrial tachycardia with a third-degree heart block. The P wave preceding

FIGURE 2-11. Arrows show ST-segment depressions in II, III, and aVF with reciprocal depressions in V2, V3, and V4.

FIGURE 2-12. ECG for patient in question 2.17.4.

each QRS complex is indicated with an *arrow* on the ECG shown in Figure 2-13. Note that there is no consistent relationship between the P waves and the QRS complexes (i.e., the PR interval varies and there is no predictability), giving the diagnosis third-degree heart block.

Question 2.17.5 The appropriate treatment of this patient with atrial tachycardia and third-degree block is:

- A) Pacemaker
- B) Isoproterenol
- C) Lidocaine
- D) Atropine
- E) No treatment needed

Answer 2.17.5 The correct answer is “A.” The treatment of a third-degree heart block is a pacemaker. Atropine will increase the atrial rate, but that is not the problem here. The problem is AV conduction. Isoproterenol will increase the ventricular rate but is arrhythmogenic and may cause hypotension. Lidocaine is not indicated in this patient.

HELPFUL TIP FOR THE RHYTHM CONNOISSEUR:

Atrial tachycardia with block is “classic” for digitalis intoxication. If this patient were on digoxin, you would treat with Digibind.

Question 2.17.6 The drug of choice for the rhythm in Figure 2-14 is:

- A) Atropine
- B) Procainamide
- C) Quinidine
- D) Metoprolol
- E) Lidocaine

Answer 2.17.6 The correct answer is “D.” This is an **accelerated junctional rhythm** that generally occurs only in the setting of **cardiac ischemia**. Note the absence of P waves. Using a Class I antiarrhythmic can extinguish this rhythm, causing asystole (usually considered a bad outcome). The patient also has inferior wall ischemia (see Fig. 2-15, with indicator *arrows* showing depressed ST segments in the inferior leads). Slowing down this rhythm with metoprolol is acceptable, but you should treat the ischemia first. If the rhythm is not causing any problem, observation is good for now.

Question 2.17.7 The rhythm shown in Figure 2-16 is best described as:

- A) Atrial flutter with 2:1 block
- B) 2:1 second-degree heart block, Mobitz type II
- C) Sinus bradycardia
- D) Third-degree heart block

FIGURE 2-13. Arrows show P waves prior to each QRS. Note the unpredictable variation in PR intervals.

FIGURE 2-14. ECG for patient in question 2.17.6.

FIGURE 2-15. Accelerated junctional rhythm; arrows show inferior ST-segment depression.

FIGURE 2-16. Rhythm strip for patient in question 2.17.7.

FIGURE 2-17. Second-degree heart block, Mobitz type II.

FIGURE 2-18. ECG for patient in question 2.17.8.

Answer 2.17.7 The correct answer is "B." This rhythm strip represents second-degree heart block, Mobitz type II. Notice that the PR interval is constant and there are dropped beats (see Fig. 2-17, with indicator arrows showing P waves with no associated QRS complexes). This patient needs a pacemaker.

Question 2.17.8 The electrocardiogram shown in Figure 2-18 is consistent with which of the following?

- A) Pericardial effusion
- B) Pneumothorax
- C) Pulmonary embolus

FIGURE 2-19. ECG for patient in question 2.17.9.

- D) Cardiac contusion
- E) None of the above

Answer 2.17.8 The correct answer is "A." This is an example of electrical alternans. Note the low QRS voltages that alternate in height from beat to beat. This type of pattern is seen with pericardial effusion. It is a late finding and one should be very concerned about tamponade.

Question 2.17.9 The ECG in Figure 2-19 is consistent with which of the following?

- A) Anterior myocardial infarction
- B) Anterolateral myocardial infarction
- C) Pericarditis
- D) Early repolarization
- E) Total heart infarction

Answer 2.17.9 The correct answer is "C." This ECG is consistent with pericarditis. This ECG demonstrates several findings that indicate pericarditis, including sinus tachycardia, diffuse ST elevations, and PR depression, which are pathognomonic (see Fig. 2-20).

► **Objectives: Did you learn to ...**

- Identify several types of cardiac arrhythmias, including heart block and junctional rhythm?
- Diagnose inferior MI by ECG?
- Describe ECG features of pericardial effusion and pericarditis?

► **CASE 2.18**

A 24-year-old female presents to the ED with a history of tachycardia and the rhythm strip shown in Figure 2-21. Her blood pressure is 115/70 mm Hg with an oxygen saturation of 98% on room air. There are no associated symptoms of chest pain, dyspnea, etc.

Question 2.18.1 The appropriate treatment of this patient is:

- A) Adenosine 6 mg IV followed by 12 mg IV
- B) Diltiazem 5 mg/kg IV
- C) Verapamil 25 mg IV
- D) Digoxin 0.5 mg IV
- E) Defibrillation

Answer 2.18.1 The correct answer is "A." This rhythm is paroxysmal supraventricular tachycardia (PSVT). There are several treatment options for PSVT, which include adenosine, diltiazem, and verapamil. However, "B" and "D" are incorrect because the dose for diltiazem is 0.25 mg/kg IV, not 5 mg/kg, and the dose for verapamil is 2.5 to 5 mg IV, not 25 mg IV. While **cardioversion** is also an option in a hemodynamically stable patient, medication should be tried first. **Defibrillation** is never recommended for a perfusing rhythm.

You treat the patient with adenosine but there is no response. Thus, you choose to try a CCB. Unfortunately,

FIGURE 2-20. ECG consistent with pericarditis.

FIGURE 2-21. Rhythm strip for patient in question 2.18.1.

the patient rapidly deteriorates with the CCB, and her heart rate actually increases, so you successfully cardiovert the patient. The ECG done after cardioversion is shown in Figure 2-22.

Question 2.18.2 This ECG represents:

- A) Normal ECG
- B) Wolf-Parkinson-White (WPW) syndrome
- C) Right bundle branch block
- D) Right-axis deviation
- E) Left ventricular hypertrophy

Answer 2.18.2 The correct answer is “B.” This is an ECG demonstrating WPW pattern. When combined with documented tachyarrhythmia, it is referred to as WPW syndrome. Note the short PR interval as well as the delta wave (Fig. 2-23).

Let’s say this patient comes back to the ED with atrial fibrillation in the upcoming week. This time you suspect WPW and want to choose a rate-controlling medication.

Question 2.18.3 Which is the BEST medication choice for this patient in light of her diagnosis of WPW?

- A) Procainamide
- B) Sotalol
- C) Diltiazem
- D) Verapamil
- E) Metoprolol

Answer 2.18.3 The correct answer choice is “A.” Patients with WPW deteriorate with beta-blockers and CCBs (“B”–“E”). The drug of choice is procainamide in patients with WPW who present with PSVT, including atrial fibrillation/flutter. The other alternative is ibutilide. Why are AV nodal blocking agents bad? The AV node is protective since it helps block most re-entrant conductions (for re-entrant arrhythmias that rely on the AV node). If you block the AV node with beta-blockers or CCBs, the re-entrant loop is allowed to go “wild” (just like you’ve probably seen that reality show, “Rhythms Gone Wild”). The clues to look for to help identify patients with WPW are a **young** patient with previous episodes of **palpitations**, rapid heart rate, or **syncope**.

FIGURE 2-22. ECG for patient in question 2.18.2.

FIGURE 2-23. ECG consistent with Wolf-Parkinson-White syndrome.

FIGURE 2-24. ECG for patient in question 2.18.4.

Question 2.18.4 The ECG shown in Figure 2-24 represents which of the following?

- A) LBBB
- B) RBBB
- C) Left anterior fascicular block (LAFB)
- D) Left posterior fascicular block
- E) None of the above

Answer 2.18.4 The correct answer is “C.” For those of us who are visually challenged, any patient with a net negative force in lead II will have left axis deviation and likely left anterior fascicular block (LAFB) (provided proper lead placement). Also, look for net negative deflection in leads III and aVF. For those who like the numbers, LAFB is present when the QRS axis is -45 to -90 degrees, there is an rS pattern (with small r waves) in leads II, III, and aVF and a qR pattern (with small q waves) in I and aVL. Because the QRS is narrow, neither LBBB (“A”) nor RBBB (“B”) can be correct. Left posterior block (“D”) is quite uncommon due to the size of the posterior fascicle.

Question 2.18.5 The ECG shown in Figure 2-25 represents which of the following?

- A) LBBB
- B) RBBB
- C) LAFB
- D) Left posterior fascicular block
- E) None of the above

Answer 2.18.5 The correct answer is “A.” This ECG represents an LBBB. Criteria include QRS width ≥ 0.12 ms, upright (monophasic) QRS in leads I and V6, and a mostly negative QRS in V1.

HELPFUL TIP:

We don’t suggest that you rely on this but ... The R–R prime is on the **right** side of the ECG in an RBBB (V1, V2, V3). The R–R prime is on the **left** side of the ECG in an LBBB (lead I).

Question 2.18.6 The ECG shown in Figure 2-26 represents which of the following?

- A) First-degree block
- B) RBBB
- C) LAFB
- D) All of the above
- E) None of the above

Answer 2.18.6 The correct answer is “D.” This ECG represents a first-degree AV block, an RBBB, and an LAFB. The RBBB is defined by a QRS width of ≥ 0.12 ms (>3 small blocks) and an rsR (“rabbit ears”) in chest leads V1–V3. This patient also has an LAFB (see question 2.18.4 for criteria).

FIGURE 2-25. ECG for patient in question 2.18.5.

FIGURE 2-26. ECG for patient in question 2.18.6.

FIGURE 2-27. ECG for patient in question 2.19.1.

► **Objectives: Did you learn to ...**

- Identify PSVT by ECG and prescribe initial treatment?
- Describe ECG findings of WPW?
- Differentiate between different types of heart block based on ECG findings?

► **CASE 2.19**

A 75-year-old patient with chronic kidney disease and diabetes presents to your ED for chest tightness, fatigue, and palpitations, and has the ECG shown in Figure 2-27.

Question 2.19.1 What is the most likely electrolyte abnormality in this patient?

- A) Hypokalemia
- B) Hyperkalemia
- C) Hyponatremia
- D) Hypermagnesemia
- E) Hypercalcemia

Answer 2.19.1 The correct answer is “B,” hyperkalemia. Note the peaked T-waves across the precordium. Note also that the patient has early repolarization. “A” is incorrect, and many of the opposite ECG findings occur with hypokalemia. ECG findings of hypokalemia include decreased amplitude of T-waves, progressing to T-wave inversions associated with ST-segment

depression, followed by increased PR interval and increased P-wave amplitude. The U-wave is a late and inconsistent finding of hypokalemia.

Question 2.19.2 All of the following are potential causes of this patient’s hyperkalemia EXCEPT:

- A) Metabolic acidosis
- B) ACE inhibitors
- C) ARBs
- D) Renal failure
- E) Furosemide

Answer 2.19.2 The correct answer is “E.” Furosemide will cause hypokalemia rather than hyperkalemia. All the other answer choices are potential causes of hyperkalemia. Other causes of hyperkalemia include a potassium load from muscle breakdown (e.g., rhabdomyolysis, burns, transfusion of old blood), tumor lysis syndrome, and other exogenous sources of potassium such as penicillin, potassium supplements, “lite” salt, and water softeners (those that use potassium). Consider also Addison disease and hypoaldosteronism. Digoxin toxicity is also a possibility.

Question 2.19.3 What is the rhythm shown in Figure 2-28?

- A) Atrial fibrillation
- B) Normal sinus rhythm with multiple PACs
- C) Third-degree heart block with rapid rate
- D) Multifocal atrial tachycardia (MAT)

FIGURE 2-28. ECG for patient in question 2.19.3.

FIGURE 2-29. Arrows show P waves of varying morphology, consistent with MAT.

Answer 2.19.3 The correct answer is “D.” This is a MAT. Note the multiple morphologies of the P waves indicated by *arrows* in Figure 2-29 as well as the irregularity of the rhythm. Here are helpful tips in diagnosing and treating MAT: three or more different P-wave morphologies with varying PR intervals. Causes include theophylline, pulmonary disease, and abnormal electrolytes (K^+ or Mg). Digoxin may worsen MAT! Rarely, AV nodal ablation with permanent pacing can be considered in refractory cases.

Question 2.19.4 All of the following are treatments of MAT EXCEPT:

- A) Nondihydropyridine CCB (verapamil, diltiazem)
- B) Beta-blocker
- C) Magnesium
- D) Improving pulmonary function and reducing hypoxia
- E) Adenosine

Answer 2.19.4 The correct answer is “E.” All of the others are indicated in the treatment of MAT. Adenosine may slow down the rhythm temporarily but is not considered a treatment of this rhythm.

► **Objectives: Did you learn to ...**

- Recognize ECG findings associated with hyperkalemia and hypokalemia?
- Describe ECG findings and treatment options for MAT?

► CASE 2.20

A 28-year-old woman with no significant past medical history presents to clinic with complaints of progressive shortness of breath; she becomes dyspneic with less activity compared to 1 year ago. If she exerts herself beyond a brisk walk, she becomes lightheaded, pre-syncope, and feels tightness in her chest. She also notes generalized fatigue. Your examination discloses a heart rate of 105 bpm and normal blood pressure.

Resting transcutaneous oximetry is 92% on room air. BMI is 24 kg/m^2 . She has JVD but clear lungs. A grade 2/6 mid-systolic murmur is heard over the left upper sternal border. Electrocardiogram is shown (Fig. 2-30).

Question 2.20.1 What is the most likely diagnosis?

- A) CAD
- B) Pulmonary hypertension
- C) Asthma
- D) Congenital aortic stenosis
- E) Mitral valve prolapse

Answer 2.20.1 The correct answer is “B.” The physical examination is consistent with right ventricular pressure overload. This is supported by the electrocardiogram demonstrating right atrial enlargement, right-axis deviation, and RVH. CAD (“A”) is almost unheard of in a woman younger than 30 years without any risk factors. Asthma (“C”) may cause her symptom complex but is not supported by her examination. Aortic stenosis (“D”) causes neither resting hypoxemia nor RVH. Because they have a fixed cardiac output (limited by lung vascular pressures), patients with pulmonary hypertension often get pre-syncope with exertion.

Note: Findings that suggest RVH on the ECG: right-axis deviation, right atrial abnormality (P -wave >2.5 boxes tall in lead II), RVH (tall R in V1), and strain pattern in leads II and III *as indicated by arrows* in Figure 2-31. Often patients with pulmonary hypertension will have an intraventricular conduction delay with R-R' in V1 (not shown on this electrocardiogram, Fig. 2-31).

Question 2.20.2 The following tests may be helpful in elucidating the cause of pulmonary hypertension EXCEPT:

- A) Chest x-ray and pulmonary function studies
- B) Chest CT scan
- C) ANA, HIV antibody/antigen testing and liver function studies
- D) Nasopharyngoscopy
- E) Polysomnogram

FIGURE 2-30. ECG for patient in question 2.20.1.

FIGURE 2-31. ECG consistent with RVH. Note large R wave in V1 and right-axis deviation.

Answer 2.20.2 The correct answer is “D.” An important part of the workup for pulmonary hypertension is defining the etiology and potentially reversible causes. There is no cookbook approach, and diagnostic workup should be tailored by the history and physical examination. Chest radiography and PFTs (“A”) can identify chronic lung disease causing (or contributing to) pulmonary hypertension. A CT scan (“B”) is done to exclude chronic thromboembolic pulmonary disease and to evaluate for fibrosis, sarcoidosis, etc. Connective tissue disease, HIV, and cirrhosis (“C”) are known to cause pulmonary hypertension. Sleep apnea (“E”) is an important, treatable cause of PHTN. Nasopharyngoscopy has no role in this workup.

An echocardiogram confirms findings suggestive of severe pulmonary hypertension and changes consistent with right ventricular pressure overload (a right heart catheterization is required for diagnosis). No intracardiac shunt is identified by echocardiogram. The remainder of her diagnostic workup fails to identify a secondary cause of pulmonary hypertension. A right heart catheterization confirms severe pulmonary hypertension but fails to identify a shunt. A vasodilator challenge (with adenosine) is performed and no change in pulmonary pressure is elicited. She is given a diagnosis of idiopathic pulmonary arterial hypertension.

The treatment of pulmonary hypertension is, in general, very specialized and a cardiologist should be involved. Exceptions include pulmonary hypertension from chronic hypoxia (smoking, sleep apnea) that are amenable to primary care management. Chronic PE can also be managed by the primary care practitioner, although the patient should still follow with a cardiologist due to the potential for right heart failure.

HELPFUL TIP:

Additional therapy for pulmonary hypertension may include prostacyclin and phosphodiesterase inhibitors (e.g., sildenafil, tadalafil, vardenafil). Some patients require anticoagulation. Management should be directed by a pulmonary hypertension specialist.

► Objectives: Did you learn to ...

- Diagnose and evaluate for pulmonary hypertension?
- Identify secondary causes of pulmonary hypertension?
- Explain the importance of co-management with a cardiology team for the treatment of pulmonary hypertension?

► CASE 2.21

A 54-year-old male presents to your clinic complaining of dyspnea and fevers. His temperature in the office is 38.5°C and heart rate is 113 bpm with pulse oximetry of 93%. On physical examination, you notice that he had nodules on his fingertips and notice a slight reddish discoloration under his fingernails.

On further questioning, he tells you that he recently moved here from a major city and had used IV drugs in the very distant past, by which he means as recently as last month.

Question 2.21.1 Your next step in management is:

- A) Order a chest x-ray and start empiric levofloxacin
- B) Order a chest x-ray and start empiric ceftriaxone and azithromycin
- C) Order a chest x-ray, echocardiogram, draw blood cultures
- D) Order a chest x-ray and start empiric piperacillin and vancomycin
- E) Order a chest x-ray and do nothing, it is probably viral

Answer 2.21.1 The correct answer is “C.” Although the chest x-ray is overkill for a case of endocarditis, it may identify other causes of fever and help evaluate for heart failure. The patient is presenting with IV drug use history, Osler nodes, and Janeway lesions (nail-bed hemorrhages), as well as fever. These easily meet three minor Duke criteria (see Table 2-9), qualifying for a “possible diagnosis of endocarditis.” Now what you need is one major criterion to definitively diagnose endocarditis. A positive echocardiogram or blood culture would qualify. Once the blood cultures are drawn, if your suspicion is high, you may start empiric antibiotics for endocarditis.

Question 2.21.2 Which valve(s) are most commonly affected by endocarditis?

- A) Aortic valve
- B) Mitral valve
- C) Pulmonic valve
- D) Tricuspid valve
- E) A and B

TABLE 2-9 REVISED DUKE CRITERIA FOR ENDOCARDITIS (DEFINITIVE DIAGNOSIS: TWO MAJOR CRITERIA OR ONE MAJOR + THREE MINOR CRITERIA. POSSIBLE DIAGNOSIS: ONE MAJOR + ONE MINOR CRITERION OR THREE MINOR CRITERIA)

Major Criteria	Minor Criteria
<ul style="list-style-type: none"> • Two positive blood cultures for organisms typical of endocarditis • Three positive blood cultures for organisms consistent with endocarditis • Serologic evidence of <i>Coxiella burnetii</i> • Echocardiographic evidence of endocardial involvement: Oscillating intracardiac mass on a heart valve, on supporting structures, in the path of regurgitant jets, or on implanted material without another anatomic explanation; cardiac abscess; new dehiscence of prosthetic valve; or new valvular regurgitation 	<ul style="list-style-type: none"> • Predisposing heart disorder • IV drug abuse • Fever $\geq 38^{\circ}\text{C}$ • Vascular phenomena: arterial embolism, septic pulmonary embolism, mycotic aneurysm, intracranial hemorrhage, conjunctival petechiae, or Janeway lesions • Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, or rheumatoid factor • Microbiologic evidence of infection consistent with but not meeting major criteria • Serologic evidence of infection with organisms consistent with endocarditis

Answer 2.21.2 The correct answer is “E.” The aortic and mitral valves are most commonly affected. There is no demonic valve, we hope, but there is the tricuspid, of course.

Question 2.21.3 Which of the following organisms is most common in acute endocarditis?

- A) *Staphylococcus aureus* and group B streptococci
- B) Alpha-hemolytic streptococci or enterococci
- C) Enterovirus
- D) Fungi
- E) *Elmo muppetel* (can you tell we are getting tired ... the jokes are getting weaker)

Answer 2.21.3 The correct answer is “A.” Staph and group B strep are generally responsible for acute endocarditis while alpha-hemolytic streptococci and enterococci are more common with subacute endocarditis. Fungi may be present in IV drug abusers. As to *E. muppetel*, it is a new species recently described by us. We grovered it in Big Bird cultures.

► **Objectives: Did you learn to ...**

- Initiate evaluation and management of bacterial endocarditis?

QUICK QUIZ: YET ANOTHER HEART FAILURE QUESTION (YOU THOUGHT WE WERE DONE...)

Cardiac resynchronization for heart failure is indicated in which of the following patients?

- A) A patient who has an ejection fraction of 30% and is in atrial fibrillation that is rate-controlled
- B) A patient who has an ejection fraction of 30% and is in atrial fibrillation that is *not* rate-controlled (say a rate of 110–115 bpm)
- C) A patient who has an ejection fraction of 30% and in normal sinus rhythm who has an LBBB
- D) A patient with an underlying arrhythmia such as PSVT who is symptomatic
- E) A or B

The correct answer is “C.” Bet we got you on this one, huh? The idea behind cardiac resynchronization is to put blood into the ventricle at the optimum time for function. This requires the atrium to be working properly. Thus, “A” and “B” are wrong. The concept is to pace the atrium and then also pace the ventricle so that the ventricle depolarizes at the optimum moment for blood ejection after the blood is sent to the LV by the atrium. This optimal blood ejection is disordered by an LBBB where depolarization of the ventricle is delayed causing a “dyssynchrony” (as it were) between the timing of atrial functioning and the timing of the ventricular depolarization. Cardiac resynchronization is “only” for patients with heart failure who are in normal sinus rhythm. So, the basic criteria for cardiac resynchronization include a QRS of >150 ms, with an LBBB, an LV ejection fraction of 30% or less, and sinus rhythm who have class III or

class IV heart failure (*J Am Coll Cardiol.* 2013;61(3):e6–75). It seems to improve the overall absolute survival by about 2%; it also reduces readmissions (*Ann Intern Med.* 2014;160:603).

QUICK QUIZ: WHAT ARE YOU ... A HEART FAILURE SPECIALIST?

Which of the following has been shown to improve mortality in patients with HFrEF?

- A) Valsartan + Sacubitril (Entresto)
- B) Ivabradine (Corlanor)
- C) Azumumumab (Coregulator)
- D) A and B
- E) B and C

The correct answer is “A.” First you need to know what these things are. Entresto combines an ARB plus a neprilysin inhibitor. Inhibiting neprilysin increases vasodilatation and sodium loss. It has been shown to be effective at reducing mortality from HFrEF. This can *replace* an ACE inhibitor or ARB. *Make sure the patient can tolerate an ARB or ACE before* starting Entresto. Use it in patients with NY class II–IV CHF, with an EF < 40%, no history of angioedema, and an adequate blood pressure. Also, it cannot be given with an ACE inhibitor because of the risk of angioedema. **Of course, you already know that an ACE inhibitor and an ARB should never be used together ... right?**

Corlanor reduces heart rate without lowering BP and is *only* indicated in heart failure patients who do not reach their target heart rate with a beta-blocker. Corlanor would be added to an ACE inhibitor or ARB, a beta-blocker, and aldosterone antagonist. It *does not* replace the beta-blocker and *does not* improve mortality. It supplements the beta-blocker in patients with heart rate > 70 bpm after maximizing other medications (including a beta-blocker if tolerated). Corlanor can also be used in patients who do not tolerate a beta-blocker. We made up “C,” although it wouldn’t be a surprise to us if we see this drug name at some point in the future.

► **CASE 2.22**

A new patient presents for his annual examination and has some questions about cardiovascular disease risk. He also wants to chat about his favorite sports team (Iowa Hawkeyes, we hope), but you gently steer him back to the matter at hand.

Question 2.22.1 The following are all considered cardiac risk factors when calculating cardiac risk and need for statins per the ACC/AHA calculator (<http://www.cvriskcalculator.com>) EXCEPT:

- A) Age
- B) Relative with early heart disease
- C) Smoking
- D) Hypertension
- E) Gender

TABLE 2-10 RISK FACTORS FOR CORONARY ARTERY DISEASE

- First-degree male relative with CAD or sudden death at age < 55 or first-degree female relative with CAD or sudden death at age < 65
- Smoking
- HDL < 40 mg/dL (HDL > 60 mg/dL is considered protective)
- Diabetes
- Hypertension (>140/90) or on antihypertensives
- Age: males >45, females >55
- Elevated LDL

Answer 2.22.1 The correct answer is “B.” The ACC/AHA calculator includes the following risk factors for CAD: age, gender, “race,” total cholesterol, HDL cholesterol, systolic and diastolic BP, diabetes, smoking and whether or not one is being treated for hypertension. Unlike many Caribbean resort destinations, the calculator is not all-inclusive. Many known risk factors for heart disease (e.g., family history, obesity) are not taken into account. The risk calculator is a tool; you must continue to apply clinical judgment. Also, the calculator, as well as the entire guideline, is not meant to be used to manage all forms of dyslipidemias. Remember from earlier in this chapter that peripheral vascular disease is considered a CAD equivalent.

See Table 2-10 for more details on risk factors.

This 55-year-old gentleman says, “All my friends take a medicine for cholesterol. Shouldn’t I take one, too?” You are worried that he is susceptible to peer pressure, but you are also thinking about protecting him from atherosclerotic cardiovascular disease (ASCVD).

Question 2.22.2 According to the 2018 ACC/AHA Blood Cholesterol Guideline, all of the following *automatically* qualify as patients who would benefit from statin therapy EXCEPT:

- A patient with known cardiovascular disease
- A 40-year-old patient with an LDL of 200 mg/dL
- A 55-year-old diabetic patient with an LDL of 130 mg/dL
- A 55-year-old nondiabetic patient without known cardiovascular disease whose 10-year ASCVD risk is calculated as 10%
- A 35-year-old smoker with hypertension

Answer 2.22.2 The correct answer is “E.” The 35-year-old patient *might* be a candidate for a statin (HMG-CoA reductase inhibitor) but is not an *automatic* candidate based on the information given. All other options describe patients who would benefit from statin therapy according to the 2018 ACC/AHA guideline. The 2018 ACC/AHA guideline relies on a risk calculator for primary prevention. See Table 2-11 for a summary of the 2018 cholesterol guidelines. It is important to note that while the ACC/AHA guideline recommends moderate-to-high-intensity statin therapy starting at a 10-year ASCVD risk score of 7.5%, the USPSTF recommends **low-to-moderate** dose statin therapy at an **ASCVD risk score of 10%**. We cannot know for sure what answer the ABFM would use for the test, but they usually side with the USPSTF.

TABLE 2-11 2018 AMERICAN HEART ASSOCIATION (AHA)/AMERICAN COLLEGE OF CARDIOLOGY (ACC) LIPID GUIDELINES

Qualify for a high-dose statin	1. LDL >190 mg/dL or 2. History of CAD (or equivalent) or 3. DM and age 40–79
Qualify for a moderate-to-high dose statin (use risk calculator) ^a	Primary prevention if 10-year risk is >7.5% and the patient has an LDL of 70–189 mg/dL and age 40–75
Qualify for a low-dose statin	Those who qualify for a statin but don't tolerate high- or moderate-dose statin

Goals of Therapy

1. The primary goal is to reach the appropriate dose of statin
2. Reduction of LDL by 50% from baseline
3. There are no fixed LDL goals (such as past goals of LDL < 100 mg/dL)

Drug Doses

1. High-dose statin = atorvastatin 40–80 mg or rosuvastatin 20–40 mg
2. Low-to-moderate dose statin = atorvastatin 10–20 mg QD, pravastatin 40–80 mg BID, and rosuvastatin 5–10 mg QD, among others

^aFind a cardiovascular risk calculator at <http://tools.cardiosource.org/ASCVD-Risk-Estimator/>.

The patient then asks you about something he read about “crap.” A light bulb goes off and you realize he wants to know about C-reactive protein (CRP).

Question 2.22.3 Which of the following best represents the role of CRP in cardiac disease in 2015?

- CRP should be measured in all patients in whom cardiac disease is suspected
- CRP should be measured only in patients with intermediate cardiac risk factors (e.g., those with a 10-year risk of CAD of 10–20%)
- CRP should be measured in patients with known heart disease in order to monitor inflammation and risk
- CRP should be measured in low-risk (<10% risk of CAD in next 10 years) patients who have no known cardiac disease. An elevated CRP suggests that these patients should be treated with a lipid-lowering therapy
- CRP has not been shown to be useful and does not contribute significantly to cardiac risk stratification

Answer 2.22.3 The correct answer is “E.” Although, high-sensitivity CRP (hsCRP) was initially thought to be a possible biomarker for cardiac risk assessment, it has been shown to be of marginal benefit. The use of hsCRP led to minimal reclassification of patients (a maximum of 11% of intermediate patients were reclassified in one study). The Class IIa recommendation to use hsCRP was published by the AHA in 2003, prior to further studies that have questioned its usefulness.

**HELPFUL TIP:**

We do not use hsCRP. However, if it were useful, it would be in the intermediate-risk patients.

Question 2.22.4 You may have noticed (we hope) that the risk calculator includes lipids as a risk factor. What does the USPSTF recommend in terms of screening for lipid disorders?

- A) Screen all adults annually starting at age 25
- B) Screen men age 35 years and older
- C) Screen women age 45 years and older
- D) Universal screening of all patients age 40 to 75

Answer 2.22.4 The correct answer is “D.” USPSTF updated its lipid testing recommendations in 2016. Here is a summary:

Screen patients 40 to 75 years of age without CAD. Treatment is suggested for those 40 to 75 years of age with elevated lipids **and** one other risk factor for CAD (risk factors for this purpose include (LDL-C > 130 mg/dL or HDL-C < 40 mg/dL), diabetes, hypertension, and smoking) **and** >10% ten-year risk of having a cardiac event based on the ACA calculator.

Use low-to-moderate dose statins. For those with a risk of 7.5% to 10%, discuss pros and cons with the patient—which of course you do with all patients anyway (*JAMA*. 2016;316(19):1997–2007). **Note that the benefit of lipid treatment outweighs the risk of diabetes** (which can be seen with statins).

HELPFUL TIP:

Fasting lipids are out. Well, not entirely. But you don't have to have patients return for fasting lipids, that's for sure. Non-fasting is fine for making decisions about risk and starting therapy (*Eur Heart J*. 2016;37:1944–1953); fasting lipids serve as complementary data.

You obtain laboratory tests. The patient has normal electrolytes and the following cholesterol panel: total cholesterol 175 mg/dL, LDL 110 mg/dL, HDL 35 mg/dL, triglycerides 150 mg/dL. He is a 55-year-old African-American male, nonsmoker, and nondiabetic who takes no medications. His systolic blood pressure is 132/85 mm Hg. You plug all his data into the ASCVD risk calculator and generate a 10-year ASCVD risk of 7.5%.

Question 2.22.5 Given the ASCVD risk you calculated, and being consistent with the 2018 ACC/AHA guideline, you recommend:

- A) No changes. Keep calm and carry on
- B) A treadmill stress test
- C) A high fiber diet
- D) Low-intensity statin therapy (e.g., simvastatin 10 mg daily)
- E) Moderate-intensity statin therapy (e.g., atorvastatin 10–20 mg daily)

Answer 2.22.5 The correct answer is “E.” Did you think this patient was a candidate for moderate statin therapy prior to this guideline? If not, you are not alone. The 2018 ACC/AHA guideline has changed the way we determine risk, expanding the use of statins. Patients whose 10-year ASCVD risk is 7.5% or greater

should be on moderate-to-high-intensity statin therapy. As noted above, we have *dueling guidelines*. Of course, you should discuss the pros and cons with every patient.

Question 2.22.6 Your astute patient appears to be goal-oriented and asks you what his target LDL should be. You reply:

- A) “Targets are so 2012. The goal is to get you on a moderate-to-high-intensity statin. There is no specific LDL goal number”
- B) “Your target LDL is <100 mg/dL”
- C) “Your target LDL is about 70 mg/dL”
- D) “Your target LDL is simply as low as we can get without causing rhabdomyolysis Well, maybe just a little rhabdo will be OK”

Answer 2.22.6 The correct answer is “A.” The 2018 ACC/AHA guideline does not recommend treating to *specific* LDL targets. Instead, appropriate statin therapy should be selected based on risk category as previously indicated. Your goal is to get the patient to a maximal dose of statin and not a specific LDL. That said, the LDL should be reduced by 50% even if that is a starting point of 400 mg/dL and the patient ends up at 200 mg/dL.

HELPFUL TIP:

There is no evidence that “titrating up” the dose of a statin is necessary or helpful in preventing side effects. Just start the final appropriate dose of a statin on day 1 of treatment.

You advise your patient to start atorvastatin 20 mg daily. You check baseline transaminases, which are normal. When your patient returns 3 months later and sees your partner (because you took a “vacation” to study for the board examination), she checks his lipids and transaminases out of habit. If only you had been there! You know that the FDA no longer recommends periodic liver enzyme testing while on a statin. Statin-related hepatotoxicity is an idiosyncratic reaction that is extremely rare and completely unpredictable, so there is no point in routinely checking transaminases. Well, your partner didn't get the memo, and you return to find your patient's ALT and AST have both doubled while on atorvastatin and are now almost twice the upper limit of normal for your lab.

Question 2.22.7 When you find transaminases are twice the upper limit of normal while on a statin, the proper response is to:

- A) Stop the statin because of the elevated liver enzymes
- B) Start a different statin since this is not a “class effect”
- C) Continue the statin and consider other causes for the elevated liver enzymes
- D) Add cholestyramine to help ease the burden on the liver
- E) Refer for liver biopsy to rule out other causes of elevated liver enzymes

Answer 2.22.7 The correct answer is “C.” Statins can be continued as long as the elevation of liver enzymes is **less than three times the upper limit of normal**. Never assume that this is a drug effect if there is a reason to believe that the patient could have another disease, such as hepatitis C.

You are compelled to perform the requisite history and physical examination to assess for other causes of liver disease. In the course of your investigations, other labs and imaging may be in order. However, liver biopsy (“E”) would be taking your fiduciary duty to the extreme. “A” is incorrect since the levels are only two times the upper limit of normal. “B” is incorrect for two reasons. First, there is no need to act to change the drug at this point. Second, *elevated liver enzymes are a class effect*. “D” is incorrect because you do not need to add another drug at this time, and cholestyramine will do nothing to “ease the burden on the liver,” whatever that means.

After a thorough history, examination, appropriate lab and imaging tests, you determine that the liver enzyme elevation was due to fatty infiltration. A month later the enzymes have come down to the upper limits of normal. When you see your patient back, he complains of pain and tenderness in his legs, shoulders and back. He also reports generalized fatigue and weakness.

Question 2.22.8 What is the most appropriate next step in the evaluation and management of this complaint?

- A) Stop his atorvastatin and replace it with rosuvastatin
- B) Double the dose of atorvastatin
- C) Check liver enzymes
- D) Check creatine phosphokinase (CPK) level
- E) Start coenzyme-Q10 (ubiquinone)

Answer 2.22.8 The correct answer is “D.” This patient is presenting with symptoms that may be attributable to statin-induced myopathy. Statins have been associated with myalgia and rhabdomyolysis. Prior to making any decisions about therapy, the next step would be to confirm your suspicions by checking the CPK level. If this patient has statin-induced muscle symptoms, he is unlikely to improve by switching to rosuvastatin (“A”); hence, increasing the statin dose (“B”) is the wrong thing to do. While it may be reasonable to check liver enzymes (“C”) due to his complaint of fatigue, myopathy is more likely, given his constellation of symptoms. Of course, in your real medical practice, you could order liver enzymes and CPK, but an examination is not real life! Finally, “E” is incorrect. Coenzyme Q10 has not been shown to prevent or treat statin-related myopathy (*Mayo Clin Proc.* 2015;90:24). But vitamin D may be useful in patients who are deficient.

You check a CPK level, and it is ... normal. Darn. You thought you had this mystery wrapped up.

Question 2.22.9 From this normal CPK, you can conclude that:

- A) He does not have statin-induced myopathy since the CPK is within normal limits
- B) His fatigue and aches are a manifestation of depression and sleep disturbance
- C) You can safely increase the dose of his statin

- D) He still may have statin-induced myopathy despite a normal CPK
- E) Your lab has a serious quality control issue

Answer 2.22.9 The correct answer is “D.” He still may have statin-induced myopathy despite a normal CPK, so “A” is incorrect. There are several crossover trials that demonstrate myopathy in patients with normal muscle enzymes. The mechanism is thought to be a mitochondrial dysfunction. “B” is incorrect, and the reverse may actually be true (myopathy causing poor sleep and anhedonia). “C” is incorrect because he may indeed have a myopathy, and a trial off one or both drugs is warranted. Remember that gemfibrozil (and less so fenofibrate), which you might prescribe for hypertriglyceridemia, interact with statins to increase the risk of statin-induced myopathy/rhabdomyolysis. Remember also that there is no evidence that treating with gemfibrozil or fenofibrate improves cardiovascular outcomes.

You stop his atorvastatin. A few weeks later, he returns and feels great! You consider starting a different agent to treat his lipids.

Question 2.22.10 Which of the following is classified as a bile acid sequestrant?

- A) Ezetimibe
- B) Colestipol
- C) Colesevelam
- D) B and C
- E) All of the above

Answer 2.22.10 The correct answer is “D.” Ezetimibe (Zetia) is not a bile acid sequestrant but rather reduces cholesterol absorption by blocking at the brush border of the small intestine. This is a mechanism that is different from any of the other lipid-lowering agents. It is relatively safe but expensive and less potent than the statins. You could also try pravastatin and fluvastatin, which are less likely to cause myopathy.

HELPFUL RANT: “DO NOTHING THAT IS OF NO USE” (MIYAMOTO MUSASHI)

Don’t feel obligated to “just do something.” There is no data suggesting that any anti-lipid drugs other than the statins, ezetimibe, and PCSK9 inhibitors (see below) reduce cardiovascular outcomes. Some, such as niacin, may actually worsen outcomes.

HELPFUL TIP:

Evidence for ezetimibe is weak, including a much-touted 2015 study (*N Engl J Med.* 2015;372:2387). First, the study is flawed and looks at a very narrow group of patients (those hospitalized with known CAD, therefore secondary prevention). It says nothing about primary prevention. Second, many of the patients were not even on a statin, the standard of care. Finally, you have to treat 50 patients for 7 years to prevent one cardiovascular event—not a glowing endorsement, especially since they weren’t on a statin.

You find yourself staring out the examination room window, ruminating on cholesterol medications.

Question 2.22.11 Side effects of ezetimibe include which of the following?

- A) Diarrhea
- B) Arthralgia
- C) Angioedema
- D) Liver enzyme elevation
- E) All of the above

Answer 2.22.11 The correct answer is “E.” “C” deserves special mention. As with ACE inhibitors, angioedema has been reported with the use of ezetimibe during post-marketing research. The rate of occurrence is not known. However, it can be life-threatening although no deaths have been reported to date. All of the other side effects are known to occur at a rate greater than with placebo.

Your patient is now OK taking maximal dose of a statin, but he has questions about a “cholesterol shot” his friend is taking. Apparently, his friend’s LDL is 300—kind of high. You assume that he is talking about a PCSK9 (pro-protein convertase subtilisin kexin type 9) inhibitor, which prevents the binding and the degrading of LDL receptors (thus, there are more LDL receptors to uptake LDL from the blood).

Question 2.22.12 The indications for the use of a PCSK9 inhibitor (Praluent® [alirocumab] and Repatha® [evolocumab]) in a patient on statins includes which of the following?

- A) Ongoing angina regardless of the percent decrease of LDL on a maximal dose of a statin
- B) Less than a 50% reduction from baseline of LDL after maximal dose statin + ezetimibe
- C) An absolute LDL of >190 mg/dL after maximal dose statin regardless of the starting LDL
- D) A cardiovascular event while on a maximal dose statin plus a bile acid sequestrant

Answer: 2.22.12 The correct answer is “B.” Indications for the use of a PCSK9 inhibitor include the following: (1) Failure to reduce the baseline LDL by 50% on a maximal dose of a statin and ezetimibe, or (2) a patient who has a cardiovascular event while on a statin plus ezetimibe and an LDL of ≥ 50 mg/dL (not a bile acid sequestrant as in “D”), or a very high LDL secondary to familial hypercholesterolemia. These drugs are expensive (>\$10,000/year), and prevent one cardiovascular event for every 74 patients treated for 2 years.

HELPFUL (BUT ABSURD) TIP:

Did you notice the 50 mg/dL LDL goal in the question answer above? That is not a typo. There are yet more 2018 guidelines from the AHA/ACC and these have

brought LDL targets back into favor. **For patients with ASCVD**, they recommend:

- 1) Aim for a 50% lowering of baseline cholesterol using a statin (as in the old guidelines) in patients with ASCVD
- 2) For “very high risk” ASCVD patients on maximal statins add ezetimibe if the LDL is >70 mg/dL. If the LDL remains >70 mg/dL, add a PCSK9 inhibitor
- 3) In those with an LDL > 190 mg/dL at baseline, don’t use the calculator. Just start them on a high-intensity statin with a goal of <100 mg/dL. If you don’t meet this goal and the patient has multiple risk factors, proceed as in #2 above to add ezetimibe and a PCSK9 inhibitor with a goal of <100 mg/dL

There are 7 more recommendations. They can be found at: <https://www.ahajournals.org/doi/10.1161/CIR.0000000000000625>. Note that these have not been endorsed by the AAFP nor the ACP (American College of Physicians). They are based on “expert opinion” and not clear science. We don’t know which recommendations will be on the test.

HELPFUL TIP:

Metamucil or other psyllium products are useful in reducing serum cholesterol and provide a “nondrug” alternative. However, at least 7 g of soluble fiber daily is required.

► **Objectives: Did you learn to ...**

- Determine risk factors for ASCVD?
- List the screening recommendations for lipid disorders?
- Describe the role of lipid-lowering therapy in the prevention of cardiac disease?
- Identify some of the potential side effects of lipid-lowering medications?

Clinical Pearls

- A false-positive troponin can be caused by a PE, heart failure, burns, sepsis, stroke, and more.
- A normal ECG during chest pain does not rule out ACS. In fact, 10% of patients with an MI will have an initially normal ECG with pain.
- Aggressive blood pressure lowering in patients with diabetes may be harmful. Use the same goal as for almost everyone else, <140/90. The JNC 8 report suggests a goal of <150/90 in those 60 years of age and older.
- Avoid the combination of a statin and gemfibrozil or fenofibrate; it can cause rhabdomyolysis. The risk is lower with fenofibrate, however.

- Do not continue nonaspirin antiplatelet agents (e.g., clopidogrel) indefinitely after stent placement. Determine a target end date (e.g., 1 year of dual aspirin–clopidogrel after placement of a DES).
- Do not do routine stress testing for asymptomatic patients preoperatively. In fact, don't perform stress testing in any asymptomatic patients.
- Do not use beta-blockers alone as antihypertensive therapy unless there is another indication (e.g., post-MI, heart failure).
- Do not use hsCRP to assess cardiac risk.
- Do not use nonstatin drugs to lower cardiac risk in patients until statins have been maximized or are not tolerated (and then only as *secondary prevention*).
- If using a beta-blocker preoperatively to reduce cardiac risk, start it well in advance of the surgery and get the patient on a stable dose before surgery.
- Perform an echocardiogram when considering the diagnosis of heart failure. It will differentiate HFREF from HFpEF.
- Perform ECG and administer aspirin 325 mg immediately to all patients presenting with symptoms of acute coronary syndrome.
- Prescribe ACE inhibitors over ARBs in patients with hypertension, cardiovascular disease, and/or chronic kidney disease.
- Prescribe statins for all patients with a history of CAD. The 2018 ACC/AHA guideline eliminated an LDL goal, although the 2018 guidelines reinstated them (but these have not been endorsed by AAFP or ACP at the time of publication). The goal is to use high-dose statins in those who are high risk (e.g., history of myocardial infarction).
- Stop all NSAIDs (except for aspirin) when admitting a patient for possible ACS. NSAIDs increase cardiac risk.
- Use the CHA₂-DS₂-VASC score when determining the need for anticoagulation in atrial fibrillation. Women with a score of 2 and men with a score of 1 are candidates for anticoagulation.

Pulmonology

3

Rachel R. Butler

▶ CASE 3.1

A 42-year-old male who works in a hog confinement area presents to your office complaining of cough, fever, wheeze, and dyspnea. He and some other workers were cleaning the confinement area with high-pressure hoses (which aerosolized hog waste, yum), and they *all* developed the same symptoms, which started between 4 and 8 hours after work. On examination, he is febrile with a respiratory rate of 28. He is able to talk in complete sentences. There are slight crackles when you auscultate the lungs. His chest x-ray is normal.

Question 3.1.1 The most likely diagnosis is:

- A) Farmer's lung (hypersensitivity pneumonitis)
- B) Organic dust toxicity syndrome
- C) Reactive airway disease
- D) Hydrogen sulfide poisoning
- E) Bronchiolitis obliterans

Answer 3.1.1 The correct answer is "B." Organic dust toxicity syndrome (ODTS) occurs when moldy or decomposed hay and other organic material (such as hog manure) is moved. Endotoxins are aerosolized and inhaled, leading to the symptoms. The tip off here is that everyone on the job site was affected. Since hypersensitivity pneumonitis ("A") is specific to the individual, generally only one worker at the site will have symptoms. Compared with ODTS, hypersensitivity pneumonitis may present with an abnormal chest x-ray with micronodular or reticular opacities. "C" is incorrect because everyone is involved, which would be highly unusual with reactive airway disease. "D" is not correct. Hydrogen sulfide poisoning presents as a toxic pneumonitis with pulmonary edema, dyspnea, hypoxia, and loss of consciousness. Hydrogen sulfide also acts as a direct cellular toxin that binds to cytochrome oxidase system, similar to cyanide. In addition, hydrogen sulfide exposure comes from cleaning manure pits (as anyone in Iowa would know). Finally, "E," bronchiolitis obliterans, is a chronic illness rather than an acute

one. Of note, there is a strong association between ODTS and subsequent development of chronic bronchitis.

Question 3.1.2 Appropriate treatment for this patient includes:

- A) Antibiotics
- B) Intubation and mechanical ventilation
- C) Supportive care
- D) A and B
- E) A and C

Answer 3.1.2 The correct answer is "C." Supportive care is the usual treatment of ODTS. Antibiotics are not needed because the syndrome is mediated by endotoxins rather than direct infection. "B" is incorrect because this patient is not in significant respiratory distress.

HELPFUL TIP:

Remember that other work exposures can cause fever, including "metal fume fever" which is caused by zinc. Patients are febrile by the end of the work week, improved over the weekend, only to reoccur in the middle of the next work week.

Keep reading to get to the objectives for this case.

▶ CASE 3.2

This patient's brother, who also works on a farm, notes that every time he unloads hay he has fever, cough, dyspnea, and sputum production. It tends to resolve in 2 to 5 days but reoccurs when he is re-exposed to hay. Does he wear a mask? Well, no. He would look silly and the guys would poke fun at him. Besides, none of the other workers on the farm are affected, and they are beginning to wonder if he is malingering. His examination reveals tachypnea and fine rales. There is no

wheezing present. A chest radiograph shows bilateral interstitial opacities.

Question 3.2.1 The most likely cause of this patient's symptoms is:

- A) *Thermoactinomyces candidus* (an actinomyces species)
- B) *T. sacchari*
- C) *Botrytis cinerea*
- D) *Cryptostroma corticale*
- E) None of the above

Answer 3.2.1 The correct answer is "A." This patient presents with classic symptoms of hypersensitivity pneumonitis or, in this case, "Farmer's lung." This is caused by exposure to the *Actinomyces* species. Acute findings include fever, chills, cough, dyspnea, and chest tightness. X-ray findings are variable and tend to be transient early on in the disease. High-resolution chest computed tomography (CT) should be obtained, which commonly shows centrilobular micronodules and ground-glass opacification in a mid-to-upper zone predominance. "B," *T. sacchari*, is involved in hypersensitivity pneumonitis from sugarcane (so-called Bagassosis). "C," *Botrytis cinerea*, is involved in hypersensitivity pneumonitis from grapes (so-called Spatlese lung). Finally, "D," *Cryptostroma corticale*, is involved in "Maple bark stripper's lung," another type of hypersensitivity pneumonitis—though why anyone would want to strip maple bark is beyond us.

Question 3.2.2 The correct treatment for this patient with Farmer's lung includes:

- A) Antibiotics
- B) Inhaled steroids
- C) Oral steroids
- D) Leukotriene inhibitors
- E) Bronchoalveolar lavage (BAL)

Answer 3.2.2 The correct answer is "C." Oral steroids are effective in the treatment of hypersensitivity pneumonitis. Neither antibiotics ("A") nor inhaled steroids ("B") are of any benefit. "E," bronchoalveolar lavage, is not a treatment. However, it can be used as a diagnostic tool. One would expect to see lymphocytes on BAL.

Question 3.2.3 You would advise this patient to:

- A) Get a new job
- B) Apply for disability
- C) Use a respirator at work and avoid exposure to this toxin if possible
- D) Sue the employer
- E) Take up worm farming or monoculture in rhubarb

Answer 3.2.3 The correct answer is "C." Wearing an appropriate respirator at work can be beneficial. Avoiding exposure is even better. As for the other answers, you are a doctor not a lawyer or career counselor. Stick with what you know!

The patient is unable to change jobs or wear a respirator because it itches and he "keeps forgetting it." But he's

persistent (or brave or thickheaded or unable to learn a new skill), and keeps farming. Three years later, he returns with a chronic cough, weight loss, dyspnea, fatigue, and clubbing of the fingers.

Question 3.2.4 Further evaluation will most likely reveal:

- A) Bronchogenic carcinoma
- B) Air space disease (e.g., a pneumonia-like picture)
- C) Decreased DLCO (Diffusing capacity of the Lungs for CO [Carbon Monoxide])
- D) Markedly abnormal bronchoalveolar lavage (BAL) with lymphocytosis
- E) Obstructive changes on pulmonary function testing

Answer 3.2.4 The correct answer is "C." Hypersensitivity pneumonitis can become chronic if exposure is not limited. In these cases, patients will generally have systemic complaints such as fatigue and possibly weight loss. Fever will be absent *as may a history of prior episodes of acute hypersensitivity pneumonitis*. Dyspnea and clubbing of the fingers are also generally noted, reflecting chronic pulmonary disease. Along with this finding, pulmonary fibrosis can occur and the DLCO may be decreased. "A" is incorrect. Hypersensitivity pneumonitis does not lead to lung cancer. "B" is incorrect. While acute hypersensitivity pneumonitis causes an alveolitis, chronic hypersensitivity pneumonitis causes pulmonary fibrosis with an occasional micronodular pattern. "D" is incorrect. BAL in chronic hypersensitivity pneumonitis does not contain the markedly elevated lymphocyte count that is seen with *acute* hypersensitivity pneumonitis. Finally, "E" is incorrect. One would see a restrictive pattern on pulmonary function testing reflecting the fibrosis and not an obstructive pattern.

HELPFUL TIP:

If you have a patient with recurrent "pneumonia," consider hypersensitivity pneumonitis. It has many causes in addition to farming, and it is idiopathic up to 25% of cases.

► Objectives: Did you learn to ...

- Recognize the clinical presentations of ODS and hypersensitivity pneumonitis?
- Manage patients with lung disease related to agricultural exposures?

QUICK QUIZ: ASTHMA

All of the following populations are at increased risk for developing asthma EXCEPT:

- A) Obese children
- B) Female children
- C) Children exposed to tobacco
- D) Children with atopy
- E) City children

The correct answer is "B." Male children have a greater prevalence of asthma. Interestingly, adult women "catch up" so

that there is gender equity in young adulthood. After age 40, the prevalence is higher in females. Of note, frequent respiratory infections seem to be *protective*. There is an inverse association between children living on farms and asthma incidence (another feather in the cap of Iowa). Presumably, this is related to the greater variety of antigen exposure.

▶ CASE 3.3

A 20-year-old woman with no significant past medical history presents with a 2-month history of episodic shortness of breath. These symptoms began with an upper respiratory tract infection. She has fits of coughing and trouble catching her breath with exertion. She states that her breath “sounds like whistles” at times. She tried a friend’s albuterol inhaler and an over-the-counter epinephrine inhaler (Primatine... yes, it is back on the market) with some improvement and wonders if she has asthma. On examination, she is breathing comfortably at 16 times per minute and her oxygen saturation is 96% on room air. Her lungs are clear to auscultation, and the remainder of her examination is unremarkable. You want to better categorize this patient’s disease.

Question 3.3.1 Which of the following tests is most appropriate to order now?

- A) Spirometry
- B) Chest x-ray
- C) Arterial blood gas (ABG)
- D) Methacholine challenge
- E) Chest CT

Answer 3.3.1 The correct answer is “A.” Since this patient has symptoms of bronchospasm, spirometry will be essential in determining if there is objective evidence of obstructive lung disease. However, spirometry results are often normal in mild cases of asthma, especially when the patient is asymptomatic. Bronchoprovocation testing, with methacholine or histamine, may be useful in such cases, but should follow basic spirometry. Although chest radiography (x-ray or CT) may reveal an occult process, it is not indicated in otherwise healthy patients with symptoms of bronchospasm. Bacterial pneumonia is a potential precipitant of bronchospasm that may be diagnosed on chest x-ray, but this patient has no constitutional symptoms (like fever) associated with serious bacterial infection. Obtaining an ABG (or better yet a venous blood gas) may be helpful when a patient presents with respiratory distress but certainly not in the office setting.

HELPFUL TIP:

A normal blood gas in a patient with an asthma exacerbation and tachypnea is an ominous sign that signals impending respiratory failure. The carbon dioxide (PaCO_2) should be low in a patient with tachypnea. Thus, a normal appearing ABG with a normal carbon dioxide level is an indication of respiratory muscle fatigue and early respiratory failure.

Question 3.3.2 If this patient has mild asthma, which of the following pulmonary function test results would you expect to find?

- A) Forced vital capacity (FVC) 50% of predicted
- B) Forced expiratory volume in 1 second (FEV_1) 100% of predicted
- C) FEV_1/FVC ratio <0.7
- D) Total lung capacity (TLC) 50% of predicted
- E) $\text{FEV}_1/\text{TLC} <0.7$

Answer 3.3.2 The correct answer is “C.” Patients with asthma will have a decreased FEV_1 . The FVC may fall as well, but FEV_1 falls first and to a greater degree as the lung becomes obstructed. The ratio of FEV_1/FVC is very sensitive to airflow limitations, and $\text{FEV}_1/\text{FVC} <0.7$ (just the raw ratio of the two numbers) is generally considered diagnostic of obstructive airway disease. The rest are incorrect. TLC is not measured by spirometry (which is why “D” and “E” are incorrect); but if it were, TLC may be increased in patients with obstructive airway disease due to air trapping.

Your patient’s office spirometry shows the following:

Normal FVC
 FEV_1 82% predicted
 FEV_1/FVC 0.68

Question 3.3.3 These findings are most consistent with which of the following?

- A) Normal spirometry
- B) Obstructive lung disease
- C) End-stage emphysema
- D) Interstitial fibrosis
- E) Obesity-hypoventilation syndrome

Answer 3.3.3 The correct answer is “B.” Always go first to the FEV_1/FVC ratio. In this case, it is <0.70 , which is suggestive of airway obstruction. The information provided here lacks data regarding DLCO which should be decreased in emphysema, so you could not really differentiate between chronic obstructive pulmonary disease (COPD) and asthma. But this is clearly not end-stage emphysema, so “C” is incorrect. “D” is incorrect. Interstitial fibrosis is generally marked by a restrictive pattern on spirometry and decreased TLC. Both flow rate (e.g., FEV_1) and FVC are decreased in interstitial lung diseases but in proportion to each other. Thus, the FEV_1/FVC is often normal or elevated. See Table 3-1 for more on interpreting spirometry results.

Six months after you discuss her findings and prescribe inhaled beta-agonist therapy, she returns with complaints of continued wheezing and difficulty breathing. Her symptoms are brought on by cold weather and exercise and she uses her inhaler two times per week or less. She woke up two nights over the last 6 months with shortness of breath and coughing. Her albuterol still works for these symptoms, but she finds them bothersome and asks, “Why haven’t I gotten over this?”

TABLE 3-1 GENERAL INTERPRETATION OF PULMONARY FUNCTION TEST RESULTS COMPARING OBSTRUCTIVE AND RESTRICTIVE DISEASE (MAY NOT BE APPLICABLE FOR ALL FORMS OF LUNG DISEASE)

PFT Result	Obstructive Pattern	Restrictive Pattern
FEV ₁	<80% predicted	Decreased in proportion to loss of lung volume
FVC	Decreased	<80% predicted
FEV ₁ /FVC	<0.7	>0.7
FEF _{25–75%}	<60% predicted	Decreased in proportion to loss of lung volume
TLC	Normal or elevated	Decreased
DLCO	Normal or elevated in asthma; normal or decreased in COPD	Decreased in intrinsic restrictive lung disease; normal in neuromuscular or musculoskeletal restrictive disease

COPD, chronic obstructive pulmonary disease; DLCO, diffusing capacity of the lung for carbon monoxide; FEF_{25–75%}, forced expiratory flow at 25–75% vital capacity; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; TLC, total lung capacity.

Question 3.3.4 How would you categorize this patient's respiratory state?

- A) Intermittent asthma
- B) Mild persistent asthma
- C) Moderate persistent asthma
- D) Severe persistent asthma
- E) Recurrent lower respiratory tract infections

Answer 3.3.4 The correct answer is "A." As of 2019—and incredibly—there have been no updates to the NHLBI National Asthma Education and Prevention Program (NAEPP) 2007 guidelines. According to those guidelines (Table 3-2), your patient meets the criteria for intermittent asthma. In such patients, mild symptoms correspond to an FEV₁ that is greater than 80% predicted—not to be confused with the FEV₁/FVC

TABLE 3-2 CATEGORIZATION OF SEVERITY OF ASTHMA AND STEPWISE APPROACH TO THERAPY

Determine Severity When Initiating Therapy

Components of Severity		Classification of Asthma Severity (≥12 years of age)			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment (Normal FEV ₁ /FVC)	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2×/month	3–4×/month	>1×/week but not nightly	Often 7×/week
	SABA ^a use for symptom control (not prevention of EIB ^b)	≤2 days/week	>2 days/week but not daily and more than 1× on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	<ul style="list-style-type: none"> • Normal EFV₁ between exacerbations • EFV₁ > 80% predicted • EFV₁/FVC normal 	<ul style="list-style-type: none"> • EFV₁ > 80% predicted • EFV₁/FVC normal 	<ul style="list-style-type: none"> • EFV₁ > 60% but <80% predicted • EFV₁/FVC reduced 5% 	<ul style="list-style-type: none"> • EFV₁ < 60% predicted • EFV₁/FVC reduced > 5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year	<div style="display: flex; align-items: center;"> <div style="width: 100%; height: 20px; background: linear-gradient(to right, #2e8b57, #2e8b57);"></div> <div style="margin: 0 5px;">→</div> </div> <div style="display: flex; align-items: center;"> <div style="width: 100%; height: 20px; background: linear-gradient(to left, #2e8b57, #2e8b57);"></div> <div style="margin: 0 5px;">←</div> </div> <p style="text-align: center; margin: 5px 0;">Consider severity and interval since last exacerbation Frequency and severity may fluctuate over time for patients in any severity category Relative annual risk of exacerbations may be related to FEV₁</p>		
	Recommended step for initiating therapy See bar chart in Figure 3–1 for treatment steps	Step 1	Step 2	Step 3 and consider short course of oral systemic corticosteroids	Step 4 or 5
		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.			

^aSABA, short-acting inhaled beta-2 agonist.

^bEIB, exercise-induced bronchospasm.

ratio which diagnoses obstructive lung disease but is not used to categorize severity.

Question 3.3.5 Which of the following is most appropriate for this patient given that she has intermittent asthma?

- A) Add theophylline
- B) Add montelukast
- C) Continue albuterol as needed
- D) Schedule albuterol every 4 hours
- E) Prednisone 5 mg daily

Answer 3.3.5 The correct answer is “C.” As already discussed, this patient appears to have intermittent asthma. She is in no respiratory distress, is oxygenating normally, and is still responding well to albuterol by her report. Although there is some debate about the role of inhaled steroids in intermittent asthma, the NAEPP and most experts do not recommend their use. Oral prednisone is certainly not indicated in this case. She should be continued on a short-acting inhaled beta-2 agonist, such as albuterol, without the addition of another medication. “D” is incorrect. Scheduled albuterol actually yields *less effective* symptom control than does PRN use. As to “A,” a pox on those still prescribing theophylline.

Your patient goes on to develop more frequent recurrent symptoms, such that she is using her albuterol inhaler more than three times per week, although her nighttime symptoms are rare.

Question 3.3.6 Which medication is the most appropriate next step in treating this patient’s asthma?

- A) Inhaled triamcinolone
- B) Inhaled salmeterol

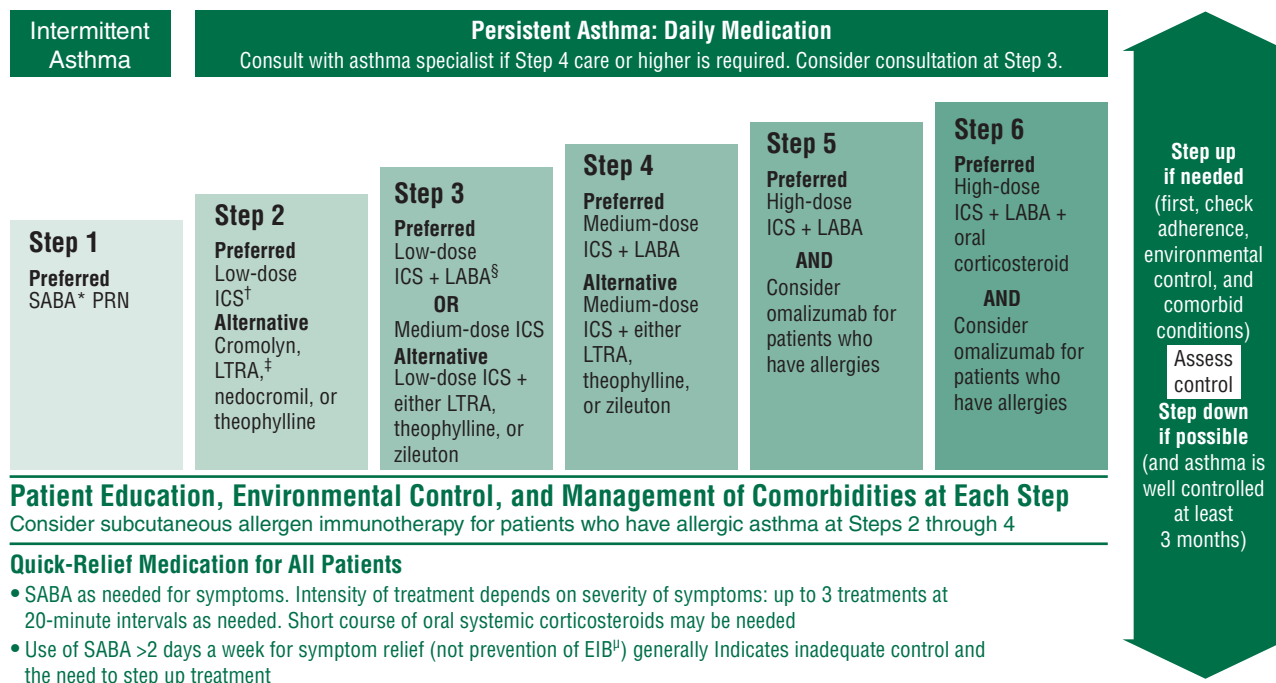

- C) Inhaled cromolyn sodium
- D) Inhaled ipratropium
- E) Oral montelukast

Answer 3.3.6 The correct answer is “A.” Your patient now has mild persistent asthma and should be started on an inhaled steroid. When asthma symptoms become more persistent (i.e., when they occur >2 days per week or the patient awakens from sleep >2 times per month), the inflammatory component of the disease should be addressed while simultaneously treating the bronchospastic component with short-acting beta-2 agonists. Anti-inflammatory drugs are the mainstay of chronic asthma therapy, and inhaled corticosteroids are the most efficacious with the fewest side effects. Although ipratropium, cromolyn sodium, and montelukast have a place in asthma treatment, none of these medications is a first-line agent. Ipratropium is an anti-cholinergic that works through its bronchodilatory effects, while cromolyn sodium is a mast cell stabilizer. Montelukast is a leukotriene inhibitor. The long-acting inhaled beta-2 agonists, such as salmeterol, are only recommended at Steps 3 and higher of persistent asthma control (Table 3-2, Fig. 3-1; NHLBI recommendations, 2007).

HELPFUL TIP:

Remember the “rule of twos”: any patient who has >2 asthma exacerbations per week requiring rescue medication or who wakes with nocturnal symptoms >2 times per month should be on an anti-inflammatory drug, preferably an inhaled corticosteroid. Asthma classification and treatment has gotten ridiculously complex. You

* Short-acting inhaled beta₂-agonist. † Inhaled corticosteroid. ‡ Leukotriene receptor antagonist. § Long-acting inhaled beta₂-agonist. ¶ Exercise-induced bronchospasm.

FIGURE 3-1. NHLBI recommended stepwise approach to asthma therapy.

may want to review this Asthma Care Quick Reference revised in September 2012 located at https://www.nhlbi.nih.gov/files/docs/guidelines/asthma_qrg.pdf.

HELPFUL TIP:

The leukotriene inhibitors (e.g., montelukast, zafirlukast) add little or nothing to maximized inhaled steroid therapy. In fact, they are clearly not as effective as inhaled steroids. They should be used only once a patient has failed inhaled steroids and should be added to the regimen; they are not a substitute for inhaled steroids.

Your patient does quite well over the next year, having very few exacerbations. During one of her visits, you note slightly edematous nasal mucosa and nasal polyps. You prescribe intranasal steroids. Then, one night when you are on call, she comes in severely dyspneic with audible wheezing. She talks in two- or three-word phrases. She reports a headache today, which she treated with aspirin (something she never takes, but a friend gave it to her thinking it was acetaminophen). Her asthma attack started about an hour after the aspirin dose. She has been otherwise well. She denies fever, rhinorrhea, nasal congestion, and sore throat. Her respiratory rate is 40, heart rate 120 bpm, and oxygen saturation 88% on room air. She has poor air movement on auscultation of her lung fields.

Question 3.3.7 Which of the following is the most likely reason for this patient's acute exacerbation of asthma?

- A) Viral upper respiratory infection (URI)
- B) Sinusitis
- C) Noncompliance with inhaled albuterol
- D) Sensitivity to aspirin
- E) Noncompliance with nasal steroids

Answer 3.3.7 The correct answer is "D." It is likely that this patient has aspirin sensitivity. Up to 10% of adults with asthma have the clinical triad of asthma, aspirin sensitivity, and nasal polyposis. Patients with asthma should be warned about the potential for exacerbations resulting from consumption of aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). The drug-induced bronchial constriction caused by these medications can have an abrupt onset with severe symptoms. Patients with aspirin sensitivity can be desensitized with daily administration of small amounts of aspirin, but this should be done carefully with close supervision. Although viral URIs frequently cause exacerbations of asthma, your patient did not report antecedent symptoms of such an infection. Further discussion of the treatment of an acute asthma exacerbation can be found in Chapter 1, "Emergency Medicine."

After a brief hospitalization, your patient recovers nicely. Prior to this incident involving aspirin, she had been free of exacerbations for about a month.

Question 3.3.8 In addition to a short course of oral steroids, which of the following medication regimens do you prescribe for this patient with *aspirin sensitive* asthma at discharge?

- A) Inhaled triamcinolone and inhaled albuterol as a "rescue"
- B) Inhaled triamcinolone, oral montelukast, and inhaled albuterol as a "rescue"
- C) Oral montelukast and inhaled albuterol as a "rescue"
- D) Inhaled albuterol as a "rescue"
- E) Inhaled salmeterol and inhaled triamcinolone

Answer 3.3.8 The correct answer is "B." Leukotriene inhibitors (e.g., montelukast, zafirlukast) have demonstrated effectiveness in reducing symptoms and improving peak flow in patients with *aspirin sensitive asthma*. Leukotriene inhibitors should be used only in asthma patients who are already using a corticosteroid inhaler—or those who cannot tolerate inhaled corticosteroid therapy. Therefore, "C" is not an appropriate choice. "D" is incorrect because there is no anti-inflammatory drug. Although "E" offers an anti-inflammatory agent, there is no rescue inhaler, and patients with asthma must always have access to a short-acting inhaled bronchodilator.

HELPFUL TIP:

Other NSAIDs have been implicated in "aspirin-exacerbated" asthma. The theory is that there is an imbalance between pro- and anti-inflammatory mediators that is exacerbated acutely by COX-1 inhibition.

Question 3.3.9 Which of the following medications, when used alone as maintenance therapy in persistent asthma, is associated with an increased risk of asthma-related mortality?

- A) Inhaled fluticasone
- B) Inhaled salmeterol
- C) Oral zafirlukast
- D) Oral prednisone

Answer 3.3.9 The correct answer is "B." Inhaled salmeterol, when used alone as a controller agent for asthma, has been associated with a two- to fourfold increase in the risk of death related to asthma or other respiratory conditions. Thus, the Food and Drug Administration (FDA) has mandated a "black box" warning be applied to salmeterol-containing products. It is not known whether inhaled steroid therapy is protective, but NHLBI/NAEPP guidelines recommend adding long-acting inhaled beta-agonists only after inhaled steroids are already in use.

HELPFUL TIP:

The importance of patient education in asthma cannot be overstated. Patients diagnosed with asthma should receive a written plan of action, detailing when to increase beta-2 agonist use and when to start an oral steroid. While there is no proven benefit to home peak

flow monitoring, this may serve to get patients more involved in management of their illness. A home peak flow meter can be used as a part of the educational process and to enhance communication between the healthcare practitioner and the patient.

HELPFUL TIP:

Asthma research is expanding the therapies available for severe asthmatics. For patients with severe asthma, frequent exacerbations despite guideline-based therapy, and an eosinophilic phenotype, new add-on therapies include anti-interleukin (IL)-5 antibodies (e.g., mepolizumab [Nucala] or reslizumab [Cinqair]), the anti-IL-5 receptor antibody benralizumab (Fasenra), or the anti-IL4 subunit alpha antibody dupilumab (Dupixent). Of note, these therapies are administered subcutaneously or intravenously and should be done in conjunction with an asthma expert.

► **Objectives: Did you learn to ...**

- Identify triggers of bronchospasm?
- Evaluate symptoms of wheezing and dyspnea?
- Classify asthma?
- Prescribe appropriate medications for intermittent and mild persistent asthma?
- Describe the triad of asthma, aspirin sensitivity, and nasal polyposis?

QUICK QUIZ: SPIROMETRY

A 60-year-old female who smokes two packs of cigarettes per day complains of shortness of breath and fullness in her throat. You obtain spirometry in the office and the results are given along with the flow/volume loop (Fig. 3-2).

FIGURE 3-2. Spirometry results for patient in “Quick Quiz: Spirometry”.

How do you interpret these findings?

- A) Chronic obstructive lung disease
- B) Restrictive lung disease
- C) Fixed upper airway obstruction
- D) Poor patient effort
- E) Within normal range

The correct answer is “C.” The flattened flow/volume loop is consistent with a fixed upper airway obstruction (e.g., laryngeal mass lesion). In this case, FEV₁ and the FEV₁/FVC ratio may look like other obstructive diseases (i.e., asthma, COPD), so you have to look at the flow/volume loop (always a good idea). Some examples of flow/volume loops are given below (Fig. 3-3).

FIGURE 3-3. Typical spirometry results in normal lungs compared to lungs with obstructive or restrictive disease.

► CASE 3.4

You are seeing a 65-year-old male in the emergency department (ED) where he presented with complaint of increasing shortness of breath. He has obvious difficulty breathing and cannot speak in full sentences. However, you are able to elicit that he has been having increasing respiratory problems over the last 3 to 4 days. He has known COPD with FEV₁ of “less than one” (normal FEV₁ is about 4 L for a 50-year-old male and 3 L for a 50-year-old female; for calculations based on age, etc., see www.hankconsulting.com/RefCal.html or <http://www.webcitation.org/75KGIXvSb>). He has been using his inhalers much more than usual but with minimal improvement. He has smoked one pack per day since age 18 (but proudly points out he quit 2 days ago) and has a past medical history of high cholesterol, obesity, and hypertension.

On examination, he has a respiratory rate of 26 to 28, heart rate of 100 bpm, blood pressure of 130/90 mm Hg, and temperature of 37.7°C. His O₂ saturation is 84% on room air. On auscultation, you do not appreciate much due to his body habitus, but you still manage to hear some wheezing. He has a normal cardiac examination and no lower extremity edema.

Question 3.4.1 What is the next best step to help this patient?

- A) Perform emergent endotracheal intubation
- B) Administer supplemental O₂ via nasal cannula
- C) Administer methylprednisolone (Solu-Medrol), 1 g IV
- D) Start antibiotics IV
- E) Obtain a chest x-ray

Answer 3.4.1 The correct answer is “B.” This patient is hypoxic, and your first priority should be to improve his oxygenation. There exists a theory that oxygenating patients with COPD will suppress their respiratory drive. The classical teaching (mostly incorrect) is that COPD causes a switch from carbon dioxide levels driving respiration to oxygen levels driving respiration. While this may be partly true, further study has suggested that the main reason COPD patients are at risk of worsening hypercapnia is due to loss of hypoxic pulmonary vasoconstriction and worsening ventilation-perfusion mismatch that occurs with excess oxygen delivery. Regardless of that, you need to first worry about this patient’s oxygenation. He is not going to thrive with an 85% O₂ saturation.

“A” is incorrect. The patient is protecting his airway and you have not attempted improving his oxygenation with less invasive methods yet. Administering steroids, IV or PO, will have no immediate effect on his respiratory status. In fact, IV steroids *might* be worse than PO steroids (there is question of whether higher IV doses cause immunosuppression and subclinical myopathy; see *Am J Respir Crit Care Med.* 2014;189:1052). Antibiotics and a chest x-ray may be reasonable, but with low O₂ saturations, your priority is to quickly improve your patient’s oxygen status.

HELPFUL TIP:

Patients admitted to a hospital for a COPD exacerbation (characterized by increased dyspnea, sputum production, and sputum purulence) should be treated with corticosteroids (oral prednisone is equivalent to IV steroids), an antibiotic that covers respiratory tract pathogens (numerous antibiotics are acceptable, including azithromycin, moxifloxacin, doxycycline, among others) and inhaled bronchodilators. Supportive therapy with supplemental oxygen and ventilation is often required as well.

Question 3.4.2 When initiating supplemental oxygen by nasal cannula, you instruct the nurse to keep the patient’s oxygen saturation:

- A) Between 96% and 100%
- B) Between 90% and 95%
- C) Between 85% and 89%
- D) At whatever saturation he looks most comfortable

Answer 3.4.2 The correct answer is “B.” The primary goal of supplemental oxygen is to reduce the risk of tissue hypoxia. Maintaining oxygen saturations above 90% (or PaO₂ 60–65 mm) will ensure tissue oxygenation. Higher oxygen saturations may result in CO₂ retention and hypercapnia, as noted earlier. Also, aiming at 100% with excessive levels of O₂ supplementation takes away an important patient assessment parameter because now you cannot tell easily whether his O₂ needs are going up or down. “D” is of special note. Patients with COPD who look comfortable may be developing hypercapnia and CO₂ narcosis. Thus, while comfort is a goal, it may not be the best judge of clinical status in patients with COPD exacerbations. To assess CO₂ levels, you will need an ABG or VBG.

Your patient is now on 5 liters per minute (LPM) of oxygen via nasal cannula. You obtain an ABG: pH 7.29, PCO₂ 74 mm Hg, PO₂ 58 mm Hg. The patient is awake and alert but says that he still feels “like dirt.” He remains tachypneic, in obvious respiratory distress, with a respiratory rate of 28. Albuterol and ipratropium are given via nebulizer.

Question 3.4.3 What is the best next step?

- A) Clearly, he is failing therapy—emergently intubate
- B) Increase his O₂ to 100% via face mask
- C) Initiate noninvasive positive pressure ventilation (e.g., BiPAP)
- D) Start IV antibiotics
- E) Obtain a chest CT with PE protocol

Answer 3.4.3 The correct answer is “C.” This patient is retaining CO₂ despite tachypnea and is in impending respiratory failure. He is also not oxygenating well despite low-flow oxygen. Noninvasive positive pressure support (BIPAP) can relieve hypercapnia and improve oxygenation by decreasing work of breathing without requiring intubation and its associated

morbidity. Often IV antibiotics (“D”) are used for empiric therapy in severe exacerbations of COPD, but again, improving the respiratory status comes first. He is hypoxic, but his main problem is CO₂ retention—increasing his O₂ delivery will not alleviate that (thus, “B” is incorrect). Although his respiratory status is tenuous, he is not in imminent respiratory failure, and intubation (“A”) is not warranted at this time. Chest CT (“E”) can rule out a PE in this hypoxic patient and may confirm COPD changes including emphysema, but will greatly delay treatment and would not change your immediate course of action—in other words, you would be barking up the wrong bronchial tree.

After several hours of noninvasive positive pressure ventilation, your patient is doing well, and he is transferred out of the intensive care unit (ICU). When you see him the next day his medications include inhaled bronchodilators, ceftriaxone, azithromycin, and prednisone. A chest x-ray shows no evidence of infiltrate. He is weaned from the positive pressure support to oxygen by nasal cannula and then, 2 days later, to room air. At discharge, he appears comfortable, with a respiratory rate of 14 and an oxygen saturation of 92% on room air.

Question 3.4.4 As you write his home-going prescriptions, what would be the best ongoing treatment for him?

- A) Inhaled long-acting beta-agonist (LABA) + albuterol
- B) Inhaled steroid + albuterol
- C) Inhaled steroid + LABA + albuterol as needed
- D) Albuterol
- E) Albuterol and theophylline

Answer 3.4.4 The correct answer is “C.” This is a bit tricky, but due to the severity of his exacerbation, “C” is the best choice. Compared to patients with asthma, where long-acting bronchodilators are not indicated as first-line therapy, COPD patients have a clear symptomatic benefit from long-acting bronchodilators. The two available choices are anticholinergics (LAMAs, or long-acting muscarinic agents [e.g., tiotropium, umeclidinium]

or LABAs [e.g., salmeterol or formoterol]). Either choice is fine, and some prefer a LAMA as first line. An inhaled steroid does not modify the long-term decline in FEV₁ in patients with COPD. However, it will reduce the frequency of exacerbations and thus improve health status. Current guidelines recommend addition of inhaled steroids with FEV₁ < 50% predicted and frequent exacerbations (e.g., 3 exacerbations in the last 3 years). See Table 3-3 for more on guideline-directed treatment. It is important to recognize there are adverse effects of inhaled corticosteroids (ICS) therapy including dysphonia, skin bruising, and oral candidiasis. In addition, ICS therapy may increase the incidence of pneumonia and cataracts, as well as diminish bone density. Therefore, for patients with COPD, other therapies are recommended (bronchodilators, smoking cessation, pulmonary rehabilitation), if possible, prior to ICS therapy. For patients who have persistent symptoms, repeated exacerbations, or severe exacerbations despite optimal long-acting bronchodilator regimen, ICS therapy is recommended.

HELPFUL TIP:

We hate cats. So, what is this CAT and MMRC deal with the GOLD criteria? These are two ways of gauging the severity of COPD. A handy pocket card for the MMRC Dyspnea Scale and CAT scale (COPD Assessment Test) can be found at <https://mdspiro.com/image/data/articles/COPD%20Pocket%20Consultant.pdf>. These should be used periodically to assess how your patient is doing.

HELPFUL TIP:

American Thoracic Society (ATS) guidelines categorize obstructive airway disease based on the percent predicted FEV₁ of the patient. The response to bronchodilator is also categorized by ATS. To state that there was significant response to bronchodilator, there has to be an increase of both 200 cc and an increase of at least 12% in the FEV₁.

TABLE 3-3 GLOBAL INITIATIVE FOR OBSTRUCTIVE LUNG DISEASE (GOLD) COPD TREATMENT GUIDE

GOLD COPD Treatment Guidelines				
Type of COPD	Exac/yr	FEV ₁	MMRC Score or CAT Score	Treatment
A	≤1	FEV ₁ ≥80%	0–1 and CAT <10	SABA PRN
B	≤1	FEV ₁ 50%–80%	≥2 and CAT <10	LABA or LAMA → combine if still symptomatic or add SABA
C	≥2	FEV ₁ 30%–50%	0–1 and CAT <10	ICS + LABA +/- or LAMA
D	≥2	FEV ₁ <30%	≥2 and CAT >10	ICS + LABA or LAMA or if FEV ₁ <50% + chronic bronchitis roflumilast or if former smoker azithromycin 250 mg/day

CAT, COPD Assessment Test; Exac/yr, exacerbations per year; ICS, inhaled corticosteroid; LABA, long-acting beta agonist; LAMA, long-acting muscarinic agent; MMRC, dyspnea scale; SABA, short-acting beta agonist. See <https://goldcopd.org/gold-reports/> for more details.

Holding his inhalers and smiling toothlessly, your patient asks, “Which of these is going to keep me alive—just in case I can’t afford them all?”

Question 3.4.5 Which of the following medication regimens has demonstrated decreased mortality in the treatment of stable COPD?

- A) Inhaled tiotropium (LAMA)
- B) Inhaled salmeterol (LABA)
- C) Inhaled ipratropium
- D) Inhaled corticosteroid
- E) None of the above

Answer 3.4.5 The correct answer is “E.” Aside from oxygen, no medical therapy has clearly demonstrated a mortality benefit for stable COPD. Again refer to Table 3-3 for stage of COPD and appropriate treatment. Another therapy to consider in advanced COPD is pulmonary rehabilitation (PR). While having no definite effect on survival, PR improves dyspnea and quality-of-life scores while reducing the number of hospitalizations and days in hospital. Also, there are oral phosphodiesterase inhibitors (e.g., roflumilast [Daliresp]) for severe COPD. As you probably already know, your authors are curmudgeons who don’t like anything new. *But roflumilast is particularly on our bad list.* It increases FEV₁ by 45 mL over placebo. It has no effect on quality of life and exacerbations are 1.3/year with placebo and 1.2/year with roflumilast. It also causes diarrhea and depression/suicidality. Nonetheless, you should know about it. Another therapy for COPD patients with recurrent exacerbations despite optimal therapy is chronic azithromycin, which may reduce the frequency of exacerbations (*Int J Chron Obstruct Pulmon Dis.* 2018;13:3813–3829). However, this should be avoided in patients with a long QT interval or if there are major concerns about hearing loss. This therapy needs to be carefully considered as studies have revealed that during 5 days of azithromycin therapy, there was a small absolute increase in cardiovascular deaths among patients with high baseline risk of cardiovascular disease (*N Engl J Med.* 2012;366:1881–1890).

HELPFUL TIP:

Note that inhaled steroids should be used in those patients in group C or D (previously severe to very severe) COPD based on the Global Initiative for Obstructive Lung Disease (GOLD) guidelines. There is no benefit in patient group A or B (previously mild-moderate COPD) and there is a downside (an increase in pneumonia).

Later that year, the same patient gets admitted to the hospital for community-acquired pneumonia. During his stay in the hospital, the hospitalist orders a CT chest “to rule out other things.” The patient recovers from his infection and returns to you with the CD of his CT chest images. The reading of the CT chest describes a 2-cm pulmonary nodule in the right upper lobe along with extensive subcarinal lymphadenopathy.

Question 3.4.6 What is the next best step in management of this patient?

- A) Repeat CT chest in 3 months
- B) Repeat CT chest in 6 months
- C) Refer for bronchoscopy with endobronchial ultrasound-guided biopsy
- D) Refer to an oncologist
- E) Refer for a mediastinoscopy

Answer 3.4.6 The correct answer is “C.” This patient probably has a malignant disease and tissue is needed to either diagnose it or rule it out (see more later in this chapter). Bronchoscopy with endobronchial ultrasound (EBUS) guided fine-needle biopsies is a minimally invasive procedure that can relatively safely obtain a tissue sample for the pathologist. There is good evidence that EBUS has high sensitivity and specificity compared with PET scanning. “A” and “B” are incorrect as this patient has a nodule that is larger than 1 cm along with mediastinal lymphadenopathy. This needs to be worked up and cannot wait 3 to 6 months. “D” is incorrect. Your patient will likely need to see an oncologist, but you need to first provide a tissue diagnosis. “E,” mediastinoscopy, would likely provide you with the diagnosis, but it is a far more invasive procedure than bronchoscopy and carries higher mortality and morbidity.

HELPFUL TIP:

It turns out that up to **half** of patients **treated** for COPD don’t actually have it. Sad but true. Check PFTs to confirm the diagnosis (*Chest.* 2015;147(2):369–376).

Your patient returns with increasing dyspnea now at rest. His biopsy was negative. Despite both of you being blue in the face, he has not quit smoking.

Question 3.4.7 Criteria for the use of continuous low-flow oxygen in those with COPD include all of the following EXCEPT:

- A) PO₂ <55 mm Hg
- B) Oxygen saturation <88%
- C) PO₂ of <59 mm Hg with evidence of cor pulmonale
- D) Episodic sleep apnea-related desaturations at night

Answer 3.4.7 The correct answer is “D.” Episodic sleep apnea-related oxygen desaturations, while a cause for concern and amenable to treatment (e.g., CPAP), are not one of the criteria for the use of continuous low-flow oxygen. The other choices are correct. “C” deserves some special attention. Evidence of cor pulmonale can include “p-pulmonale” on ECG, peripheral edema, or a hematocrit >55%.

Question 3.4.8 Concerning hypoxemic patients with COPD (resting oxygen saturation of <88%), which of the following is true?

- A) Patients on continuous, low-flow O₂ become oxygen dependent and cannot function without it

- B) Continuous low-flow O₂ used for at least 8 hours a day helps to reverse pulmonary hypertension
- C) Concurrent smoking is a contraindication to the prescribing continuous low-flow home O₂ because patients are spontaneously combusting right and left (like Spinal Tap drummers)
- D) Low-flow O₂ used at least 15 hours a day significantly enhances survival
- E) Low-flow O₂ is a well-tolerated and effective treatment for obstructive sleep apnea

Answer 3.4.8 The correct answer is “D.” Patients who use continuous low-flow O₂ at home have an improved rate of survival. Patients should be encouraged to use O₂ at least 15 hours a day, if possible, to obtain this benefit. “B” is incorrect because patients need at least 15 hours of O₂ per day to have any significant benefit with regard to pulmonary hypertension. “C” is incorrect. Clearly, smoking while on O₂ is not a good idea, but patients can turn off their O₂ supply while smoking.

HELPFUL TIP:

Data suggests that up to 20% of patients hospitalized with a COPD exacerbation of unknown origin may actually have a PE. Don't narrow your differential too soon!

► Objectives: Did you learn to ...

- Recognize a patient presenting with signs and symptoms of COPD?
- Describe diagnostic and staging criteria for COPD?
- Develop a plan to manage hypoxemia and hypercapnia?
- Manage medications for acute exacerbations of COPD?
- Direct therapy for chronic COPD?
- Identify causes of dyspnea other than COPD presenting in a patient with known COPD?

QUICK QUIZ: COPD

In a patient with COPD, a lung transplantation referral can be considered:

- A) Once the patient requires oxygen
- B) When you feel you have run out of interventions
- C) Once insurance accepts your referral
- D) After the patient meets strict criteria for the referral
- E) If the patient's family keeps asking for the referral

The correct answer is “D.” The International Society for Heart and Lung Transplantation created a set of criteria for when to consider transplantation and, more importantly, when should you consider *referral* for a lung transplant consultation. In COPD patients, the indication for *referral* is easy to remember and consists of BODE index >5 (BODE stands for **B**ody-mass-index, **O**airflow **O**bsttruction, **D**yspnea, and **E**xercise, which are the characteristics used in the index). The BODE index is an alternative to the GOLD criteria. The BODE index incorporates functional criteria such as breathlessness and 6-minute walking

distance. Find a BODE calculator here: <http://www.qxmd.com/calculate-online/respirology/bode-index>. Criteria for *transplantation* in COPD are more complex and are beyond the scope of this book.

► CASE 3.5

Ms. Sarah Bellum (if you're not smiling, try saying the name out loud or the joke is just lame . . .) is a 32-year-old female who presents to your ED with shortness of breath. She just flew home from the International Conference on Balance and Coordination in London. Immediately after walking through her front door, she became acutely short of breath. This is associated with some moderately sharp chest pain located along the left side of her chest. The pain seems worse when she attempts to breathe deeply.

Question 3.5.1 Which important question(s) do you next ask Ms. Bellum?

- A) Do you smoke cigarettes?
- B) When was your last menstrual period?
- C) Have you had surgery recently?
- D) Do you have a history of kidney disease?
- E) All of the above.

Answer 3.5.1 The correct answer is “E.” Each of these questions addresses risk factors associated with pulmonary embolism (PE) and/or deep vein thrombosis (DVT). Smoking cigarettes and recent surgery are strong risk factors, as is an active pregnancy. Addressing a patient's menstrual cycle serves as a natural segue to a discussion about the use of oral contraceptives, which, too, is a prominent risk factor. As for renal disease, nephrotic syndrome has been associated with an increased risk of PE.

After further verbal probing, you discover that Ms. Bellum recently completed her menstrual cycle. The other presented questions turned up no risk factors. However, your smooth segue did reveal that she takes low-dose estrogen for birth control. You also learn that her aunt had a blood clot in her leg once. She has no further details but does not think that her aunt had any further complications from this condition. Regardless, PE just took a violent leap to the top of your differential. You glance at her vitals (temperature 37.1°C, heart rate 92 bpm, blood pressure 129/68 mm Hg, respiratory rate 21, SpO₂ 95% on room air) and notice that she appears mildly uncomfortable but not in any acute distress. Her physical examination is entirely unremarkable. You order an ECG to evaluate for potential cardiac etiologies for her symptoms.

Question 3.5.2 Assuming Ms. Bellum does have a PE, what is her ECG most likely to show?

- A) S₁Q₃T₃
- B) Nonspecific ST-T wave changes
- C) Sinus tachycardia

- D) Normal sinus rhythm
- E) Multifocal atrial tachycardia

Answer 3.5.2 The correct answer is “D.” The most common ECG finding associated with the diagnosis of PE remains normal sinus rhythm. With that said, the most common *arrhythmia* found in patients with a PE is sinus tachycardia. But alas, Sarah had a normal heart rate. The other choices can certainly be found with this condition but are far less frequent. Of note, the “textbook” $S_1Q_3T_3$ ECG rarely occurs and historically traces back to a handful of patients in the 1930s that had massive pulmonary emboli. Even if you do spot this pattern on an ECG, it is not specific enough to confirm the diagnosis. In the end, the clinical signs attributed to pulmonary emboli (such as the shortness of breath and chest pain) are more valuable than any abnormal ECG finding.

As you attempt to rule out other potential etiologies for the patient’s symptoms (e.g., pneumonia, atelectasis, and pneumothorax), you order a trusty old chest radiograph.

Question 3.5.3 What is the *most common* radiographic finding in a patient with a PE?

- A) Pleural effusion
- B) No acute cardiopulmonary processes
- C) Westermark sign
- D) Hilar/mediastinal enlargement
- E) Hampton hump

Answer 3.5.3 The correct answer is “B.” Admittedly, this one is a bit tricky. Approximately 75% of the chest radiographs in the setting of PE are abnormal. However, there are numerous causes for these abnormalities and none of them individually surpass the frequency of the normal chest radiographs. Specifically, the “textbook” findings of Westermark sign (loss of peripheral vascular markings) and Hampton hump (a wedge-shaped opacity due to pulmonary infarction) are infrequent, and both have a low sensitivity and low specificity. In short, all the other options can be seen as the result of a PE, but none is more frequent than a normal chest radiograph.

ECG and chest radiograph in hand, you turn your attention toward ordering the appropriate laboratory tests to solidify your presumptive diagnosis. You are working with a medical student who suggests a number of lab tests. You agree with most of them but shoot him down on one.

Question 3.5.4 Which test should you AVOID ordering?

- A) CBC
- B) D-dimer
- C) PT/PTT
- D) Basic metabolic panel (Na^+ , K^+ , Cl^- , CO_2^- , BUN, Cr^- , and glucose)
- E) Urine pregnancy test

Answer 3.5.4 The correct answer is “B.” The D-dimer can be a blessing for some but is the bane of existence for others. In this

patient, a D-dimer is not useful. This test has great sensitivity but poor specificity. It is positive in far more conditions than PE. Used as a “rule-out” test for PE, it only applies in low-risk patients. Ms. Bellum is not a low-risk patient as suggested by the Pulmonary Embolism Rule-out Criteria (aka, “PERC”; see Helpful Tip) due to her use of exogenous estrogen. The Wells criteria for PE place her in the moderate-risk group (16.2% risk of PE). As such, even a negative D-dimer is insufficient for ruling out the diagnosis. As for the other tests, they all serve a valuable role in her evaluation. For instance, the CBC (“A”) could provide evidence of anemia, while the PT/PTT (“C”) may reveal a coagulopathy. Assessing her renal function (“D”) may be needed for her evaluation and treatment planning, and the same can be said for verifying her gestational status (“E”). Plus, a urine pregnancy test is performed on almost every woman in an ED. It might as well be part of the triage process.

That pesky med student seemed to know a lot about the PERC rules and Wells criteria. But when he listed the Wells criteria, he got one wrong.

Question 3.5.5 The Wells criteria for PE include all of the following EXCEPT:

- A) Estrogen use
- B) Pulse >100 bpm
- C) Previous history of venous thromboembolism
- D) Clinical symptoms and signs consistent with PE
- E) Hemoptysis

Answer 3.5.5 The correct answer is “A.” While an important risk factor for PE, estrogen use is not included in the Wells criteria. All the others count in the Wells criteria (Table 3-4). Using a medical calculator website, such as www.mdcalc.com, is most helpful.

TABLE 3-4 WELL’S SCORE FOR PEA

Clinically suspected DVT	3 points
No alternative diagnosis more likely than PE	3 points
Tachycardia >100	1.5 points
Immobilization for ≥ 3 days or surgery in the previous 4 weeks	1.5 points
History of DVT or PE	1.5 points
Malignancy within 6 months	1 point
Presence of hemoptysis	1 point

Score >6: high probability of PE (78%)

Score 2–6: moderate probability of PE (27.8%)

Score <2: low probability of PE (<3.4%).

“D-dimer is *only* useful to rule out the low-probability patient. Otherwise, the post-test probability with a normal D-dimer does not change enough to get you to a low-enough risk to rule out a PE.

**HELPFUL TIP:**

The PERC rules are a validated set of rules that allow categorization of a patient into a low-risk group to rule out PE clinically. If the patient meets **all** of the following, PE is ruled out (*assuming you believe the patient is low risk to begin with*). Find a calculator here: <https://www.mdcalc.com/perc-rule-pulmonary-embolism>.

- 1) Age <50 years
- 2) Heart rate <100 bpm
- 3) SaO₂ >94% on room air
- 4) No unilateral leg swelling
- 5) No hemoptysis
- 6) No recent history of trauma or surgery
- 7) No prior DVT or PE
- 8) No hormone use

**HELPFUL TIP:**

Remember not to get a D-dimer on *no-risk* patients. This simply increases the CT rate and exposure to unnecessary radiation. The *fatal* cancer rate in a 20-year-old female undergoing a *single* 64-slice chest CT is 1:142 (*JAMA*. 2007;298(3):317–323)! Plus, 25% of “positive” CTs are false positive, damning them to the hell of anticoagulation (*Am J Roentgenol*. 2015;205:271). This is especially common in low-risk patients and single subsegmental PEs.

The CBC, coagulation studies, and basic metabolic panel all return within normal limits. In addition, Ms. Bellum is not pregnant. Thus, you wish to (finally) solidify that diagnosis you have suspected for quite some time.

Question 3.5.6 Since you do not put her in the low-risk category by your clinical judgment, what diagnostic study should you order?

- A) VQ (ventilation–perfusion) scan
- B) CT scan of the chest without contrast
- C) CT scan of the chest with contrast
- D) Pulmonary angiogram
- E) Compressive Dopplers of the lower extremities

Answer 3.5.6 The correct answer is “C.” The American College of Radiology (ACR) lists the CT scan of the chest with contrast (i.e., CT angiography or CTA) as the modality of choice in stable patients with a suspected PE. Its benefits: it is noninvasive, cheaper than pulmonary angiography, and far more available than VQ scans. It should be noted that pulmonary angiography still remains the “gold standard” for diagnosing pulmonary emboli, but that is more of an academic point. As for VQ scans, they are not available in many locales and often return nondiagnostic. However, they can be used in a patient *with a normal chest x-ray*. A V/Q scan is likely to be non-diagnostic in those with an abnormal chest x-ray (e.g., COPD patients). A chest CT without contrast (“B”) will not enhance the pulmonary arteries,

making the diagnosis of a PE far more difficult, if not impossible. Since most pulmonary emboli are believed to arise from the lower extremity venous system, “E,” Dopplers of the legs, could be considered if the patient was a poor candidate for both CTA and VQ scan (e.g., COPD and Stage 4 chronic kidney disease). But this approach is obviously not diagnostic of PE; it would just help you determine if the patient has an active thrombosis, and you would manage the same whether she has a PE or DVT or both.

**HELPFUL TIP:**

In pregnancy, both chest CT and V/Q scanning are acceptable imaging options and involve acceptable radiation levels (*Obstet Gynecol*. 2011;118(3):718–729).

As keenly suspected, Ms. Bellum’s CTA of the chest reveals a moderate-sized pulmonary embolus in the left pulmonary artery. Her vital signs are still stable and her pain is well-controlled with oral hydrocodone. She is surprised by the diagnosis you give her but appears to be taking it in stride.

Question 3.5.7 What is the optimal management plan for the patient moving forward?

- A) Bolus her with unfractionated heparin (UFH), start her on oral warfarin, and discharge her to home
- B) Start the patient on low-molecular-weight heparin (LMWH), initiate oral warfarin therapy, and admit the patient to the family medicine service
- C) Start apixaban (Eliquis) or rivaroxaban (Xarelto) and discharge to home
- D) Start her on oral warfarin and discharge her to home with primary care follow-up in the next 2 to 3 days
- E) B or C

Answer 3.5.7 The correct answer is “E.” Let’s dissect why. “A” and “D” are both incorrect because they do not include adequate anticoagulation. Certainly “B” is the classic approach. However, this patient meets the “HESTIA” criteria for early discharge from the ED (see Table 3-5), and need not be admitted, so many physicians now would choose discharge on a direct anticoagulant. Early discharge has been found to be safe in low-risk patients [those with all HESTIA criteria negative and a low Pulmonary Embolism Severity Index (*Ann Intern Med*. 2018;169(12):855–865 and *Acad Emerg Med*. 2018 Sep; 25(9):997–1003)]. To calculate the PESI, use an online calculator, such as <https://www.mdcalc.com/pulmonary-embolism-severity-index-pesi>. With regard to selecting an anticoagulant, current evidence does not support the use of one agent over another; UFH, LMWH, and fondaparinux followed by warfarin are all appropriate as are the newer agents (e.g., apixaban, dabigatran, and rivaroxaban). Both warfarin and dabigatran require an overlap with heparin. With UFH, LMWH, or fondaparinux transitioning to warfarin, continue these drugs until the patient’s INR has been therapeutic (INR of 2–3) for at least 24 hours and the overlap is for **at least 5 days**. Dabigatran requires 5 days of

TABLE 3-5 MODIFIED HESTIA CRITERIA FOR DISPOSITION OF PATIENT WITH A PULMONARY EMBOLISM

Modified HESTIA criteria: Any POSITIVE response mandates admission for PE treatment. If all are negative, check the Pulmonary Embolism Severity Index (PESI).

- Hemodynamically unstable by clinician judgment
- Thrombolysis or embolectomy needed
- Active bleeding or high risk for bleeding: GI bleeding or surgery ≤ 2 weeks ago, stroke ≤ 1 month ago, bleeding disorder or platelet count $< 75/L$, uncontrolled HTN (sBP > 180 or dBP > 110)
- Oxygen needed to maintain $SpO_2 > 90\%$
- PE diagnosed while on anticoagulation
- Requiring IV pain medication
- Medical or social reason for admission (e.g., concurrent infection, poor/no support system)
- Creatinine clearance < 30 mL/min by Cockcroft–Gault formula
- Severe liver impairment
- Pregnant
- Known history of heparin-induced thrombocytopenia

heparin overlap (and of course we don't check the INR). Avoid edoxaban (Savaysa) if possible. It can only be used in those with a CrCl of **less than** 95 mL/min. Also, it requires dose adjustment for those with a CrCl of between 50 and 15 mL/min (do not use under CrCl 15 mL/min).

Question 3.5.8 How long are you going to maintain this patient on anticoagulation?

- A) 3 months
- B) 6 months
- C) 9 months
- D) Lifetime

Answer 3.5.8 The correct answer is "A." For a PE that has a reversible cause (oral contraceptive pills in this patient with a long airplane trip), 3 months of anticoagulation is adequate. For those with a second PE, lifetime anticoagulation is warranted. For those with a cryptogenic PE or PE from an acquired or inherited thrombophilia (e.g., Factor V Leiden), recommendations are all over the place from 3 months to life. Nine months is likely adequate for a patient with a PE from an irreversible cause, *although patients go back to their pre-treatment risk as soon as you stop anticoagulation*. And, a first PE trumps everything else in terms of risk factors for a second PE—including all those fancy thrombophilia tests! So, finding a thrombophilia does not necessarily help your decision-making process. Note that some guidelines suggest anticoagulation for life after a first cryptogenic/unprovoked PE if benefit seems to outweigh risks. This should be decided after 3 months of anticoagulation (*Chest*. 2016;149(2):315–352).

**HELPFUL TIP:**

An elevated A–a gradient suggests a ventilation/perfusion mismatch and occurs in a number of conditions, including atelectasis, right-to-left shunt, acute respiratory distress syndrome (ARDS), air embolism, resolving severe asthma, COPD with oxygen treatment, and

bronchiectasis with impaired gas exchange. Thus, an elevated A–a gradient is not specific for PE. Likewise, a normal A–a gradient and normal oxygen saturation do not rule out PE! In fact, in patients without underlying lung disease, the PIOPED study found no difference in the oxygen saturation and A–a gradient among patients with and without PE.

**HELPFUL TIP:**

Only 88% of patients with a PE are hypoxic, 70% have dyspnea or tachypnea, 65% have pleuritic pain, and as few as 30% are tachycardic. The point here is to have a high clinical suspicion in the right situation despite the lack of the classic triad. To make things worse, the troponin and BNP can be elevated in patients with a PE.

**HELPFUL TIP:**

Compression stockings may prevent post-thrombotic syndrome, the recurrent swelling and edema often found after a DVT—or may not! Evidence is conflicting. Consider prescribing compression stockings routinely in these patients.

Thrombolysis is generally not indicated for a DVT unless there is impending gangrene (phlegmasia). It will prevent post-thrombotic syndrome with a number needed to treat (NNT) of 7 for proximal DVTs but doesn't change quality of life. This comes at the number needed to harm (NNH) of 1 in 22 patients requiring a blood transfusion, NNH of 1 in 11 developing a PE, and **NNH of 1 in 5 requiring a vena cava filter** (*JAMA Intern Med*. 2014;174(9):1494–1501).

Your patient does well, completes her course of apixaban, and has no further episodes over the next 2 years. She develops gallstones and plans to have an elective laparoscopic cholecystectomy. A surgeon colleague sends her back to see you for a preoperative evaluation. You find no evidence of cardiac, pulmonary, or hematologic disease. She is no longer on warfarin and is doing well.

Question 3.5.9 Which of the following postoperative management strategies do you recommend?

- A) Aspirin 81 mg PO daily
- B) Warfarin 5 mg PO daily
- C) UFH 5,000 units subcutaneously daily
- D) Enoxaparin 40 mg subcutaneously daily
- E) No antiplatelet or anticoagulant drugs

Answer 3.5.9 The correct answer is "D." Even for a relatively minor surgical procedure where anesthesia is used for 30 minutes or less and the postoperative recovery is usually quick, your patient is at moderate risk for venous thromboembolism. Her

history of PE puts her in a higher risk category, and she requires prophylaxis. Of the choices available, enoxaparin would be the most appropriate. LMWH and UFH are both acceptable for prevention of DVT/PE in the postoperative period, but “C” is wrong because UFH must be dosed every 8 to 12 hours rather than daily. “A” is incorrect. Aspirin is sometimes used postoperatively, but the dose should be 160 mg/day or greater. Also, compared with heparin and its derivatives, aspirin is less efficacious in the prevention of thrombus. “B” is incorrect. Warfarin alone is not appropriate in this setting due to its slow onset of action. Of course, early ambulation is also indicated.

HELPFUL TIP:

The optimal length of time that patients require prophylaxis for venous thromboembolism after surgery is unknown. Arguments can be made for prophylaxis until the patient is ambulating several hundred feet per day.

► Objectives: Did you learn to ...

- Recognize risk factors for a PE?
- Understand the variability of symptoms and signs in PE?
- Appreciate the PERC rules and Wells criteria and how they can be used to rule out a PE?
- Implement treatment and prevention for PE?
- Understand the A–a gradient?

QUICK QUIZ: VENA CAVAL FILTERS

Which statement best describes the use of vena caval filters in preventing PE?

- Vena cava filters reduce the risk of PE but only in patients who are maintained on anticoagulation
- Retrievable vena caval filters have been shown to have a *short-term* advantage while the patient is in the hospital; they should be removed as soon as possible
- Vena cava filters unequivocally reduce PE risk in both anticoagulated and non-anticoagulated patients
- One need not workup a patient for a PE in the presence of a vena cava filter, which is almost 100% effective.

The correct answer is “B.” All of the rest are wrong. All evidence suggests that vena caval filters are essentially useless in preventing PE (*JAMA*. 2015;313(16):1627). In addition, they can break with strut migration to the heart or through the vena cava. The 2016 ACCP guidelines recommend against vena caval filters in patients who can be anticoagulated even after a recurrent PE. And, they may increase mortality in those who have contraindications to anticoagulation (*JAMA Netw Open*. 2018;1(3):e180452). They may have some short-term benefit for inpatients such as with trauma. For patients with a recurrent DVT/PE while on anticoagulation, the proper approach is to accelerate the anticoagulation: if they are on warfarin, apixaban, dabigatran, or rivaroxaban, switch (at least temporarily) to enoxaparin; if they are on enoxaparin, increase the dose by 1/4–1/3.

► CASE 3.6

A 50-year-old male who is a heavy drinker with a history of squamous cell carcinoma of the neck presents to your office complaining of abdominal pain. He has been coughing and expectorating bloody sputum and notes a low-grade fever, chills, and mild dyspnea starting about 1 week ago. He denies nausea, emesis, and chest pain. His squamous cell carcinoma was treated with external beam radiation several years ago. Examination reveals an afebrile male in mild distress. His vital signs are normal, and his lungs sound clear. The abdominal examination reveals only mild epigastric tenderness.

The chest x-ray is available for your review (see Fig. 3-4). Your colleague, who is on call today, walks by and asks if you have any admissions for her.

Question 3.6.1 You consider this 50-year-old with a cough and reply:

- “Yes. This gentleman will need the ICU”
- “Yes. This gentleman will need a respiratory isolation room”
- “No. I’m sending this gentleman home with metronidazole”
- “No. I’ll workup this gentleman as an outpatient”

Answer 3.6.1 The correct answer is “B.” Because he is expectorating bloody sputum and has a cavitary lesion on chest x-ray (right upper lobe), this patient should be admitted to a respiratory isolation room until tuberculosis is ruled out. He will need further evaluation and possibly intravenous antibiotic therapy, both of which may be accomplished during his hospitalization. “A” is incorrect. There is no need to send this patient to the ICU based on his current picture. “C” is also incorrect. Metronidazole alone is not an appropriate therapy for this patient even if this is bacterial.

FIGURE 3-4. Question 3.6.1 patient’s chest x-ray.

Question 3.6.2 What is the best next step in the diagnosis of this process?

- A) Bronchoscopy
- B) Sputum cultures
- C) Blood cultures
- D) Chest CT
- E) Open-lung biopsy

Answer 3.6.2 The correct answer is “D.” The chest x-ray demonstrates a cavitary lesion in the right upper lobe. Chest CT is warranted for further characterization of the lesion. From history, examination, and chest x-ray, it is not possible to determine whether the lesion is an abscess or a malignant process. An indolent course with low-grade fever is characteristic of lung abscess. However, the pre-existing squamous cell carcinoma has potential to have spread to the lungs, and squamous cell carcinoma is known to cause cavitations. Culture of sputum and blood, including evaluation of first morning sputum for acid-fast bacilli (AFB), will be an essential part of the assessment but may not yield as much information as chest CT, and sputum culture should be done in conjunction with cytology and Gram stain. Bronchoscopy should be postponed until CT results are available. Bronchoscopic biopsy is potentially detrimental if the lesion is an abscess since the airway could flood with pus if the entire cavity wall is penetrated.

Chest CT further confirms a parenchymal abscess in the right upper lobe with cavitation and air within the cavity. Bronchoscopy reveals pus in the airway and extrinsic compression of the bronchi. A lavage sample is obtained, but biopsies are not taken due to the clinical impression that this is a lung abscess.

Question 3.6.3 What organisms are most commonly isolated in lung abscesses?

- A) Anaerobic bacteria
- B) Aerobic bacteria
- C) Tuberculosis
- D) Mixed aerobic/anaerobic bacteria

Answer 3.6.3 The correct answer is “A.” Anaerobes are isolated most often, followed by mixed anaerobic/aerobic bacteria, followed by aerobic bacteria alone (especially staphylococci).

Gram stain of sputum demonstrates Gram-positive cocci and Gram-negative rods. Cultures are pending. Tuberculin skin test is negative.

Question 3.6.4 What is the most appropriate therapy for this patient?

- A) Refer for surgical drainage
- B) Oral levofloxacin
- C) Intravenous clindamycin
- D) Intravenous metronidazole
- E) Intravenous ceftriaxone

Answer 3.6.4 The correct answer is “C.” Most lung abscesses are polymicrobial, but the most important aspect in treatment appears to be the use of an antibiotic active against anaerobes. Intravenous clindamycin is the usual choice for lung abscess due to its coverage of anaerobes and *Streptococcus pneumoniae*. Metronidazole is less effective, failing in up to 50% of cases of putrid lung abscess. A beta-lactam with beta-lactamase inhibitor (e.g., piperacillin/tazobactam) is another good choice. Ceftriaxone and levofloxacin offer poor coverage of anaerobes. Surgical drainage of lung abscesses is needed in only 5% to 10% of cases. Most resolve with just antibiotics.

► **Objectives: Did you learn to ...**

- Recognize the presence of a cavitary lesion on chest x-ray?
- Identify the common causes of cavitary lesions?
- Manage a patient with a lung abscess?

► **CASE 3.7**

A 53-year-old male is accompanied by his wife to your office and complains of a cough for 6 weeks. It is worse at night and any time he lies down. He denies sputum production, shortness of breath, chest pain, and wheezing. He takes an antacid once or twice per day to settle his stomach and notes very bad heartburn. He smoked three packs of cigarettes per day until 1 year ago, when he quit “cold turkey.” He takes only hydrochlorothiazide for hypertension. He has no cardiac disorders. His wife reports that he snores at night, and she adds, “He’s always hacking and clearing his throat—all night.” The review of systems is negative. In order to sleep better, he has recently started having a shot (or 2 . . . or 3 . . .) of whiskey before going to bed.

Question 3.7.1 What is the most likely cause for the cough?

- A) Gastroesophageal reflux
- B) Lung cancer
- C) Antihypertensive medication
- D) Alcohol abuse
- E) Congestive heart failure (CHF)

Answer 3.7.1 The correct answer is “A.” This patient appears to have a chronic cough that is most likely due to gastroesophageal reflux disease (GERD). He takes antacids and exhibits throat clearing, which can be a subtle sign and is not typically identified by patients as reflux. In addition, he drinks alcohol at bedtime, further predisposing to reflux. He has a history of smoking, which does place him at increased risk for developing a bronchogenic carcinoma, but a lung mass would not be a common cause for cough. Hydrochlorothiazide is not known to cause cough (although angiotensin-converting enzyme [ACE] inhibitors are). Also, it is unlikely that symptoms would be isolated to nighttime if his cough were medication-related.

**HELPFUL TIP:**

Remember that ACE inhibitors may cause cough in 5% to 20% of patients taking them. For patients who develop a cough and are on an ACE inhibitor, a brief trial off the medication may save a costly workup for chronic cough. Usually, symptoms resolve within 1 week but may persist for 1 month. Cough due to an ACE inhibitor may first occur up to 6 months after starting the ACE inhibitor.

**HELPFUL TIP:**

Asymptomatic reflux disease does not exacerbate asthma. So, don't blame asthma on *asymptomatic* nocturnal reflux (*Am J Respir Crit Care Med.* 2009;180(9):809–816 and *N Engl J Med.* 2009;360(15):1487–1499).

On physical examination, you note a mildly overweight male in no distress. His vital signs are normal. His lungs are clear to auscultation. The nasal and oropharyngeal mucosae are intact, moist, and not inflamed. The remainder of the examination is unremarkable. Chest x-ray shows flattened diaphragms but is otherwise negative. You suspect GERD, but also entertain other diagnoses.

Question 3.7.2 Which of the following is your next step in managing this patient's cough?

- A) Start a proton pump inhibitor
- B) Start an inhaled steroid
- C) Order 24-hour esophageal pH monitoring
- D) Obtain spirometry
- E) Obtain a chest CT

Answer 3.7.2 The correct answer is "A." An empiric trial of an effective gastric acid-suppressing medication in this *symptomatic patient* is likely to relieve the cough if the diagnosis is accurate. The ACCP recommends starting therapy with a proton pump inhibitor rather than an H₂-blocker. The usual anti-reflux measures, such as avoiding fatty foods, alcohol, and food before bedtime, should be instituted as well. Prescribers must be aware that sometimes a complete resolution of cough takes months. A 24-hour pH monitor ("C") is invasive and often not necessary if an empiric trial of gastric acid suppression resolves the problem. Starting the evaluation of chronic cough with a chest x-ray is part of the ACCP recommendations, but CT scan ("E") is not indicated with a negative chest x-ray. If the cough does not resolve with empiric therapy, spirometry should be considered.

He does not respond after 2 months of empiric treatment, and he is becoming more concerned. The examination is unchanged. Spirometry is normal with a normal flow volume loop.

Question 3.7.3 Which of the following management options is LEAST likely to benefit this patient?

- A) Combination antihistamine and decongestant
- B) Inhaled corticosteroid
- C) Inhaled beta-2 agonist
- D) Antibiotics

Answer 3.7.3 The correct answer is "D." This patient has no signs or symptoms of sinusitis or bacterial pulmonary infection, so treating with an antibiotic is inappropriate and unlikely to help. However, some form of empiric therapy might be tried. He could have postnasal drainage without signs on physical examination, and empiric therapy with combination antihistamine and decongestant may improve the cough. Inhaled corticosteroids and beta-2 agonists are the mainstay of chronic asthma therapy and may help relieve this patient's chronic cough. This patient could yet have "cough-variant asthma" despite normal spirometry results.

Question 3.7.4 The three most common causes of chronic cough (cough lasting longer than 8 weeks) are:

- A) Postnasal drip, asthma, GERD
- B) GERD, COPD, congenital lung disease
- C) Lung cancer, postnasal drip, COPD
- D) Obstructive sleep apnea, respiratory infections, asthma

Answer 3.7.4 The correct answer is "A." Epidemiologic studies have demonstrated that most cases of chronic cough are due to postnasal drainage (often termed "upper airway cough syndrome"), asthma, or symptomatic GERD. Most cases of chronic cough seem to have only a single cause, although some will have more than one cause. Empiric therapy should be aimed at these top three causes. Of course, infection (pertussis in particular), malignancy, and other causes of cough are important to consider—and potentially rule out—as well.

The evaluation of chronic cough should proceed in a logical manner. Usually, history and physical examination will find the cause. If this is unrevealing, consider a stepwise evaluation addressing each of the chronic etiologies in Table 3-6 in order. If this still does not give you an answer, consider a methacholine challenge test to see if you can reproduce the symptoms that would lead you to a presumptive diagnosis of asthma with normal spirometry.

TABLE 3-6 SELECTED COMMON CAUSES OF ACUTE AND CHRONIC COUGH

Acute	URI, pertussis, allergic rhinitis, COPD exacerbation, asthma, acute sinusitis
Chronic	GERD, postnasal drip, asthma, chronic sinusitis, allergic/vasomotor rhinitis, ACE inhibitors, eosinophilic bronchitis, chronic bronchitis, postinfectious asthma

ACE, angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; GERD, gastroesophageal reflux disease; URI, upper respiratory infection.

**HELPFUL TIP:**

Look in the ears—cerumen impaction can cause a chronic cough and is often overlooked. Remember medications, especially ACE inhibitors (as above); other drugs that can cause cough include amiodarone, ARBs (lower risk than ACEIs), olanzapine, and some asthma medications (e.g., albuterol, montelukast).

► **Objectives: Did you learn to ...**

- Recognize the most common causes of chronic cough?
- Evaluate a patient with chronic cough?
- Develop a management plan for chronic cough?

► **CASE 3.8**

You see a 38-year-old female in follow-up for a recent episode of sinusitis. The illness has been present for about 6 weeks and has not responded to 2 weeks of appropriate antibiotics. She continues to have intermittent nosebleeds, fatigue, arthralgias, low-grade fevers, and night sweats. Two new complaints have surfaced: she has a cough productive of white sputum and she occasionally expectorates quarter-sized clots of blood. She has pleuritic chest pain, but denies dyspnea, tobacco use, and cardiac or pulmonary disease.

She is afebrile with a respiratory rate of 16, blood pressure 120/74 mm Hg, and pulse rate 92 bpm. Her oxygen saturation is 98% on room air. There is dried blood in the nares, but the oropharynx is clear. Cardiac and pulmonary examinations are unremarkable.

Question 3.8.1 Which initial test is most appropriate?

- A) Chest x-ray
- B) Sputum cytologic analysis

- C) Bronchoscopy
- D) Chest CT
- E) CBC

Answer 3.8.1 The correct answer is “A.” Hemoptysis is alarming to the patient and the physician—we hope. A stepwise approach is warranted with chest x-ray as the first step. Sputum for cytology might help if the suspicion for lung cancer was substantial, but the yield is likely to be low here. She may eventually require bronchoscopy if suggested by initial studies. Chest CT is likely to be part of the evaluation, but a chest x-ray should be performed first. Obtaining blood for a CBC is also important, although likely to be normal in the setting of minor hemoptysis.

You obtain the chest x-ray pictured in Fig. 3-5.

You obtain the following laboratory results:

CBC: Leukocytosis, thrombocytosis, and normochromic, normocytic anemia

ESR: 70 mm/hr

Urine dipstick: Positive for protein, heme, and red cells

Question 3.8.2 Which of the following tests will best assist you in the diagnosis of this patient?

- A) Antineutrophil cytoplasmic antibody (ANCA)
- B) Antiglomerular basement membrane antibody
- C) Antinuclear antibody (ANA)
- D) A and B
- E) A and C

Answer 3.8.2 The correct answer is “D.” This patient is presenting with the classic triad of granulomatosis with polyangiitis (GPA), a disease of the upper respiratory tract, lower respiratory tract, and kidneys, formerly known as Wegener’s granulomatosis (as a response to Wegener’s association with the Nazi Party, professional bodies and journals have replaced his name

FIGURE 3-5. Patient’s chest x-ray.

with a descriptive name). She has some of the additional signs and symptoms associated with GPA, as well. Common findings include pleuritic chest pain, myalgias, arthralgias, ptosis, fever, weight loss, and purpuric skin lesions, among others.

ANCA, and especially c-ANCA that is more specific for GPA, is present in up to 90% of patients with GPA. An ANA is not helpful in diagnosing GPA. An antiglomerular basement membrane antibody (anti-GBM) may be helpful in diagnosing Goodpasture syndrome (named for an American pathologist—not a Nazi—so he gets to keep the eponym). Goodpasture syndrome can be clinically easily confused with GPA; they both present with respiratory and renal involvement. Thus, anti-GBM antibody will be helpful in differentiating these two. However, about 10% of patients with Goodpasture syndrome will also have GPA—just to add to the confusion. For a partial list of causes of hemoptysis, see Table 3-7.

Question 3.8.3 Which of the following is NOT a radiographic finding of granulomatosis with polyangiitis?

- A) Nodules that may be cavitory
- B) Alveolar opacification
- C) Pleural opacities
- D) Widened mediastinum

Answer 3.8.3 The correct answer is “D.” A widened mediastinum is not one of the classic findings in GPA. However, one may, on occasion, see hilar adenopathy. All of the other choices can be found in GPA. In the patient’s x-ray (Fig. 3-5), a right upper lobe mass is easily distinguished. In a young, non-smoking female presenting with these symptoms, such a lung mass should lead to the consideration of GPA or possibly an infectious process. She is less likely to have a malignant process.

HELPFUL TIP:

A major, and probably the most common cause, of hemoptysis is bronchitis. This is especially true in smokers and the elderly.

The diagnostic evaluation is in progress. Laboratory tests are pending, and a chest CT is scheduled. You have arranged for a

pulmonologist to see her. When you are on call, the physician covering the ED calls you to admit her for “massive hemoptysis.” When you arrive, the patient looks comfortable and has normal vital signs. She begins a fit of coughing, expectorating several ounces of bright red blood. Her systolic blood pressure falls to 80 mm Hg. Her respiratory rate is 40. Her work of breathing has increased considerably. The situation does not improve after 5 minutes of observation, and her O₂ saturation is now 83% on room air.

Question 3.8.4 Remembering the movie *Moulin Rouge* (which has nothing to do with this case except for hemoptysis), what is your first action in this situation?

- A) Arrange emergent bronchoscopy
- B) Transfuse 2 units of blood
- C) Perform endotracheal intubation
- D) Provide bolus IV normal saline

Answer 3.8.4 The correct answer is “C.” Massive hemoptysis is variably defined as 100 to 600 mL of blood expectorated per day, and it can result in hemodynamic compromise and asphyxiation. Quantification of the blood loss by the patient is usually unreliable. The main cause of mortality with hemoptysis is not hypovolemia but rather asphyxiation from blood in the lungs. As with any patient in acute respiratory distress, the airway must be controlled first. The best choice here is to perform intubation. Since this patient is known to have a potential source for bleeding in the right lung, intubation of the left mainstem bronchus may protect the left lung from the blood. Also, placing this patient on her right side (so that the bleeding source is dependent) may protect the left lung. If available, emergent bronchoscopy may allow identification of the bleeding site and selective lung intubation. However, bronchoscopy is not well suited for stopping the hemorrhage. The most that a bronchoscopist can do is place an endobronchial blocker and seal off the bleeding lobe. Interventional radiology should usually be the first treatment once the bleeding site has been localized. Emergent surgery is indicated if the bleeding remains brisk and not responsive to other interventions. Fluid resuscitation is important. However, before any of these other measures is undertaken, the airway must be protected.

TABLE 3-7 CAUSES OF HEMOPTYSIS

Vascular	PE, vasculitides (Goodpasture syndrome, granulomatosis with polyangiitis), arteriovenous malformation
Neoplastic	Bronchogenic carcinoma, metastatic disease
Connective tissue	Lupus, rheumatoid arthritis
Cardiac	CHF, mitral stenosis
Infectious	TB, bronchitis, pneumonia, abscess
Drugs	Anticoagulants, cocaine, solvents
Miscellaneous	Trauma, foreign body, epistaxis, hematemeses

CHF, congestive heart failure; PE, pulmonary embolism.

HELPFUL TIP:

It is important to understand that patients with hemoptysis do not die of exsanguination but rather drown in their own blood—which is such a more pleasant image. The volume of blood needed to cause asphyxiation is surprisingly low and nowhere near the volumes that GI bleeders lose. Of note, small volume hemoptysis may be clinically significant in patients with underlying lung disease such as COPD due to less reserve and increased dead space. Also, a low oxygen saturation will occur long before you notice any change in the hemoglobin. Therefore, serial hemoglobins make little sense in hemoptysis patients.

The patient stabilizes in the ICU. You plan to start treatment for her granulomatosis with polyangiitis. She does better and is discharged in 2 days.

HELPFUL TIP:

The 5-year mortality of untreated granulomatosis with polyangiitis is 90%. These patients need aggressive treatment. Cyclophosphamide + steroids or rituximab + steroids seem to be the best combinations.

► Objectives: Did you learn to ...

- Perform an appropriate evaluation on a patient with hemoptysis?
- Recognize the major causes of hemoptysis?
- Diagnose granulomatosis with polyangiitis?
- Identify and treat massive hemoptysis?

► CASE 3.9

A 35-year-old African-American female presents with dyspnea worsening over the last 2 months. She also complains of cough, generalized fatigue, and intermittent low-grade fevers. She does not smoke. Chest x-ray shows hilar adenopathy and small bilateral pleural effusions. Spirometry is consistent with a restrictive pattern.

Question 3.9.1 Of the following, which is the most likely diagnosis?

- A) Granulomatosis with polyangiitis
- B) Sarcoidosis
- C) Bronchogenic carcinoma
- D) Pneumonia
- E) Microscopic polyangiitis

Answer 3.9.1 The correct answer is “B.” The findings of hilar lymphadenopathy and a restrictive pattern on spirometry are most consistent with sarcoidosis. The chest x-ray findings do not support the diagnosis of granulomatosis with polyangiitis. Besides, it can’t be “A”—we just did that case (and when would you see two GPA cases in a row on a test—let alone in your career?). “E” is incorrect. Microscopic polyangiitis is a systemic vasculitis related to GPA, presenting with similar features as GPA but without granulomatous disease. Bronchogenic carcinoma (“C”) is unlikely in this relatively young non-smoker who does not demonstrate findings of carcinoma on x-ray. The clinical history is not typical of pneumonia (“D”), and chest x-ray shows no infiltrate. Tuberculosis (TB), although not an answer option, should also be considered, and the appropriate history and testing should be completed. In fact, TB and sarcoidosis often present in a similar fashion as may some fungal diseases and others.

Question 3.9.2 Which of the following is NOT commonly associated with sarcoidosis?

- A) Hypercalcemia
- B) Elevated ACE levels

- C) Reduced diffusion capacity
- D) Hypothyroidism
- E) Facial or peripheral nerve palsy

Answer 3.9.2 The correct answer is “D.” Sarcoidosis is marked by the presence of non-caseating granulomas. While sarcoid can infiltrate the thyroid, it rarely, if ever, causes hypothyroidism. Pulmonary sarcoidosis includes a decreased diffusion capacity and decreased vital capacity. Other laboratory findings include hypercalcemia, hypercalciuria, elevated liver and pancreatic enzymes, and elevated ACE levels. Neurologic involvement occurs in up to 5% of patients and frequently presents as facial paralysis but may present as any central nervous system lesion. Peripheral nerves may also be involved.

Question 3.9.3 Which of the following is NOT found as a part of sarcoidosis?

- A) Erythema nodosum
- B) Myocardial infarction
- C) Cardiac arrhythmias
- D) Elevated liver enzymes
- E) Vision loss

Answer 3.9.3 The correct answer is “B.” Sarcoidosis does not cause myocardial infarctions. While there is cardiac involvement with sarcoidosis, the manifestations are bundle branch block, cardiac arrhythmias, and sudden death. Many organs can be affected by sarcoidosis, including the skin, eye (iritis), heart, lung, liver, nervous system—essentially anywhere granulomas form.

Question 3.9.4 Which of the following is true about ACE levels in sarcoidosis?

- A) An elevated ACE level is specific for sarcoidosis
- B) ACE levels often correlate with disease severity in sarcoidosis
- C) ACE inhibitors are effective in the treatment of sarcoidosis
- D) All of the above

Answer 3.9.4 The correct answer is “B.” One can follow ACE levels to track the progress of the disease. However, since treatment is based on symptoms, following ACE levels is not recommended. “A” is incorrect. ACE levels may be elevated in silicosis, miliary TB, and asbestosis, among others. “C” is incorrect. ACE inhibitors are not used to treat sarcoidosis.

This patient is found to have only pulmonary sarcoidosis with some mild systemic symptoms.

Question 3.9.5 Which of the following is the best initial choice for management?

- A) Observation
- B) Oral corticosteroids
- C) Oral antibiotics
- D) Inhaled corticosteroids
- E) Methotrexate

Answer 3.9.5 The correct answer is “A.” This patient has apparent pulmonary-limited disease and has minimal systemic

symptoms. Nearly 50% of patients with sarcoidosis may have spontaneous resolution of their symptoms without treatment. In fact, treatment may actually prolong the disease process. If her pulmonary or systemic symptoms worsen or are causing major life problems, she should be started on oral steroids. Systemic corticosteroid therapy is the mainstay of treatment for sarcoidosis. Methotrexate and other immune-modulating drugs may be employed as well and offer a steroid-sparing effect, but these are not first-line agents. Evidence for the use of inhaled corticosteroids is lacking. Antibiotics are not effective.

► **Objectives: Did you learn to ...**

- Recognize the clinical manifestations of sarcoidosis?
- Manage a patient with mild sarcoidosis?

► **CASE 3.10**

A 57-year-old male with no prior medical history comes in to clinic with a 1-week history of right rib pain and low-back pain. The rib pain is worse with deep breaths and especially bothers him at night. There has been no trauma. He has lost 20 lb in the last 3 months. He has a cough productive of white sputum. He denies any other symptoms. He smokes one to two packs of cigarettes per day but does not drink alcohol.

Vital signs: temperature 36.5°C, pulse rate 95 bpm, blood pressure 110/70 mm Hg, respiratory rate 16. On room air, his oxygen saturation is 96%. There is no adenopathy. His lung sounds are clear on the left and decreased on the right. There is dullness to percussion and decreased tactile fremitus over the right lower lung field.

Question 3.10.1 Based on this patient's history and physical examination, what do you expect to find on chest x-ray?

- A) Normal chest x-ray
- B) Cavitory lung lesion
- C) Pleural effusion
- D) Expanded lung fields
- E) Pneumothorax

Answer 3.10.1 The correct answer is "C." This patient's findings suggest pleural effusion. Everything is diminished in pleural effusion: there is dullness to percussion, decreased breath sounds, decreased tactile fremitus, and decreased voice transmission. A cavitory lung lesion presents with either a normal examination or findings similar to an infiltrate (e.g., crackles, increased fremitus, and dullness to percussion). Expanded lung fields on chest x-ray are often seen in patients with COPD or asthma, and examination findings include prolonged expiratory phase, wheezing, and resonance to percussion. Pneumothorax presents with hyperresonance to percussion, decreased breath sounds, and decreased fremitus.

HELPFUL TIP:

Chest radiographs have a low sensitivity for rib fractures. However, this is really not a problem. The presence or

absence of a rib fracture is generally immaterial. What we are interested in is whether or not there is anything underlying the rib fracture, such as a pulmonary contusion or hemothorax.

Your suspicions are confirmed. The chest x-ray shows obliteration of the right hemidiaphragm, and the posterior costophrenic angle is obscured on the lateral view, consistent with pleural effusion. There is also a right upper lobe lung mass.

Question 3.10.2 Which of the following will provide the most information and guidance for your thoracentesis?

- A) Supine chest x-ray
- B) Chest CT
- C) Lateral decubitus chest x-ray
- D) Chest ultrasound
- E) Apical view chest radiograph

Answer 3.10.2 The correct answer is "D." Prior to performing a thoracentesis, you must know whether the effusion is loculated or freely flowing. Portable ultrasound has become a validated and widely accepted modality to diagnose and assess pleural effusion. Also, ultrasonography has been found to be more sensitive for detection of pleural fluid than a chest radiograph. Chest CT is somewhat more sensitive but more cumbersome, exposing the patient to additional radiation, and does not allow a bedside diagnosis and treatment. A decubitus film, with the affected side down, would allow you to see the effusion "layer out" unless it is loculated but again is less sensitive. A supine chest x-ray may cause the effusion to "layer out" too, but you will not be able to see it as well, which is why effusions may be missed when a patient is unable to stand or sit upright for his x-ray.

Question 3.10.3 Relative and absolute contraindications to thoracentesis include all of the following EXCEPT:

- A) Herpes zoster in the area of needle placement
- B) Coagulopathy
- C) Diaphragmatic rupture
- D) Positive pressure ventilation
- E) History of recurrent laryngeal nerve injury or compromise

Answer 3.10.3 The correct answer is "E." Absolute contraindications include chest wall compromise (e.g., burn, cellulitis, herpes zoster, ruptured diaphragm) and cases where chest tube thoracostomy would be more appropriate. Relative contraindications are poor patient cooperation, coagulopathy, anticoagulation therapy, very small effusions (<10 mm on decubitus film view), positive pressure ventilation, and pleural adhesions.

Question 3.10.4 On ultrasound, the effusion appears free flowing and not loculated. What is the most appropriate next step?

- A) Referral for surgical drainage
- B) Place a chest tube to drain the effusion

- C) Perform an ultrasound-guided diagnostic thoracentesis at the bedside
- D) Order two pizzas, one for you and one for the patient (you have both had a long day and are hungry)

Answer 3.10.4 The correct answer is “C.” The patient has a relatively large pleural effusion. Ultrasound-guided thoracentesis is a good first step in evaluating this effusion. Ultrasound guidance is quickly becoming the standard of care as it has been shown to decrease complications of pneumothorax as well as the number of unsuccessful clinical attempts or “dry taps.” Referral to a thoracic surgeon (“A”) may eventually be necessary, but this would not be the first step. Placing a chest tube (“B”) into an effusion is not recommended at this point, and the diagnostic study should be obtained first.

Ultrasound-guided thoracentesis is successful in obtaining fluid. The fluid is amber and cloudy, with a pH 7.3, lactate dehydrogenase (LDH) 800 IU/L, glucose 65 mg/dL, total protein 5.5 g/dL, WBC 1,300/mm³, RBC 50,000/mm³. Serum studies done the same day include LDH 155 IU/L, glucose 99 mg/dL, and total protein 7 g/dL. Cytology, Gram stain, and culture of the pleural fluid are pending.

Question 3.10.5 Which of the following is the most accurate statement regarding the pleural fluid analysis?

- A) The fluid is due to infection
- B) The fluid is due to cancer
- C) The fluid is a transudate
- D) The fluid is an exudate

Answer 3.10.5 The correct answer is “D.” Pleural effusions are broadly categorized as exudates and transudates (see Tables 3-8 and 3-9). Such a categorization helps to narrow the differential diagnosis. In this case, several elements of the pleural fluid are consistent with an exudate. LDH and protein can be used to determine whether the pleural fluid is transudative or exudative. Per Light’s criteria, a pleural effusion is *suggestive* of an exudative process if two of any of the following criteria are met: pleural fluid LDH $>2/3$ the upper limit of normal serum LDH, a pleural LDH:serum LDH ratio of >0.6 , and a pleural protein:serum protein ratio of >0.5 . All three of these indicators point to an exudate in this case. Also, exudative effusions tend to have a higher degree of cellularity than transudative effusions. With the information given, it is difficult to determine if the effusion is related to infection, cancer, or some other process.

TABLE 3-8 CATEGORIZATION OF PLEURAL FLUID AS AN EXUDATE OR TRANSUDATE

Exudate characterized by

- Pleural fluid to serum protein ratio >0.5
- Pleural fluid to serum LDH ratio >0.6
- Pleural fluid LDH greater than 150 mg/dL (two-thirds the upper limit of normal serum LDH)

TABLE 3-9 CATEGORIZATION OF PLEURAL EFFUSIONS BY CLASS (TRANSUDATE VERSUS EXUDATE)A

Type of Effusion	Potential Causes
Transudative effusions	Heart failure, cirrhosis, nephritic syndrome, atelectasis, myxedema, pulmonary embolism, urinothorax
Exudative effusions	Bronchogenic carcinoma, metastatic neoplasm, mesothelioma, pneumonia, TB, chylothorax, pancreatitis, esophageal rupture, collagen vascular diseases (rheumatoid arthritis, Sjögren syndrome), trauma, drugs (nitrofurantoin, amiodarone, methotrexate), heart failure with diuretic therapy, pulmonary embolism

Note: Heart failure and pulmonary embolism can cause exudative and transudative effusions.

^aSee *exudate* criteria (Table 3-8). Everything else is a transudate.

The pleural fluid cytology comes back negative. The patient’s symptoms and examination have not changed. Repeat radiograph still shows an upper lobe mass.

Question 3.10.6 What is the most appropriate next step in approaching this pleural effusion?

- A) Await pleural fluid culture results
- B) Perform bedside chest tube drainage of the effusion
- C) Refer for surgical evacuation of the effusion
- D) Refer for bronchoscopy
- E) Place a chest tube for chemical pleurodesis

Answer 3.10.6 The correct answer is “D.” The effusion is clearly exudative, and the patient appears to have a lung mass. Biopsy of the lung mass via bronchoscopy is indicated. A negative pleural fluid cytology does not rule out lung cancer. Positive cytology indicates advanced stage lung cancer. Chest tube drainage of a pleural effusion is not recommended except under extraordinary circumstances. Intermittent thoracentesis is preferred and has lower morbidity. Surgical evacuation of the fluid would be indicated if the patient were symptomatic, and the effusion was loculated and/or related to infection. If the effusion grows, or is drained and recurs, it may respond to pleurodesis. Otherwise, pleurodesis is not indicated at this time.

HELPFUL TIP:

Patients with malignant pleural effusions are not likely to benefit from surgery since the tumor is not localized and is not resectable by this point. Long-term outcomes with a malignant pleural effusion are bleak.

Now that you have gained expertise with ultrasound of a pleural effusion, your colleague sends you a patient that has a pleural effusion on chest x-ray. Your colleague asks you

whether you could “tap” the fluid for him as he does not feel comfortable with the portable ultrasound. Also, he has a tee time in 30 minutes.

Question 3.10.7 On ultrasound, you quickly visualize the chest and see a septated and loculated pleural effusion. What is the best next step?

- A) Return the patient back to his doctor—the effusion is too small to access
- B) Perform ultrasound-guided needle thoracentesis
- C) Refer to a thoracic surgeon
- D) Place a small-bore chest tube
- E) Head to the golf course with your colleague. Nothing you can do here

Answer 3.10.7 The correct answer is “C.” A loculated and septated pleural effusion can very often be seen in empyema and evacuation usually requires surgical intervention. Thoracentesis would unlikely be successful and would expose the patient to an unnecessary procedure after which he would still need to see a surgeon. Placing a chest tube blindly into a loculated pleural effusion is unsafe. That procedure should be done under visualization; most commonly, video-assisted thoracic surgery would be utilized. Intrapleural fibrinolytics may improve outcomes but should be done in consultation with a thoracic surgeon or pulmonologist.

► **Objectives: Did you learn to ...**

- Recognize the historical and physical examination findings of pleural effusion?
- List potential etiologies of pleural effusion?
- Narrow the differential diagnosis based on pleural fluid findings?
- Decide when to perform diagnostic and therapeutic thoracentesis?
- Decide when to perform chest tube drainage?

► CASE 3.11

A 60-year-old male presents to the ED for a cough. His symptoms began with a cold 2 weeks ago, and the other symptoms have improved, but the cough has persisted. He has mild production of white sputum with no hemoptysis. The patient denies fevers, night sweats, chills, and weight loss. He’s had no chest pain or dyspnea. He smokes one pack of cigarettes per day, works in construction, and does not have a regular doctor. In fact, with some pride, he says, “I haven’t seen a doctor in over 30 years.” On physical examination, you find a fit-appearing male in no acute distress. His vital signs are normal. His lung sounds are diminished bilaterally, but the remainder of the examination is unremarkable. While breathing ambient air, the patient’s oxygen saturation is 94%. You obtain a chest x-ray, which is shown in Fig. 3-6.

Question 3.11.1 Your next step is to:

- A) Prescribe a 5-day course of azithromycin
- B) Refer the patient to a pulmonologist

FIGURE 3-6. Question 3.11.1 patient’s chest x-ray.

- C) Order a high-resolution CT scan of the chest
- D) Have the patient return to you in 3 months to repeat a chest x-ray
- E) Reassure the patient and have him return as needed

Answer 3.11.1 The correct answer is “C.” The chest x-ray in Fig. 3-6 shows a single nodule in the right lower lobe. The nodule is round, less dense than bone, and appears to be >1 cm in diameter. These are sometimes called “coin lesions.” There are no other abnormalities. The most appropriate next step in the evaluation is to order a high-resolution CT scan of the chest. Treatment with azithromycin is inappropriate in this setting, as this patient has no signs of pulmonary infection on examination or chest x-ray. Referral to a pulmonologist is premature without first investigating the nodule by CT scan. Delaying further imaging and evaluation is also inappropriate since 15% to 75% of solitary pulmonary nodules (SPNs) ≥ 8 mm are ultimately diagnosed as cancer.

Question 3.11.2 Which of the following is NOT considered a benign pattern of calcification on CT scan?

- A) Diffuse, homogeneous calcification
- B) Central calcification
- C) Laminar calcification
- D) Spiculated, irregular calcification
- E) “Popcorn” calcification

Answer 3.11.2 The correct answer is “D.” We are accustomed to thinking of calcified nodules as being benign, but that is not always the case. Irregular, spiculated calcification is not reassuring. The other options are considered indicative of a benign lesion. Two patterns on CT are relatively specific for cancer: a scalloped border and the corona radiata sign, which is composed of fine linear strands extending out from the nodule.

Question 3.11.3 All of the following are useful to help assess the risk of cancer in a patient with a solitary pulmonary nodule (SPN) EXCEPT:

- A) Smoking status
- B) Age
- C) Diameter of the nodule
- D) Gender

Answer 3.11.3 The correct answer is “D.” Determining the probability of cancer in patients with an SPN is an inexact science. The risk of cancer is generally assessed as low, intermediate, or high based on patient and radiograph characteristics. Although men are slightly overrepresented in lung cancer diagnoses, this is generally thought to be due to greater smoking rates in men and to occupational hazards. Gender itself does not help to risk-stratify patients with an SPN. Smoking increases the risk of an SPN being cancer, with greater use increasing the risk of cancer. As with most cancers, increasing age is associated with a higher risk. The diameter of the nodule is also important. If the diameter is <8 mm, the risk of cancer is low. When the diameter is ≥ 3 cm, the SPN is now referred to as a “pulmonary mass” and is highly likely to be cancerous. An SPN >3 cm in diameter should be considered cancer until proven otherwise.

The Fleischner Society has published an updated set of widely accepted recommendations regarding follow-up of incidentally found pulmonary nodules in 2017. The guideline does not apply to patients <35 years or with a history of cancer or immunosuppression (see Table 3-10).

HELPFUL TIP:

There is a calculator to help you determine the risk of malignancy for SPNs: <http://reference.medscape.com/calculator/solitary-pulmonary-nodule-risk> (this is the Mayo Clinic model). Another calculator based on the Fleischner criteria is at MD-Calc.

Later that week, your patient returns with his CT scan in hand. His cough is somewhat better (therapeutic CT scan radiation therapy ... you know, like those CT scans in California that were mis-programmed and cooking people’s brains accidentally? Really ...). You review the CT scan with him. It shows a round, smooth nodule measuring 2 cm in diameter and located in the periphery of the right lower lobe. There are no calcifications in the nodule and no other abnormalities.

Question 3.11.4 Which of the following is the most appropriate next step?

- A) Referral for bronchoscopy
- B) High-resolution CT scan every 3 months
- C) Chest x-ray every 3 months
- D) Bone scan
- E) Referral to a thoracic surgeon

Answer 3.11.4 The correct answer is “E.” This patient needs a biopsy. There are several factors that put your patient at higher

TABLE 3-10 FLEISCHNER SOCIETY 2017 GUIDELINES FOR MANAGEMENT OF INCIDENTALLY DETECTED PULMONARY SOLID NODULES IN ADULTS

Nodule Type	Size			Comments
	<6 mm (<100 mm ³)	6–8 mm (100–250 mm ³)	>8 mm (>250 mm ³)	
Single				
Low risk	No routine follow-up	CT at 6–12 months, then consider CT at 18–24 months	Consider CT at 3 months, PET/CT, or tissue sampling	Nodules <6 mm do not require routine follow-up, but certain patients at high risk with suspicious nodule morphology, upper lobe location, or both may warrant 12-month follow-up (recommendation 1A).
High risk	Optional CT at 12 months	CT at 6–10 months, then CT at 18–24 months	Consider CT at 3 months, PET/CT, or tissue sampling	Nodules <6 mm do not require routine follow-up, but certain patients at high risk with suspicious nodule morphology, upper lobe location, or both may warrant 12-month follow-up (recommendation 1A).
Multiple				
Low risk	No routine follow-up	CT at 3–6 months, then consider CT at 18–24 months	CT at 3–6 months, then consider CT at 18–24 months	Use most suspicious nodule as guide to management. Follow-up intervals may vary according to size and risk (recommendation 2A).
High risk	Optional CT at 12 months	CT at 3–6 months, then at 18–24 months	CT at 3–6 months, then at 18–24 months	Use most suspicious nodule as guide to management. Follow-up intervals may vary according to size and risk (recommendation 2A).

Notes: These guidelines apply to newly detected indeterminate nodules in persons 35 years of age or older. Low-risk patients have minimal or absent history of smoking and no other known risk factors. High-risk patients have a history of smoking or of other known risk factors.

risk of having a malignant cause for the SPN, including his age and tobacco use. These put him into an intermediate- to high-risk category for cancer. Although the nodule is smooth on CT, its size is >8 mm and there are no calcifications. This patient should be referred for transthoracic fine-needle biopsy or open biopsy. “A” is tempting but incorrect. Bronchoscopy is insensitive in the peripheral lung, especially when the lesion is relatively small. “B” and “C” are also wrong here but are appropriate in other settings. In this case, repeat imaging over time may delay a diagnosis of malignancy. Without symptoms of bone pain or confirmation that the SPN is a cancer that might metastasize to bone, a bone scan will have a very low yield.

Your patient returns from the surgeon much relieved. Fine-needle biopsy proved the SPN to be a hamartoma. Now your patient wants to quit smoking for good, and he thinks that he will need some assistance. You recommend nicotine replacement products and bupropion, but your patient claims to have had an allergic reaction to bupropion. Fortunately, you know of an effective alternative.

Question 3.11.5 To assist with tobacco cessation, you prescribe which of the following?

- A) Varenicline
- B) Fluoxetine
- C) Olanzapine
- D) Metoprolol
- E) Clonidine

Answer 3.11.5 The correct answer is “A.” Randomized trials have demonstrated the effectiveness of the nicotine partial agonist, varenicline (Chantix). This FDA-approved medication appears to be at least as effective as bupropion as an aid to smoking cessation. It had been thought that varenicline caused psychiatric side effects. This has been disproven in randomized, post-marketing, trials. Varenicline seems safe even for those with psychiatric disorders. However, the FDA still suggests that patients who develop depression, aggressive behavior, etc., stop varenicline and contact their provider. Fluoxetine and other selective serotonin reuptake inhibitors have not demonstrated a benefit. In schizophrenic patients, the use of atypical antipsychotic medications may aid in smoking cessation when compared with typical antipsychotics. Clonidine is sometimes used to help patients who are withdrawing from narcotics, and it may have some limited role in smoking cessation but is not very effective. You can also combine therapies: varenicline + nicotine replacement therapy (NRT) or use two types of NRT, such as gum + patch (*BMC Public Health*. 2015 Jul 22;15:689).

As you are walking out of your patient’s room, your patient says, “Hey Doc, my brother smokes too, is there a test you can do to make sure he doesn’t have lung cancer?”

Question 3.11.6 You respond:

- A) “Sure, I’ll put in an order for him to get an outpatient chest x-ray”
- B) “Tell him to make an appointment and we will discuss the risks/benefits of low-dose CT scan”
- C) “Here have him expectorate in this cup, and I’ll send his sputum for cytology”
- D) “Nah, we don’t recommend lung cancer screening at this time”
- E) “Yes. We just need a Ouija board and a magic 8-ball”

Answer 3.11.6 The correct answer is “B.” In 2013, the USPTF issued a grade B recommendation for annual lung cancer screening with low-dose CT scan in adults aged 55 to 80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years. Screening should be discontinued once a person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery. These recommendations are based on the National Lung Screening Trial that showed that for every 1,000 people who got screening for lung cancer, 3 fewer died of lung cancer because of screening. About 300 people need to be screened to save one life from lung cancer. Patients should be given the risks/benefits of lung cancer screening since approximately 365/1,000 patients will have a false-positive result (usually because of a benign pulmonary nodule) that leads to more CT scans (extra radiation), more invasive procedures (biopsies and surgeries), and patient stress and anxiety. Confused yet? Don’t worry, the American Thoracic Society has developed a patient decision guide found at <https://www.thoracic.org/patients/patient-resources/decision-aid-for-lung-cancer-screening-with-ct.php>. It is important to stress that this lung cancer screening should not take the place of efforts to stop smoking! Of note, “A” and “C” are incorrect because neither plain chest radiographs nor sputum cytology have been shown to improve lung cancer mortality.

► **Objectives: Did you learn to ...**

- Weigh risk factors when evaluating an SPN?
- Develop a plan for evaluating an SPN?
- Assist a patient with smoking cessation?
- Learn the risks/benefits of lung cancer screening in the appropriate patient population?

► **CASE 3.12**

A 74-year-old male presents to your ED for weakness, cough, and fatigue. His wife relates an incomplete recovery since his myocardial infarction last year. He continues to have poor appetite and listlessness, and she thinks that he may be depressed. He is short of breath and confused. His wife says that yesterday he developed a fever, chills, and a new cough productive of white sputum. His past medical history is otherwise remarkable for a cholecystectomy. He is taking aspirin (secondary prevention, not primary!), metoprolol, and atorvastatin.

Vitals: temperature 39°C, respiratory rate 30, pulse 90 bpm, blood pressure 140/80 mm Hg. Oxygen saturation on room air is 90%. He is thin, pale, and oriented to person only. The lung examination is remarkable for rales in the left lower field, with dullness to percussion and increased tactile fremitus. The remainder of the examination is normal.

The chest x-ray shows a left lower lobe infiltrate. Other laboratory data currently available: hemoglobin 12.4 g/dL, WBC 14,100/mm³, platelets 340,000/mm³, creatinine 1.9 mg/dL, BUN 50 mg/dL, and normal electrolytes, troponin, and CK. An ECG shows normal sinus rhythm.

Question 3.12.1 What is your next step in managing this patient's medical condition?

- A) Place a chest tube on the left
- B) Perform chest CT
- C) Administer inhaled bronchodilators
- D) Administer parenteral antibiotics
- E) Perform intubation and mechanical ventilation

Answer 3.12.1 The correct answer is "D." Given the clinical picture and chest x-ray findings, the patient most likely has community-acquired pneumonia. Therefore, the administration of parenteral antibiotics is the best choice. "A" is incorrect. Since there is no effusion, a chest tube would be useless. "B" is incorrect. CT is not required in this straightforward case of pneumonia. "C" is incorrect. The patient is not wheezing and there is no indication for bronchodilators at this time. As for "E," since your patient's respiratory status is stable, he does not require intubation.

HELPFUL TIP:

Remember that it is impossible to tell a "typical" versus an "atypical" pneumonia by radiograph. Do not base your therapy for community-acquired pneumonia on the radiographic appearance. Atypical organisms can cause lobar consolidation and typical pneumonias can appear diffuse. Note that treatment guidelines make no mention of radiographic appearance.

HELPFUL TIP:

There are several scoring systems to help decide on whether a patient with pneumonia needs to be admitted, their likely mortality rate, etc. Some of the popular ones include the Pneumonia Severity Index and the CURB-65. Both are available at MD-Calculator.

HELPFUL TIP:

The variables for CURB-65 include:
 Confusion (based on a specific mental test or disorientation to person, place, or time)
 Urea (BUN) >20 mg/dL
 Respiratory rate >30 breaths/min

Blood pressure <90/60 mm Hg

Age >65 years

Patients with a score of 0 or 1 have a low risk of death and are generally safe for outpatient management.

Question 3.12.2 Based on patient-specific characteristics and your knowledge of causative factors involved in pneumonia, which of the following is LEAST likely to be the agent causing this patient's infection?

- A) *Mycoplasma pneumoniae*
- B) *S. pneumoniae*
- C) *Haemophilus influenzae*
- D) *Pseudomonas aeruginosa*

Answer 3.12.2 The correct answer is "D." When a pathogen is identified in adult community-acquired pneumonia, it is usually *S. pneumoniae* ("B"). In fact, *S. pneumoniae* makes up 40% to 60% of all cases of community-acquired pneumonia in the elderly. Non-typeable *H. influenzae* ("C") composes about 5% to 10% of cases. *Mycoplasma pneumoniae* ("A") is implicated in 5%, and it is more common in young adults. *P. aeruginosa* pneumonia is uncommon in healthy elders and more likely to occur in patients with serious underlying lung disease or immunodeficiency (think cystic fibrosis). Approximately 5% of patients or more are infected with multiple agents.

Question 3.12.3 On the basis of your assessment of his risk, you decide to admit this patient to the hospital. An IV is in place. Which of the following IV antibiotic regimens do you choose?

- A) Penicillin
- B) Azithromycin
- C) Penicillin and gentamicin
- D) Azithromycin and ceftriaxone
- E) Piperacillin/tazobactam and ciprofloxacin

Answer 3.12.3 The correct answer is "D." The 2007 Infectious Disease Society of America / American Thoracic Society (IDSA/ATS) guideline for community-acquired pneumonia (still not updated as of the writing of this book) recommends that for community-acquired pneumonia treated in the hospital setting, the optimal antibiotic regimen must offer good coverage of *S. pneumoniae*, *H. influenzae*, and atypical organisms such as *Mycoplasma* and *Chlamydia* species. Most *S. pneumoniae* bacteria are resistant to penicillin ("A") and about 20% to 30% are resistant to macrolides such as azithromycin ("B"). Therefore, these agents should not be used alone in the treatment of pneumonia in hospitalized patients. Gentamicin ("C") has no activity against *S. pneumoniae* but has a role in *P. aeruginosa* infections. Ceftriaxone offers good Gram-negative coverage and activity against *S. pneumoniae*. Azithromycin covers atypical organisms. For these reasons, "D" is the best choice. An alternative regimen would be monotherapy with a respiratory fluoroquinolone, such as moxifloxacin or levofloxacin (remembering the cautions associated with fluoroquinolones). The combination of piperacillin/tazobactam with ciprofloxacin ("E") is reserved

for patients with more severe pneumonia, requiring ventilation and ICU care.

Initial blood cultures grow *S. pneumoniae*. Sputum Gram stain and culture are negative. The patient initially does well and defervesces after 2 days of IV antibiotics. However, on day 3, he again spikes a fever. He looks moderately ill. Your examination reveals increased dullness to percussion on the left. There is no jugular venous distention (JVD) or peripheral edema. The radiograph is shown in Fig. 3-7.

Question 3.12.4 The most likely diagnosis at this point is:

- A) Anaerobic abscess
- B) Development of resistant *S. pneumoniae*
- C) Parapneumonic effusion
- D) Transudate secondary to heart failure
- E) Drug-induced transudate

Answer 3.12.4 The correct answer is “C.” The most likely problem in this patient is a parapneumonic effusion. “A,” an anaerobic abscess, is unlikely given that there are no air/fluid levels and the fact that the fluid appears to be in the pleural space. “B” is unlikely. Development of resistance should take more than 3 days, especially since this patient is on two drugs. “D” is unlikely given that this patient does not have a history of heart failure, is febrile, and has no JVD, etc. “E” is unlikely. None of the drugs that he is on is known to cause pleural effusions.

You place a chest tube to drain the pleural effusion (free flowing on ultrasound) and continue the current antibiotic regimen. The patient does well and is discharged 1 week later on clarithromycin after sensitivities conclude that his organism is susceptible to it.

Six weeks after the onset of illness, he returns for follow-up to ensure clearing of the chest x-ray. He is feeling well. He is alert and oriented, and his lung examination is now normal. There is no lymphadenopathy in the neck or supraclavicular areas. The x-ray still shows left lower lobe infiltrate, unchanged in size from the initial x-ray. The pleural effusion has resolved.

Question 3.12.5 Which of the following is the most appropriate next step in the evaluation and management of this patient?

- A) Chest CT
- B) Chest x-ray in 2 weeks
- C) Chest x-ray in 6 weeks
- D) Prescribe amoxicillin/clavulanate
- E) Refer for bronchoscopy

Answer 3.12.5 The correct answer is “C.” There are no clear guidelines regarding follow-up chest x-ray in patients who had pneumonia. The British Thoracic Society published recommendations in 2007 where it advised repeating chest x-ray in 6 weeks in patients with a smoking history. The reason for that recommendation is a chance that the infiltrate would obscure an underlying malignancy. Those over age 50 should also have follow-up x-ray. Bacteremic pneumococcal pneumonia has been associated with very slowly clearing x-rays, up to 3 to 5 months in some cases. Thus, repeating the chest x-ray in 2 weeks is unlikely to show resolution, so “B” is incorrect. In elderly patients, the chest x-ray takes longer to normalize than in younger patients.

The patient is clinically doing well and does not require treatment for a persistent pulmonary infection, so “D” is incorrect. Chest CT (“A”) and bronchoscopy (“E”) would give more information, but in the absence of systemic symptoms, such as weight loss, persistent cough, hemoptysis, or fever, they are not

FIGURE 3-7. Question 3.12.4 patient's chest x-ray.

indicated. It is important to consider the fact that this “infiltrate” may represent a neoplastic process if it does not resolve within several months.

HELPFUL TIP:

Even with extensive evaluation (blood culture, sputum culture, etc.), an infectious agent is only identified in 50% of cases of pneumonia. Thus, treatment is usually empiric. Sputum cultures do not alter antibiotic therapy or disease outcome in most patients with pneumonia, and 30% of patients with pneumonia are not able to produce sputum. Blood cultures are of little or no value in pneumonia, but are still recommended in most guidelines for hospitalized patients. If possible, do blood cultures before initiating therapy.

HELPFUL TIP:

“Health care associated pneumonia” (HCAP) is no more (e.g., pneumonia acquired in a nursing home, in patients on hemodialysis, with recent IV therapy, within 90 days of a prior admission, etc.). The application of HCAP guidelines has not resulted in better outcomes and in most settings has led to harm through significant overuse of anti-MRSA and antipseudomonal antibiotics (*Clin Chest Med.* 2018;39(4):765–773). **Hospital Acquired Pneumonia (HAP) is still a thing and comprises a pneumonia that occurs >48 hours after admission.**

So what’s to do? Despite the limitations of HCAP criteria, two findings are consistent. The first is that prior detection of MRSA or *Pseudomonas* predicts a much higher risk of these pathogens causing pneumonia. Physicians should cover empirically for these pathogens if they are known to have been identified in the past (vancomycin + piperacillin/tazobactam). The second is that the implications for missing these pathogens is of most concern in patients with significant sepsis and/or requiring intensive care. These patients should still have MRSA and *Pseudomonas* coverage (as above). Finally, *hospital acquired pneumonia (HAP) and ventilator-associated pneumonia* should both be treated empirically with a regimen that covers MRSA, *Pseudomonas*, and other Gram negatives. Non-invasive cultures should be collected and the antibiotic regimen adjusted according to the results (*Clin Infect Dis.* 2016;63(5):e61–e111).

HELPFUL TIP:

Proton pump inhibitors and H₂-blockers are associated with an increased risk of pneumonia. Stop them when you can.

HELPFUL TIP:

Steroids *may* be helpful in hospitalized patient with community-acquired pneumonia who are not severely immunosuppressed, are not on chronic steroids, and don’t have uncontrolled diabetes (a relative contraindication to steroids). The dose is prednisone 40 mg daily for 3 to 7 days. See *Lancet.* 2015;385(9977):1511–1518 and *Clin Infect Dis.* 2018;66:346 if you want to try this at home (well, in the hospital).

In one of life’s funny little coincidences, the next day you diagnose this patient’s 36-year-old healthy son with a community-acquired pneumonia. He has a fever, cough, and left lower lobe infiltrate on chest x-ray, but he is hemodynamically stable. You determine that he’s fit for outpatient management.

Question 3.12.8 Which of the following drug regimens is appropriate for the treatment of this patient in the outpatient setting?

- A) Cephalexin 250 to 500 mg PO QID for 10 days
- B) Penicillin V 250 mg TID for 10 days
- C) Clarithromycin 500 mg BID for 10 days
- D) Doxycycline 100 mg BID for 10 days
- E) C or D

Answer 3.12.8 The correct answer is “E.” The treatment of community-acquired pneumonia requires coverage of “typical” and “atypical” organisms. Neither “A” nor “B” covers atypical organisms. Guideline-recommended choices for the outpatient treatment of community-acquired pneumonia include doxycycline and macrolides such as clarithromycin (doxycycline has the least resistance). Additional options include the respiratory fluoroquinolones such as moxifloxacin, gemifloxacin, or levofloxacin. However, respiratory fluoroquinolones should not be used in all cases. The IDSA/ATS consensus guidelines recommend that respiratory fluoroquinolones be reserved for patients with serious underlying disease (e.g., COPD, diabetes, immunocompromised states). Of the appropriate regimens, doxycycline and erythromycin are the least expensive, but erythromycin is associated with a high rate of gastrointestinal intolerance.

HELPFUL TIP:

2007 IDSA/ATS guidelines for Community-Acquired Pneumonia recommend treating patients with community-acquired pneumonia for the minimum duration of 5 days. However, prior to discontinuation of treatment, they should also be afebrile for 48 to 72 hours and should have no more than one of the following criteria of instability: heart rate >100 bpm, respiratory rate >24, systolic blood pressure <90 mm Hg, O₂ saturation <90% on room air, PaO₂ <60 mm Hg on room air, inability to maintain oral intake, confusion. Should

the patient have more than one of these criteria, longer antimicrobial therapy is indicated (and hopefully you do not still have them in the community!).

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of community-acquired pneumonia in different patient populations?
- Determine the appropriate disposition for a patient with community-acquired pneumonia?
- Initiate outpatient and inpatient treatment for community-acquired pneumonia?

► **CASE 3.13**

While you are covering the ED, a 60-year-old female comes in by ambulance. She is unresponsive, and her husband states that he found her 30 minutes ago surrounded by bottles of pills and an empty bottle of vodka. She has a history of COPD, hypertension, osteoarthritis, and depression. The EMTs brought in her pill bottles, which include lorazepam, acetaminophen/hydrocodone, hydrochlorothiazide, aspirin, and sertraline. Only a few tablets are left in the bottle of hydrochlorothiazide. She is wearing a nonrebreather face-mask with 50% oxygen. Her respirations are shallow with a rate of 8. The remainder of her vitals: temperature 36°C, blood pressure 90/50 mm Hg, and pulse rate 90 bpm. Oxygen saturation is 88% and increases to 94% with some assisted breaths. One nurse is obtaining a blood gas while another gives naloxone. You decide that this patient cannot protect her airway and choose to intubate her. The blood gas drawn just before intubation shows pH 7.16, PaCO₂ 60 mm Hg, and PaO₂ 40 mm Hg.

Question 3.13.1 These findings imply which of the following processes?

- A) Metabolic acidosis
- B) Metabolic alkalosis
- C) Respiratory alkalosis
- D) Mixed metabolic/respiratory acidosis
- E) Mixed metabolic/respiratory alkalosis

Answer 3.13.1 The correct answer is “D.” The pH is acidotic (<7.4). In a patient whose baseline PaCO₂ is not known to you, you might assume her PaCO₂ is usually 40 mm Hg, which is the accepted normal for most patients.

If the acidosis is purely due to acute respiratory changes and CO₂ retention, a rise in PaCO₂ of 10 should be accompanied by a fall in pH equal to 0.08. In this case, the change in PaCO₂ is 20. So, $20/10 \times 0.08 = 2 \times 0.08 = 0.16$ resulting in a pH of $7.4 - 0.16 = 7.24$.

However, this patient’s pH is measured at 7.16, lower than expected for a pure respiratory acidosis presenting acutely. Thus, you can determine that the acidosis is both metabolic (perhaps from lactic acidosis from hypoperfusion) and respiratory.

HELPFUL TIP:

It is clear that low tidal volumes are protective in patients with acute respiratory distress syndrome/acute lung injury (ARDS/ALI) and prevent VILI (ventilator-induced lung injury). It is unclear whether the same strategy should be employed for all the patients. There is data that shows that even slightly injured lung is more prone to VILI, so it is reasonable to aim for a tidal volume of 6 to 8 mL/kg of predicted body weight in all patients. In addition, patients with asthma or COPD can quickly develop dynamic hyperinflation with higher tidal volumes. Ventilated patients with obstructive disease generally need more time for exhalation.

Your patient is on assist-control mode of ventilation. A nasogastric tube, 2 IVs, and a bladder catheter are in place. She is given IV N-acetylcysteine. Her blood pressure improves to 112/67 mm Hg, and her oxygen saturation is 99%. Her chest x-ray shows an endotracheal tube terminating 3 cm above the carina and no infiltrates. Thirty minutes after you intubated her, with the ventilator rate at 14 breaths/min, FiO₂ 100%, and tidal volume at 400 mL, you obtain another ABG: pH 7.35, PaCO₂ 45 mm Hg, PaO₂ 130 mm Hg. She takes 6 to 8 spontaneous, assisted breaths, while the ventilator provides the remaining breaths. She appears to be perfusing her periphery well.

Question 3.13.2 Your next action is to:

- A) Decrease the tidal volume to allow for permissive hypercapnia
- B) Increase the tidal volume to achieve a pH of 7.45 to 7.50
- C) Reduce FiO₂ while maintaining oxygen saturations at or above 90%
- D) Change to pressure support ventilation

Answer 3.13.2 The correct answer is “C.” Your patient is perfusing well, and her PaO₂ and measured oxygen saturation are much improved. You should now decrease the FiO₂, with the goal being to achieve an FiO₂ of less than 60% while maintaining adequate perfusion and oxygen saturation. An FiO₂ of 100% is somewhat toxic and can lead to airway injury. “A” is incorrect. However, permissive hypercapnia (allowing CO₂ to rise to >80 mm Hg as long as the patient tolerates it) may be useful in ventilated patients with COPD, ARDS, or asthma; it allows you to reduce tidal volumes and pressures without doing harm. But remember that you still need to maintain oxygenation. “B” is incorrect. Your patient is doing reasonably well with her slightly acidotic pH, which has corrected very quickly. It may be inadvisable to attempt to increase her pH beyond 7.40, as she may develop respiratory alkalosis that can then lead to cardiac arrhythmias. Because of her low respiratory rate, she should remain on some type of assisted volume-cycled ventilation. “Pressure support ventilation,” as its name implies, only augments patient-triggered breaths with increased airway pressure.

This pressure is in addition to the background positive end-expiratory pressure (PEEP); PEEP is used to prevent alveolar collapse and subsequent lung injury.

HELPFUL TIP:

Permissive hypercapnia is an approach to the ventilated patient where the provider allows CO_2 build up and decrease in pH (even down to levels of 7.1) in order to provide long expiratory times and low minute ventilation to prevent hyperinflation and barotrauma.

Question 3.13.3 In this patient, which of the following ventilator management techniques will unequivocally decrease her FiO_2 requirement?

- A) Increase the respiratory rate
- B) Increase the positive end-expiratory pressure (PEEP)
- C) Decrease the tidal volume
- D) Addition of inhaled nitric oxide (NO)

Answer 3.13.3 The correct answer is “B.” Two standard techniques are usually employed to improve a patient’s oxygenation: increasing FiO_2 and PEEP. PEEP maintains positive pressure in the airways at the end of expiration. Its use increases lung compliance and decreases ventilation/perfusion mismatching, resulting in better oxygenation. Since $\text{FiO}_2 > 60\%$ over periods longer than 48 hours may result in oxygen toxicity, PEEP may be employed to reduce the need for high levels of FiO_2 . “A” and “C” are incorrect. Increasing respiratory rate or tidal volume will cause increases in minute ventilation, which reduces PaCO_2 , but has little effect on PaO_2 . Decreasing minute ventilation, through decreased respiratory rate or tidal volume, causes CO_2 retention and increased PaCO_2 . “D” is incorrect. Nitric oxide has been shown to improve oxygenation in select patients with severe pulmonary hypertension and ARDS, but *does not improve overall outcomes and is potentially nephrotoxic*.

You follow the patient during her hospitalization. The next day she is more alert and is able to follow commands. Her ventilator requirements have decreased. You consider extubation.

Question 3.13.4 All of the following parameters predict a poor outcome for attempted weaning from ventilation EXCEPT:

- A) Minute ventilation supplied by ventilator is $< 10 \text{ L/min}$
- B) $\text{PaO}_2 < 55 \text{ mm Hg}$ while on $\text{FiO}_2 > 35\%$
- C) Rapid shallow breathing index (RSBI) of 140
- D) Physical examination findings of increased respiratory effort

Answer 3.13.4 The correct answer is “A.” Preparing to withdraw a patient from mechanical ventilation—typically called weaning or liberation—relies considerably on judgment, but a few objective parameters can be helpful. In general, the patient to be liberated must be awake, alert, and cooperative. She should have reasonably good oxygenation on a lower FiO_2 , have

PEEP $< 8 \text{ cm H}_2\text{O}$, and be able to generate adequate inspiratory pressures. Minute ventilation from the ventilator of less than 10 L/min is associated with greater success with weaning.

Poor prognostic indicators include a minute ventilation from the ventilator $> 10 \text{ L/min}$, $\text{PaO}_2 < 55$ with $\text{FiO}_2 > 35\%$, and RSBI > 105 (see Helpful Tip). Patients with poor cardiopulmonary reserve or who have significant underlying disease may also have difficulty weaning. Allow patients a period of breathing on their own (e.g., a T-piece) before extubating. This way, if the patient fails, you can simply hook her back up to the ventilator.

HELPFUL TIP:

Rapid Shallow Breathing Index (RSBI) is one of the predictors of successful extubation. It is calculated by dividing respiratory rate by tidal volume in liters while patient is maintained on pressure support ventilation with minimal settings (pressure of 5–10, PEEP 5–8). For example, patient breathing 20 times per minute with 500 mL of tidal volume has RSBI of $20/0.5 = 40$. Patient breathing 34 times per minute with tidal volume of 210 mL has RSBI of $34/0.21 = 161$ and is obviously not ready to be extubated.

HELPFUL TIP:

ICU setting is much different than OR; extubations in the ICU carry higher risk of failure. Do not feel bad if your patient needs to be re-intubated. There is no perfect predictor of successful ICU extubation and data show that up to 15% of ICU patients will require re-intubation despite good predictors of successful extubation.

HELPFUL TIP:

Minute ventilation (for the patient) is calculated by multiplying respiratory rate by tidal volume. Thus, a person getting 20 breaths/min from the ventilator at 400 mL/breath generates a minute ventilation = $(20 \text{ breaths/min} \times 400 \text{ mL/min})/1000 = 8 \text{ L/min}$.

► Objectives: Did you learn to ...

- Recognize a mixed respiratory/metabolic acidosis?
- Calculate expected pH changes in acute respiratory acidosis?
- Institute ventilation with appropriate initial ventilator settings?
- Identify potential complications of ventilation?
- Wean a patient from the ventilator?

► CASE 3.14

A 52-year-old male smoker presents for a 3-month history of productive cough. He reports multiple episodes of pneumonia, but continues to produce copious sputum between episodes of pneumonia. Chest x-ray is unremarkable. Chest

CT shows enlarged peripheral airways with thickened airway walls in the lower lobes bilaterally. Sputum culture grows several types of bacteria, including *P. aeruginosa*.

Question 3.14.1 Which of the following do you recommend as initial therapy?

- A) Corticosteroids
- B) Antibiotics
- C) Chemotherapy
- D) Supplemental oxygen
- E) Wedge resection of the affected lung tissue

Answer 3.14.1 The correct answer is “B.” This patient’s findings are consistent with the diagnosis of bronchiectasis, a chronic inflammatory disease of the medium-sized bronchi. Appropriate initial therapy consists of prolonged courses of antibiotics, usually 2 weeks of a narrow-spectrum antibiotic followed by reassessment. Doxycycline, amoxicillin, clarithromycin, amoxicillin/clavulanate, and trimethoprim/sulfamethoxazole are often used. Respiratory quinolones demonstrate some limited use in patients with *Pseudomonas*. Patients should be directed to discontinue tobacco use and take inhaled bronchodilators. Resection of the affected lung tissue may be necessary but should not be the initial therapy. Supplemental oxygen therapy is used if oxygenation is poor. Chemotherapy and prolonged oral corticosteroids are not used to treat bronchiectasis.

HELPFUL TIP:

Patients with acute exacerbations of bronchiectasis are often treated with prolonged courses of antibiotics tailored to previous sputum cultures. For those with recurrent exacerbations (2–3 per year), preventative therapy with a macrolide antibiotic is recommended, after cultures exclude nontuberculous mycobacterial (NTM infection) due to the concern for development of resistance. For those with recurrent exacerbations and *Pseudomonas aeruginosa* in their sputum, a trial of inhaled antibiotics (such as tobramycin) may be used. It is also recommended patients regularly use airway clearance techniques to help remove airway secretions. Pulmonary rehabilitation may also offer a benefit to patients with moderate-to-severe airflow limitation on pulmonary function testing.

Question 3.14.2 In most adults with bronchiectasis, its cause is:

- A) Genetic
- B) *Pseudomonas* infection
- C) Tobacco smoking
- D) Allergic bronchopulmonary aspergillosis (ABPA)
- E) Unknown

Answer 3.14.2 The correct answer is “E.” There are limited data regarding the etiology of bronchiectasis, but many conditions and environmental exposures seem to have an association.

In most patients, no cause is identified. Children are more likely than adults to have an identified etiology of their bronchiectasis, and the most common causes in kids are foreign body aspiration, cystic fibrosis, and gastroesophageal reflux. Identified etiologies in adults include those mentioned for children and pulmonary infections, ABPA, COPD, rheumatic or other inflammatory diseases, immunodeficiencies, and cigarette smoking.

► **Objectives: Did you learn to ...**

- Identify findings consistent with bronchiectasis?
- Treat a patient with bronchiectasis?

QUICK QUIZ: DYSPNEA

A 75-year-old gentleman presents to your office with emphysema diagnosed elsewhere. He reports dyspnea on exertion after 1 to 2 blocks. He smokes 10 cigarettes per day and does not have underlying cardiac disease. Physical examination is remarkable for fine crackles in both lung bases. Chest x-ray shows increased interstitial markings in the lower lobes. He has no pulmonary function testing on record.

Of the following tests, which is the most likely to confirm or alter the diagnosis?

- A) Spirometry, diffusing capacity, lung volumes
- B) Spirometry, ABG, diffusing capacity
- C) ABG, diffusing capacity, lung volumes
- D) ABG, lung volumes, chest CT

The correct answer is “A.” This case demonstrates a commonly seen phenomenon: patients who smoke and have dyspnea are assumed to have obstructive lung disease, particularly emphysema. However, pulmonary function tests are required to make the diagnosis of obstructive disease. Furthermore, this patient’s chest x-ray shows increased interstitial markings in the lower lung fields suggesting interstitial lung disease. This disease process is associated with a restrictive pattern on pulmonary spirometry. Lung volumes and diffusing capacity will provide a more complete picture. Thus, spirometry, diffusing capacity, and lung volumes would allow you to make the diagnosis. In interstitial lung disease, spirometry shows a FEV₁/FVC ratio >0.7, a decreased diffusing capacity, and decreased total lung capacity (the hallmark of restrictive lung disease). ABG is unlikely to help differentiate restrictive from obstructive lung disease, so options “B” through “D” are not correct.

HELPFUL TIP:

The diffusing capacity, as measured by DLCO, is low in the following disease states: emphysema, interstitial lung disease (e.g., sarcoid, alveolitis, pulmonary radiation, pulmonary toxicity from drugs such as amiodarone, pulmonary fibrosis), *Pneumocystis pneumonia*, and pulmonary vascular disease. Anemia will also cause a low DLCO—so a hemoglobin or hematocrit should always be ordered with DLCO.

**HELPFUL TIP:**

DLCO can be *increased* by pulmonary hemorrhage, polycythemia, massive obesity, left-to-right intracardiac shunting, asthma, and left heart failure (increase capillary volume in the lungs).

**QUICK QUIZ: PULMONARY INFECTIONS**

A 72-year-old woman you admitted to the hospital for pneumonia is having worsening dyspnea and hypoxemia. She is decompensating despite 3 days of antibiotic therapy with intravenous levofloxacin. According to her husband, the couple had been working on their Iowa farm, and made a trip to an old barn to collect manure *a week before the patient developed a cough and fever* (so this is not hypersensitivity pneumonitis, nor organic dust toxicity syndrome). The barn was noted to be the home of numerous birds. Her respiratory rate is 32, and her oxygen saturation is 89% on 5 L/min of oxygen by nasal cannula. Chest x-ray reveals a diffuse interstitial infiltrate, enlarged mediastinal nodes, and normal heart size.

Which of the following is the most likely culprit for the cause of her current illness?

- A) *S. pneumoniae*
- B) *H. influenzae*
- C) *Coxiella burnetii*
- D) *Histoplasma capsulatum*
- E) *Blastomyces dermatitidis*

The correct answer is "D." The case described here is classic for an environmental exposure to a large dose of *Histoplasma* organisms. Histoplasmosis is often transmitted by bird or bat droppings. *Histoplasma* occurs most commonly in the Mississippi and Ohio River valleys, causing a self-limited disease in most persons. Patients who have *Histoplasma* infection frequently develop calcified mediastinal lymph nodes after resolution of the infection. Diagnosis can be made by urinary antigen or bronchoscopic biopsy. The bacterial causes are unlikely to be important factors here, as she was on a broad-spectrum antibiotic for 3 days with no improvement. *C. burnetii*, the agent causing Q fever, is rare and tends to affect workers exposed to fresh animal material, such as placentas. *Blastomyces* is found in the same regions as *Histoplasma*, but the site of exposure tends to be more moist, unlike the dry environment inside a barn. We all have granulomas from histoplasmosis on CXR in Iowa.

▶ **CASE 3.15**

A 42-year-old female comes to your office with a history of asthma that has been difficult to control. She relates symptoms that have been worsening over the last 4 to 6 weeks. She received two courses of oral corticosteroids during that time. Her symptoms improved with this therapy but quickly returned after completing the steroids. She denies fever,

chills, and night sweats, but complains of a chronic cough productive of brownish-colored sputum. She is a homemaker in a suburban area and has no pets. Physical examination reveals wheezing throughout all lung fields but is otherwise normal. Laboratory evaluation includes CBC with increased eosinophils, normal C-reactive protein, and an elevated IgE level of 1250 ng/mL. A high-resolution CT scan of the chest reveals central bronchiectasis.

Question 3.15.1 What is the most likely diagnosis?

- A) Hypersensitivity pneumonitis
- B) Acute eosinophilic pneumonia
- C) Allergic bronchopulmonary aspergillosis (ABPA)
- D) Bacterial pneumonia
- E) Churg–Strauss vasculitis

Answer 3.15.1 The correct answer is "C." This patient's history points to the diagnosis of ABPA, which is characterized by the presence of severe asthma, brownish mucus plugs, peripheral eosinophilia above 10%, elevated serum IgE, and central bronchiectasis. IgE elevation is required to be greater than 1,000 ng/mL. "A" is unlikely but a bit tricky. First, there is no history of exposure to a causative agent. Second, let's focus on symptoms. Constitutional symptoms—often fever—are present in the acute form of hypersensitivity pneumonitis. However, they need not be present in the subacute and chronic forms of the disease. So, based on symptoms, this could be hypersensitivity pneumonitis. However, the radiologic findings of hypersensitivity pneumonitis would include interstitial lung disease, rather than central bronchiectasis. Thus, this is not likely hypersensitivity pneumonitis.

"B" and "D" are incorrect. Note that she has no significant constitutional symptoms that might be more typical of acute eosinophilic pneumonia or bacterial infection. You would also expect an infiltrate on the chest CT. "E" is incorrect. Churg–Strauss vasculitis is characterized by transient patchy interstitial infiltrates, fever, weight loss, elevated sedimentation rate, abnormal liver enzymes, and a peripheral blood eosinophilia >1,000 cells/μL. This is often related to using an oral steroid and a leukotriene inhibitor simultaneously. It is not related to inhaled steroid use. Extrapulmonary manifestations (CHF, pericarditis, tender subcutaneous nodules, peripheral neuropathy—most commonly mononeuritis multiplex) distinguish Churg–Strauss from other eosinophilic pulmonary conditions.

Question 3.15.2 Which of the following would be the next best step in confirming the diagnosis?

- A) Sputum cultures
- B) Transbronchial biopsy
- C) Methacholine challenge
- D) Allergy skin testing for *Aspergillus* species
- E) p-ANCA

Answer 3.15.2 The correct answer is "D." Most but not all of the following criteria (Table 3-11) need to be present in order to make the diagnosis of ABPA. Transbronchial biopsy is unnecessarily invasive, and the other tests will not help to confirm the diagnosis.

TABLE 3-11 CRITERIA FOR THE DIAGNOSIS OF ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS (ABPA)

- Asthma
- Central bronchiectasis
- Elevated total serum IgE > 1,000 ng/mL
- Immediate skin test reactivity to *Aspergillus*
- Elevated serum-specific IgE and/or IgG to *Aspergillus fumigatus*
- Peripheral blood eosinophilia > 10%
- Pulmonary infiltrates

Question 3.15.3 The most appropriate treatment for this patient with ABPA would include which of the following?

- A) Antibiotics
- B) Oral corticosteroids
- C) Leukotriene receptor antagonist
- D) Itraconazole
- E) Inhaled ipratropium bromide

Answer 3.15.3 The correct answer is “B.” Oral corticosteroids are the treatment of choice for ABPA. Patients are typically treated for several months with tapering doses rather than short courses of steroids. Serum IgE levels and chest x-rays are used to monitor response to treatment. Please note that “D” is incorrect, and azoles are *not* the mainstay therapy in ABPA. The goal of treatment is suppression of the immune system responding to the fungal antigen. There are studies that show benefit of adding an antifungal agent as a steroid-sparing agent. However, there are risks associated with concomitant use of steroids and azoles, namely, marked adrenal suppression. Hence, oral corticosteroids should be your first choice.

► **Objectives: Did you learn to ...**

- Identify the clinical presentation of ABPA?
- Diagnose and treat a patient with ABPA?

► **CASE 3.16**

A 16-year-old female comes to your office with complaints of sneezing spells, itchy watery eyes, and nasal congestion for the past 2 years. These symptoms are worse during the spring and fall and when she plays with her cat. She denies any other constitutional symptoms and has no other past medical history. She has tried over-the-counter loratadine without relief. She has lived in the same residence for the past 6 years and denies any other environmental exposures. Her examination reveals pale nasal mucosa and swollen nasal turbinates bilaterally. Her lungs and skin are clear.

Question 3.16.1 You are not clear if this is allergic rhinitis or nonallergic rhinopathy (previously known as vasomotor rhinitis). The most effective way to determine if this is allergic is to:

- A) Do a methacholine challenge test
- B) Do a Hansel stain of nasal mucus

- C) Check overall IgE levels
- D) Perform a nasal mucus electrophoresis to visualize allergic bands
- E) Waft hot peppers under her nose...see what happens

Answer 3.16.1 The correct answer is “B.” The best way to tell if this is allergic is to do a Hansel stain of the nasal mucus. This will show eosinophils if it is allergic. If this is nonallergic rhinopathy, eosinophils will be absent. If it is infectious, there will likely be a predominance of neutrophils. “A” is incorrect. A methacholine challenge test is helpful in diagnosing asthma, not allergic rhinitis. Neither “C,” IgE levels, nor nasal mucus electrophoresis have any use here (and nasal mucus electrophoresis has no use anywhere that we know of... and it is disgusting). IgE is only elevated in 40% of patients with allergic rhinitis. Does anyone ever actually do a Hansel stain? Probably not, but once again, this is for the Board Examination, not real life.

Question 3.16.2 The Hansel stain shows eosinophils. “Eureka!” you shout. Which of the following would be the most appropriate next step in managing her symptoms?

- A) Recommend allergen-impermeable encasements for mattress and pillow
- B) Use topical decongestant sprays
- C) Change classes of antihistamines
- D) Refer for allergy evaluation, including percutaneous aeroallergen skin testing
- E) Recommend a high-efficiency particulate air filter for the home

Answer 3.16.2 The correct answer is “C.” Although all of the above choices may provide relief for allergic symptoms, the best first step would be to try changing the class of antihistamines. Antihistamines (and NSAIDs for that matter) are grouped into classes based on chemical structure. One class may be helpful for a patient when another class does not work.

The other choices are suboptimal. Without skin testing, avoidance measures may be needless, costly, and ineffective. Skin testing alone (“D”) would not immediately improve her symptoms, and you would still need to do something with therapy (we hope) while waiting 3 months to see an allergist. Allergen-impermeable encasements (“A”) are currently recommended for patients with dust mite allergy. Although filters (“E”) are often recommended for pet allergies, the data regarding their effectiveness in reducing allergic symptoms is contradictory. Topical decongestant sprays (“B”) are an inappropriate choice secondary to the addictive nature of these medications and the risk of causing rebound symptoms. Removing a pet from the bedroom may reduce—but not eliminate—allergen exposure. Further evaluation should be performed prior to recommending any such lifestyle modifications. Another reasonable option would be a trial of intranasal corticosteroid. Finally, you could also put an allergen impermeable encasement around the cat ...

Your patient’s 17-year-old brother is in the next examination room. He is a Boy Scout who just returned from a backpacking trip in the four corners area of New Mexico, Arizona,

Colorado, and Utah. He has noted myalgias, fever, and chills. He knows that you are reviewing pulmonary medicine for your upcoming Board Examination, so he presents to your office complaining of dyspnea that has been getting markedly worse over the past several days. He has no URI symptoms such as coryza, rhinorrhea, ear pain, etc. Additionally, he has nausea, vomiting, and diarrhea with severe abdominal pain. His respiratory rate is 40 with an oxygen saturation of 88% on room air. ("See," he says, "I told you I'm sick.") You place him on nasal oxygen and order a chest x-ray, which shows bilateral pulmonary edema.

Question 3.16.3 Based on the epidemiology and chest x-ray appearance, your best guess at this point in the disease is:

- A) Plague
- B) Coccidiomycosis
- C) Hantavirus from Sin Nombre (No Name) strain
- D) Noncardiogenic pulmonary edema from smoking paraquat (you never know what is going on at those Boy Scout camps)
- E) Ischemic cardiomyopathy from cocaine use (you never know what is going on at those Boy Scout camps)

Answer 3.16.3 The correct answer is "C." This is a typical history and physical examination for hantavirus. The absence of URI symptoms, the presence of GI symptoms, and the non-cardiogenic pulmonary edema are all symptoms/signs of hantavirus. In fact, it may present as an acute abdomen. It is spread by aerosolization of mouse excrement or urine. "B" is incorrect. Although coccidiomycosis, "Valley Fever," is found in the same geographical region, it presents with lower respiratory symptoms, a thin walled cavitory lesion, erythema nodosum (10%), and eosinophilia. Coccidiomycosis is generally a low-grade, subacute process that lasts weeks to months. It does not cause non-cardiogenic pulmonary edema. "A," pneumonic plague, while also found in the same area, causes high fever, bloody sputum, pleuritic chest pain, and develops over hours to days. It can be rapidly fatal if not recognized and treated within the first day. "D" and "E" are wrong for so many reasons that we won't bother to enumerate them here, but you never *do* know what goes on at camp.

Question 3.16.4 Laboratory findings suggestive of hantavirus include all of the following EXCEPT:

- A) Thrombocytopenia
- B) Leukocytosis with a left shift
- C) A lymphocytic predominance
- D) An immunoblast count <10%

Answer 3.16.4 The correct answer is "D." In fact, thrombocytopenia, a 10% or greater immunoblast count, and a left shift constitute the so-called diagnostic triad in a patient with appropriate clinical findings. Immunoblasts are the most immature cell in the lymphocyte line (they still enjoy scribbling on walls and drinking irresponsibly). Overall, case fatality rate of hantavirus is up to 50%. Care is supportive. Extra-corporeal membrane oxygenation may be used in seriously ill patients. There is often

an oliguric phase that needs careful management to prevent fluid overload. This can be problematic because patients are often hypotensive and there is a proclivity toward giving them fluids.

► **Objectives: Did you learn to ...**

- Assess and treat allergic rhinitis?
- Diagnose and manage a hantavirus infection?

Clinical Pearls

- A normal CO₂ on a blood gas in a dyspneic patient suggests CO₂ retention and portends a declining respiratory status.
- A venous blood gas has essentially the same values as an arterial blood gas except for the O₂ which you can get from a transcutaneous monitor. Venous gases hurt less.
- Always use spirometry to diagnose COPD. Only 55% of those diagnosed using clinical signs and symptoms have COPD; the rest have a different underlying cause for their dyspnea.
- Asymptomatic GERD does not cause asthma exacerbations.
- Be judicious when treating sarcoid with steroids; use them only when symptoms are severe or intolerable by the patient. They can prolong the course of the disease.
- Blood cultures are not generally helpful in pneumonia (but someone will want them).
- Do not use a long-acting beta-agonist in asthma without an inhaled steroid. It worsens outcomes.
- Do not use inhaled steroids in mild-to-moderate COPD. They increase pneumonia and confer no benefit.
- For COPD patients, initiate treatment in symptomatic patients with a short-acting inhaled bronchodilator (e.g., albuterol), then add a long-acting inhaled bronchodilator (e.g., tiotropium) if symptoms are not controlled.
- It is impossible to reliably differentiate a "typical" from an "atypical" pneumonia by x-ray.
- When discharging a patient on oxygen, make sure there is still an oxygen requirement and it was not a function of the acute illness that brought the patient to the hospital.

Allergy and Immunology

Wendy W. Shen

CASE 4.1

A 15-year-old girl has a history of acute difficulty breathing when playing basketball. Her symptoms include *inspiratory wheezing/stridor*, increased respiratory rate, throat tightness, and chest discomfort. Premedication with adequate doses of albuterol has no effect.

Question 4.1.1 What is the most likely diagnosis?

- A) Exercise-induced asthma inadequately treated
- B) Gastroesophageal reflux disease
- C) Musculoskeletal chest pain
- D) Hyperventilation
- E) Vocal cord dysfunction

Answer 4.1.1 The correct answer is “E.” Vocal cord dysfunction (VCD) is one of the most common asthma mimics. Patients with VCD present with hoarseness, coughing, dyspnea, and loud *inspiratory (and/or expiratory) wheezing/stridor*, along with other symptoms as mentioned above. Although laryngoscopy is the gold standard for the diagnosis of paradoxical vocal cord motion, pulmonary function testing (PFT) often is performed first due to asthma being in the differential diagnosis, and spirometry may indicate airway obstruction due to an extrathoracic component. The PFTs should show evidence of paradoxical inspiratory vocal cord adduction during symptoms which causes airflow restriction at the level of the larynx, and results in a flattened inspiratory loop on flow-volume diagram (see Chapter 3). VCD presents a diagnostic challenge, and often leads to unnecessary treatment for the misdiagnosis of asthma. In this patient, a β_2 -agonist was ineffective, even though she displays symptoms with exertion. This argues against answer “A.” The distinction between VCD and asthma may be less clear in other patients, since the two disorders sometimes coexist. The clinical history does not support the diagnoses of gastroesophageal reflux disease (“B”), musculoskeletal chest pain (“C”), or hyperventilation (“D”).

You make the diagnosis of VCD. However, the patient also complains of rhinorrhea, itchy eyes, sneezing, and itchy nose

that worsen in the spring and fall. Because you realize that we need to discuss it in this book, you kindly refer her for allergy testing (thank you!).

Question 4.1.2 With regard to radioallergosorbent testing (RAST) for allergic rhinitis, which of the following is true?

- A) RAST is less expensive than traditional skin testing
- B) RAST is more sensitive than traditional skin testing
- C) RAST has a limited role in testing those with allergic rhinitis
- D) Antihistamine use is a contraindication to the use of RAST

Answer 4.1.2 The correct answer is “C.” RAST will be negative in up to 25% of those with a positive skin test, has poorly reproducible results, and is more expensive. Thus, skin testing remains the procedure of choice for identifying allergens. RAST can be used if skin testing is unavailable.

Question 4.1.3 Which of the following medications does NOT need to be discontinued prior to aeroallergen skin testing?

- A) Intranasal steroid spray
- B) Atenolol
- C) Amitriptyline
- D) Cyproheptadine
- E) Azelastine nasal spray

Answer 4.1.3 The correct answer is “A.” Intranasal steroid sprays do not need to be discontinued prior to skin testing as they do not interfere with immediate-type hypersensitivity reactions. Antihistamines, on the other hand (amitriptyline [“C”], cyproheptadine [“D”], or azelastine [“E”] and others), may blunt dermal reactivity. Although azelastine is administered as a nasal spray, its administration may interfere with skin test reactivity within 2 days of usage. Beta-blockers, such as atenolol (B), have been shown to affect skin test reactivity and should be avoided in patients undergoing skin testing.

Aeroallergen skin prick and intradermal testing reveals positive reactions to dust mites, cat, ragweed, and tree pollens.

The patient relates that she gets considerable nasal congestion and has tried over-the-counter decongestants with no relief.

Question 4.1.4 Which of the following interventions would provide the most relief for her nasal symptoms?

- A) Diphenhydramine 25 mg PO BID
- B) Montelukast 10 mg PO QHS
- C) Intranasal steroid spray daily
- D) Ipratropium bromide nasal spray BID
- E) Getting rid of the cat. No one should have a cat. They are evil.

Answer 4.1.4 The correct answer is “C.” Intranasal corticosteroids would provide the most relief in this patient by addressing nasal congestion in addition to the other nasal symptoms mentioned. Although antihistamines are very helpful in relieving nasal symptoms such as rhinorrhea, nasal itching, and sneezing, they are generally not as effective for nasal congestion. Likewise, montelukast is a leukotriene modifier, which is approved for the treatment of allergic rhinitis, but studies suggest that intranasal steroids are superior. In addition, nasal steroids are not systemic (although a bit may be absorbed). Ipratropium (“D”) is mainly effective for rhinorrhea only, not nasal congestion. Nasal saline irrigations may be beneficial as they promote thinning of nasal secretions and drainage. However, it may not predictably improve nasal congestion. As to “E,” yes, cats are evil and shed. But as family doctors we are supposed to be accepting of our patient’s quirks.

HELPFUL (AND REALLY COOL) TIP:

Intranasal steroids also improve ocular symptoms. Whether some of the drug gets up the nasolacrimal ducts or is otherwise aerosolized into the eye is unclear. Obviously, do not put intranasal steroids directly in the eye. For moderate-to-severe allergic rhinitis, a combination of intranasal steroid and intranasal antihistamine is more effective than either alone.

She returns to you a year later, having tried intranasal steroid sprays and high-dose antihistamines, without gaining significant relief. She has instituted appropriate avoidance measures during the interim (there goes the cat...thankfully), also without improvement in symptoms. Because you know we need to address it in this book, you recommend allergen immunotherapy.

Question 4.1.5 All of the following statements are true regarding allergen immunotherapy EXCEPT:

- A) Patients should carry emergency epinephrine to all immunotherapy shot appointments
- B) It is unnecessary to stop beta-blocker therapy prior to starting immunotherapy
- C) Patients should be observed in the office for at least 30 minutes after immunotherapy injections
- D) At least 3 years of immunotherapy should be given to avoid recurrence of symptoms

Answer 4.1.5 The correct answer is “B.” It has been shown that patients taking beta-blockers may be at increased risk of having more severe systemic reactions to immunotherapy. Patients should be treated with an alternative antihypertensive during immunotherapy. The current practice parameters for allergen immunotherapy recommend that emergency epinephrine should be readily available for the treatment of systemic allergic reactions associated with immunotherapy (“A”). To monitor for these immediate reactions, patients should be observed in the office setting for at least 30 minutes after immunotherapy shots are administered (“C”). Based on studies of seasonal symptom scores, the beneficial effects of allergen immunotherapy begin during the first year of therapy and continue throughout the treatment period. It is generally recommended that the initial course of allergen immunotherapy should last for 3 to 5 years in order to ensure maintenance of therapeutic effects (and a reliable revenue stream for allergists).

You are also seeing your patient’s brother, who has a history of ragweed and grass allergy. He states that he is “allergic” to needles, too (funny guy). Accordingly, you decide to use sublingual (SL) desensitization instead of subcutaneous (SQ) routes. Luckily, there are FDA-approved sublingual preparations for desensitization to ragweed, Timothy grass and a 5-grass combination as well as for dust mites.

Question 4.1.6 Which of the following is true regarding SL desensitization?

- A) It is more effective than SQ desensitization
- B) It is overall safer than SQ desensitization; there are fewer adverse systemic reactions than with SQ desensitization
- C) It can cause airway obstruction by causing tongue and pharynx edema
- D) It is well studied as a combination therapy with SQ desensitization
- E) B and C

Answer 4.1.6 The correct answer is “E.” SL desensitization causes fewer anaphylactic reactions but can cause airway obstruction from local edema. “A” is incorrect. The majority of studies show that SQ desensitization is more effective than SL desensitization. “D” is also incorrect. The use of SL therapy in combination with SQ desensitization is contraindicated and may increase the rate of anaphylactic reactions. As a final note, most patients who require desensitization need treatment for more allergens than just Timothy grass or ragweed or the 5-grass combination limiting the usefulness of SL therapy. Patients are often also allergic to tree pollen, animal dander, and other allergens that cannot be treated with SL therapy.

HELPFUL TIP:

Beta-blockers should be stopped in patients with a history of anaphylaxis if possible. Beta-blockers amplify anaphylaxis and make it more difficult to treat.

► Objectives: Did you learn to ...

- Recognize symptoms of vocal cord dysfunction?
- Recognize symptoms of allergic rhinitis?
- Provide appropriate management for allergic rhinitis?
- Describe the role of immunotherapy in treating allergic rhinitis?

**QUICK QUIZ: ALLERGIC REACTIONS**

A 52-year-old man with common variable immunodeficiency (CVID) receives his first infusion of intravenous immunoglobulin (IVIG) therapy. Ten minutes into the infusion, he complains of difficulty breathing and generalized pruritus.

Based on the traditional classification of hypersensitivity reactions, which of the following best categorizes this patient's reaction?

- A) Type I—Immediate hypersensitivity reaction
- B) Type II—Cytotoxic reaction
- C) Type III—Immune complex reaction
- D) Type IV—Delayed-type reaction

The correct answer is “A.” Based on the clinical history and timing of the above event, you should suspect an immediate hypersensitivity reaction (Type I). Type I reactions typically occur within seconds to minutes after exposure to the offending agent and are due to cross-linkage of IgE antibodies that are bound to surfaces of mast cells or basophils, with subsequent release of mediators such as histamine. Pruritus, urticaria, angioedema, laryngeal edema, and possible generalized anaphylaxis can occur. To see why Types II to IV are incorrect, refer to Table 4-1 for definitions of the immunologic reaction types.

**QUICK QUIZ: CAN I HAVE THAT BANANA OR NOT?**

A slightly deranged patient of yours has a serious latex allergy and wants to play “fruit roulette.”

You tell her that all of the following may be associated with cross-reactivity in latex allergic patients EXCEPT:

- A) Celery
- B) Banana
- C) Avocado
- D) Kiwi

The correct answer is “A.” Celery is so boring; it can't even cause an allergic reaction in those with latex allergy. Symptoms of oral allergy syndrome can include oral pruritus with or without angioedema of the lips, tongue, palate, and posterior oropharynx. Cross-reactivity has been reported between:

- Ragweed antigens: May result in sensitization to the gourd family and banana.
- Birch pollen allergy: May result in sensitivity to apple, carrots, parsnips, celery, hazelnuts, and potatoes.
- Latex-fruit cross-reactivity: May occur with banana, avocado, passion fruit, kiwi, and chestnut, but not celery. Your patient should be warned about these potential reactions.

**HELPFUL TIP:**

The vast majority of patients who report penicillin (and other) allergies are not truly allergic. In the case of penicillin, 0.5% of those with reported penicillin allergy had skin reactions during testing and less than 10% had **any** reaction to a full dose of penicillin. Many patients misinterpret an adverse reaction (such as nausea) as an allergy.

TABLE 4-1 CLASSIFICATION OF IMMUNOLOGIC REACTIONS

Reaction Type	Mechanism	Clinical Features	Timing
Type I—Immediate	Antigen exposure causes cross-linkage of IgE antibodies that are bound to surfaces of mast cells and basophils, with subsequent release of mediators such as histamine.	Anaphylaxis Angioedema Bronchospasm Urticaria	Less than an hour after exposure
Type II—Cytotoxic	IgG or IgM antibodies are directed against antigens on the individual's own tissues, and subsequent complement activation leads to cell destruction.	Graft rejection Hemolytic anemia Neutropenia Thrombocytopenia	At least 5 days but sometimes many weeks after exposure
Type III—Immune complex	IgG or IgM antigen–antibody complexes form and deposit within blood vessels and tissues, causing complement activation and neutrophil recruitment, ultimately resulting in tissue damage.	Localized arthus reaction Serum sickness	1 week or more after exposure
Type IV—Delayed	Antigen exposure to sensitized T cells causes a reaction.	Contact dermatitis Stevens–Johnson syndrome	24–72 hours after exposure

**HELPFUL TIP:**

There is essentially no cross-reactivity between penicillin and third-generation cephalosporins (but there is with first- and second-generation cephalosporins, up to 5%). As long as the patient did not have true anaphylaxis, feel comfortable using third-generation cephalosporins in penicillin-allergic patients.

**QUICK QUIZ: CONTRAST ALLERGY**

A 57-year-old man with chest pain is scheduled for an elective cardiac catheterization. You remember that the patient has a history of generalized urticaria with lip and tongue angioedema shortly after receiving contrast dye for a CT scan several years back.

Which of the following interventions should be recommended for this patient prior to undergoing the planned procedure?

- A) Use of higher-osmolality radiocontrast media if possible
- B) Give a test dose of radiocontrast media and proceed as usual if testing is negative
- C) Administration of prednisone and diphenhydramine as premedications
- D) Percutaneous and intradermal skin testing with radiocontrast media
- E) Desensitization procedure for radiocontrast media

The correct answer is "C." Anaphylactoid reactions to radiocontrast material are typically non-IgE-mediated; however, they look very similar to a Type I immunologic reaction and can be severe and life threatening. This patient will require premedication for this elective procedure. The appropriate premedication regimen for contrast dye allergy includes (1) diphenhydramine 50 mg IM/PO 1 hour before the procedure and (2) prednisone 50 mg PO 13 hours, 7 hours, and 1 hour before the procedure. "A" is incorrect. The use of **lower-osmolality** radiocontrast media is associated with fewer adverse reactions and is appropriate for contrast-allergic patients. "B" is incorrect. Test dosing for radiocontrast media should **NOT** be done; patients with no reaction to test doses have had severe reactions to full doses. In addition, test doses themselves have been reported to result in fatalities. Skin testing ("D") **can** be done, especially within a window of a few months after the reaction for retrospective evaluation, but the current consensus is that it has no clinical utility in predicting hypersensitivity reactions. There is no desensitization procedure available.

**HELPFUL TIP:**

There is no cross-reaction between shellfish and iodine-based contrast material. The allergy to seafood is an allergy to the protein (tropomyosins) in the seafood, not the iodine. Think about it for a second. How many people have you seen dropping dead from an anaphylactic reaction to iodized salt?

▶ CASE 4.2

An 18-month-old boy comes to clinic with a history of eczematous rash covering his extremities and face. His parents state that it worsens after the ingestion of certain foods. He has had increased fussiness over the last several months, as well as some difficulty gaining weight. Food allergy is suspected.

Question 4.2.1 Which of the following foods is **NOT** commonly implicated in food allergy?

- A) Milk
- B) Corn
- C) Wheat
- D) Soy
- E) Egg

Answer 4.2.1 The correct answer is "B." Corn is not often implicated in food allergies (a good thing too, since we are writing this in Iowa, surrounded by corn). Although many foods are potentially antigenic, the great majority of food allergies involve only a few foods. Studies have shown that eight foods account for 93% of reactions, and these foods are, in order of frequency: egg, peanuts, milk, soy, tree nuts, fish, crustacean, and wheat. Although these food allergies may be outgrown, sensitivity to peanuts, tree nuts, fish, and crustaceans tend to be life-long.

**HELPFUL TIP:**

The peak incidence of food allergies occurs around age 1 year, with most allergies identified by the age of 2 years. Cow's milk and egg allergies tend to resolve by adulthood. The 2017 addenda to the Guideline for the Prevention of Peanut Allergy in the United States from the American Academy of Allergy, Asthma and Immunology recommended introduction of highly allergenic foods such as peanut products as early as 4 months of age. This recommendation was based on the data from landmark Learning Early About Peanut (LEAP) trial, which showed a statistical decrease in the prevalence in peanut allergies in those infants with severe eczema and/or egg allergy with early introduction of peanut products at age 4–11 months (*N Engl J Med.* 2015;372:803–813).

Two months later, this patient required an emergency room visit after developing increased work of breathing, wheezing, and an urticarial rash after eating. You refer him for testing. He is tested by both percutaneous skin testing and RAST and is found to have egg allergy.

Question 4.2.2 Which of the following vaccinations should **NOT** be given to this patient in light of his egg allergy?

- A) MMR vaccine
- B) Inactivated polio vaccine
- C) Influenza vaccine
- D) Conjugated pneumococcal vaccine (Pneumovax)
- E) All of the above should be provided without concern

Answer 4.2.2 The correct answer is “E.” This patient should receive all of the above vaccinations without concern. “A” is incorrect. It had been common practice to withhold measles vaccination from children with a history of anaphylactic reaction to egg; the measles vaccine is prepared in chick-embryo fibroblast cultures. However, the MMR is safe to use in children with an egg allergy. Options “B” and “D” do not contain egg-related products and can therefore be given safely to this patient. Option “C” needs particular mention. It was previously common practice to provide an “egg free” influenza vaccination such as Flucelvax or Flublok to egg-allergic patients. As of 2016, the CDC recommends that individuals with a history of an egg allergy *of any severity receive any recommended age-appropriate influenza vaccination* as there is little cross-reactivity with egg allergies. If the patient has a history of a severe reaction to egg (anaphylactic reaction of symptoms other than hives), it is recommended for the individual to receive their influenza vaccination in a monitored healthcare setting under the guidance of a provider trained to recognize and treat severe allergic reactions (this can be a pharmacist). If a patient has a reaction to the influenza vaccine, it is contraindicated for the patient to receive the influenza vaccine in the future.

► **Objectives: Did you learn to ...**

- Identify common food allergens?
- Recognize important associations between food allergy and selected vaccines?

► **CASE 4.3**

A 34-year-old female establishes care in your clinic. Her medical history consists of intermittent colicky, abdominal pain, and episodes of angioedema in the past with an unclear etiology. She has not noticed urticaria with those episodes. She has received multiple laparoscopic procedures that were unrevealing. During the initial interview, she relates several past episodes of lip and tongue swelling, for which she has not sought medical assistance. She has tried diphenhydramine without significant improvement. The swelling episodes resolve without intervention after 3 to 4 days.

Question 4.3.1 Which of the following laboratory tests would be most helpful in establishing the diagnosis in this patient?

- A) ANA
- B) C3 complement level
- C) C4 complement level
- D) Complete blood count (CBC)
- E) SS-A and SS-B

Answer 4.3.1 The correct answer is “C.” This patient’s presentation should raise concern for hereditary angioedema (HAE). This entity is clinically characterized by recurrent episodes of angioedema involving any part of the body. Thus, it can present with laryngeal angioedema (the major cause of death) or recurrent abdominal pain (generally with a normal white count and

“always” without peritoneal signs). Urticaria is **NOT** a feature of this disorder. HAE is caused by a C1-esterase inhibitor deficiency; C1-esterase is a protease that normally acts to degrade C4. If there is an absence of C1-esterase *inhibitor*, C4 levels will be low as C1-esterase will continue to degrade C4. It is possible that a patient with HAE will have a normal level of C1-esterase inhibitor but will have a nonfunctional allele. So always check a C-1 esterase inhibitor level and C-1 esterase activity as well as a C4 level. If there is a nonfunctional allele, the C-1 esterase inhibitor level will be normal but C-1 esterase inhibitor function will be decreased.

While awaiting the test results, you discuss HAE with your patient.

Question 4.3.2 In order to minimize future attacks of angioedema, you recommend which of the following?

- A) Avoidance of estrogen containing medications
- B) Avoidance of ACE inhibitors
- C) Testing and treatment of *Helicobacter pylori*
- D) All of the above

Answer 4.3.2 The correct answer is “D.” Education is the cornerstone of treatment of HAE. Patients need to know what triggers to avoid and how to identify symptoms early. Most attacks are precipitated by trauma (often head and upper airway trauma), medical procedures (dental and oral surgery in particular), emotional stress, infections, menstruation, or the use of medications, especially oral contraceptives and ACE inhibitors. Interestingly, *H. pylori* infection has been associated with HAE, and *H. pylori* eradication reduces the frequency of angioedema attacks.

Your patient is ultimately diagnosed with HAE.

Question 4.3.3 In this particular patient, which medication would be most helpful in preventing future episodes?

- A) Emergency epinephrine
- B) Oral diphenhydramine
- C) Fresh frozen plasma (FFP)
- D) Androgens (e.g., danazol)
- E) No prophylactic treatment is available

Answer 4.3.3 The correct answer is “D.” Emergency epinephrine and antihistamines are not generally effective, as HAE is not allergic in nature. Prophylactic treatment in the form of attenuated androgens (danazol) is available. Attenuated androgens appear to work by up-regulating the synthetic capability of hepatic cells that make C1-esterase inhibitor, thus decreasing the effect of C1 esterase and raising the C4 level. This, in turn, reduces the number and severity of acute exacerbations.

A subcutaneous C1 inhibitor (Takhzyro[®]) was approved by the FDA in 2017 for prophylaxis in patients 12 years and older. Treatment of acute episodes of HAE includes FFP that contains C1-esterase inhibitor, the C1-esterase inhibitor replacement protein products (e.g., Ruconest, Berinert; Cinryze; Haegarda),

and bradykinin/kallikrein inhibitors (ecallantide and icatibant). FFP would not be a long-term preventive measure, so “C” is incorrect.

HELPFUL TIP:

Make sure patients with HAE receive the hepatitis B vaccination series as they may require blood products for acute treatment of angioedema.

► Objectives: Did you learn to ...

- Identify a patient presenting with hereditary angioedema?
- Manage a patient with hereditary angioedema?

► CASE 4.4

Your patient's sister presents to clinic the next day with a similar history of angioedema symptoms, only less frequent and less severe.

Question 4.4.1 What is the likelihood that she has HAE as well?

- A) Infinitesimally small because HAE is a rare disorder
- B) About 25% because HAE is autosomal recessive
- C) About 50% because HAE is autosomal dominant
- D) Almost 100% because you can tell that she's got bad luck
- E) Unknown because multiple gene involvement renders a simple calculation impossible

Answer 4.4.1 The correct answer is “C.” HAE is transmitted in an autosomal dominant fashion with incomplete penetrance, which may be why the patient's sister is less symptomatic. New mutations do arise and cause a minority of cases.

Later that same night, you are called to the ED to see a patient with facial swelling. “Really?” you ask. “Yeah, really. Get in here,” This patient is a 35-year-old female friend of your patient with HAE (so, her BFF not her biologic sister). She is worried that she too has HAE. This is the first ever episode of lip and face swelling, associated with itching in her mouth and a few hives on her arm and torso. She had shrimp gumbo for dinner, but has never had a reaction to shrimp before. She denies any recent trauma, surgery, or medication use. She is in no respiratory distress. Her O₂ saturation is 99% on room air and BP is 118/76 mm Hg. On lung examination, there is no stridor or wheezing.

Question 4.4.2 The most appropriate next step in the treatment of this patient is:

- A) Supportive care and monitoring overnight in the intensive care unit (ICU)
- B) Administration of FFP
- C) Administration of epinephrine IM × 1

- D) Administration of diphenhydramine, cimetidine, and prednisone PO
- E) Prophylactic intubation

Answer 4.4.2 The correct answer is “D.” This patient is different from your HAE patient. It is unlikely that she has HAE for several reasons: she's never had this reaction before, she has urticaria associated with the angioedema, and she did not experience an inciting event. This episode of angioedema and urticaria is more likely to have been caused by a typical allergic reaction and mast-cell release. For these types of reactions, antihistamines and steroids are the mainstay of therapy. However, the efficacy of steroids, antihistamines, and epinephrine is limited in angioedema (but it is worth a try). “A” is incorrect because it is overkill to admit her to the ICU, and you should be treating her rather than just monitoring her. “B” is incorrect because FFP treats HAE not allergic angioedema. “C” is incorrect because this patient is not having a full anaphylactic reaction. Epinephrine would be appropriate if she had wheezing, airway compromise, or hypotension. If you chose “E” for a walking, talking patient with no airway compromise, well . . . that just makes us sad. Note that steroids do not seem to add anything to the treatment of **urticaria** (vs. levocetirizine alone) (*Ann Emerg Med.* 2018;71(1):125–131), but should be reserved for patients with angioedema.

► Objectives: Did you learn to ...

- Differentiate HAE from allergic angioedema?
- Manage an anaphylactoid reaction?

Warning: The next section is about immunodeficiency syndromes. As Dante would say: “Abandon hope all ye who enter here.” (One of the editors has a dog named Dante and she [the dog] says this all the time . . . to squirrels). See Table 4-2 for a quick review.

The main points and **the most important cases** are mentioned below. For those of you who are gluttons for punishment (gluttony is only Dante's third circle), look at the table.

The main points:

- Rule out the obvious: Does the patient have HIV, cancer, diabetes, lupus, or other chronic disease or is he/she on immunosuppressing drugs that predispose to recurrent infections?
- 1% to 3% of patients are heterozygous for an IgG subtype deficiency, the most common type of immunoglobulin deficiency. These patients may be asymptomatic or may present with recurrent sinusitis, otitis, skin infections, etc. IgG deficiency can be diagnosed by immunoglobulin electrophoresis. These patients often do not have an appropriate response to vaccinations.
- 1 in 700 patients are IgA deficient. Most are hereditary, but it can also be caused by several drugs (including captopril and thyroxine). Usually this resolves upon stopping the drug. Most patients with IgA deficiency are asymptomatic, although some have recurrent sinus and GI infections. Also, these patients frequently develop autoimmune disease and may have anaphylaxis to blood products.

TABLE 4-2 IMMUNODEFICIENCY SYNDROMES

Syndrome	Age of Onset	Defect/Laboratory Findings	Manifestations	Organisms Likely to Cause Infection
Humoral				
X-linked agammaglobulinemia	Late first year of life but up to age 50 (in very mild disease)	Low IgG, almost undetectable IgM, IgD, IgE, and IgA. No B cells	Multiple, recurrent infections (generally start at 6–18 months) especially lung, sinuses, ears, CSF. Eventually bronchiectasis and pulmonary insufficiency	<i>Streptococcus</i> , <i>Haemophilus</i> , <i>Giardia</i>
Common variable immunodeficiency	Variable but >2 years of age and mostly by age 30. May be older	Low levels of serum immunoglobulins	Sinus and respiratory infections. GI infections especially <i>Giardia</i> . Enhanced chance of lymphoma as adult. Autoimmune disorders	<i>Pneumococcus</i> , <i>Haemophilus</i> , <i>Mycoplasma</i> , <i>Giardia</i>
Hyper IgM syndrome	First 2 years of life	Elevated IgM, no IgG, IgA, IgE (although few may have very low level IgA, IgE)	Recurrent severe sinopulmonary infections. Autoimmune disorders	<i>Encapsulated bacteria</i> , <i>Giardia</i> , <i>Pneumocystis</i> , <i>Cryptosporidium</i> , <i>Histoplasmosis</i>
IgA deficiency	Not before age of 6 months; more severe disease presents by age 5	Low IgA levels, normal immunoglobulins otherwise	Most asymptomatic. May have respiratory tract infections. Watch for anaphylaxis with blood products	<i>Haemophilus</i> , <i>Pneumococcus</i>
Cellular				
Myeloperoxidase deficiency	Variable	Poor phagocytic killing	None except in the presence of other defects (e.g., diabetes), systemic candidiasis	<i>Candida</i>
Chronic granulomatous disease	Infant, toddler but occasionally in late life	Neutrophil dysfunction measured by nitroblue tetrazolium testing (and other tests)	Recurrent life-threatening illnesses especially pulmonary, hepatic, skin, and lymphatic abscesses	<i>Staphylococcus</i> , <i>Aspergillus</i>
Leukocyte adhesion deficiency	Early (poor separation of umbilical stump) or later if mild disease. Those with mild disease rarely have life-threatening illnesses	Poor adhesion of leukocytes to endothelium, etc.	Periodontal and dental infections, recurrent infections of skin, upper and lower airways, bowel, perirectal area	<i>Pseudomonas</i> and other gram-negative rods, <i>Staphylococcus</i>
Hyper IgE (Job syndrome)	First weeks to month of life	Elevated IgE levels, poor leukocyte chemotaxis	Facial abnormalities (hypertelorism; prominent, protruding triangular mandible; broad, somewhat bulbous nose). Eczema, mucocutaneous candidiasis, sinus, pulmonary, and skin infections. Recurrent “cold abscesses” in skin secondary to lack of inflammation	Multiple organisms, but especially <i>Staphylococcus</i> , <i>Haemophilus</i> , <i>Candida</i>
Wiskott–Aldrich	Early. Fatal by age 10 without bone marrow transplant	Low IgM, diminution of cellular immunity ability to respond to polysaccharide capsules	Eczema, thrombocytopenia with purpura, recurrent infections	Encapsulated organisms
Severe combined immunodeficiency syndrome	Early, by 6 months. Death by 2 years	Leukopenia, no mature T cells, low serum immunoglobulin levels	Colon and lung infections including diarrhea and abscesses	Multiple organisms, including viruses
DiGeorge syndrome	Early—in infancy	Absent thymus, reduced T3 + cells	Recurrent infections but variable in penetrance. Some have normal or near-normal immune function. Craniofacial abnormalities, congenital heart disease, chromosomal abnormalities, and hypocalcemia	<i>Pneumococcus</i> , <i>Haemophilus</i>

- Symptomatic immunoglobulin deficiencies can be treated with IVIG. The most common side effects of IVIG administration include renal failure, anaphylaxis, and thromboembolic disease.

▶ CASE 4.5

A 35-year-old male is seen by you in the hospital setting, after being admitted for pneumonia. Blood cultures reveal *Streptococcus pneumoniae*. The patient was well until age 25 when he began having recurrent infections and developed an autoimmune hemolytic anemia. He also relates frequent sinus infections (real ones ... not the kind we so often see) requiring antibiotics 8 to 10 times a year. His last bout of pneumonia required a stay in the ICU.

Question 4.5.1 You suspect an immunodeficiency in this individual. What is the most useful test in making the diagnosis in this patient?

- A) Complement levels
- B) Immunoglobulin levels
- C) CBC and differential
- D) Bone marrow biopsy
- E) Nitroblue tetrazolium test

Answer 4.5.1 The correct answer is “B.” The clinical picture for this patient is most consistent with common variable immune deficiency (CVID). CVID, or acquired agammaglobulinemia, is similar to X-linked agammaglobulinemia, but generally has a later age of onset. In addition, it is associated with various gastrointestinal disorders, autoimmune disorders, and malignancy. Immunoglobulin levels are decreased secondary to inadequate B-cell differentiation. Therefore, the most useful laboratory test for the diagnosis of CVID would be serum immunoglobulin levels. With regard to the other options and other tests you might do to evaluate otherwise unexplained immunodeficiency:

- Immunodeficiency can be secondary to complement disorders and complement levels will be low in these patients.
- Nitroblue tetrazolium test will be abnormal in patients with phagocytic disorders.
- Response to vaccines will be muted or absent in humoral immunodeficiency (e.g., immunoglobulin deficiency).
- Delayed hypersensitivity skin testing (e.g., candida and mumps) may indicate a T-cell defect.

Question 4.5.2 Which of the following is the most appropriate treatment plan for this patient?

- A) Prophylactic antibiotics
- B) Bone marrow transplantation
- C) Gene therapy
- D) IVIG replacement
- E) No treatment needed

Answer 4.5.2 The correct answer is “D.” The treatment of choice for CVID includes replacement IVIG, especially in

this patient who has a history of life-threatening infections. Prophylactic antibiotics may be required in addition to IVIG in some patients. Gene therapy is not currently possible because the genetic defect has not been identified. Although bone marrow transplantation is useful in other immunodeficiency states, it is not indicated in CVID.

HELPFUL TIP:

Patients with CVID may develop lymphoproliferative disorders (e.g., non-Hodgkin lymphoma). New adenopathy should be taken seriously.

▶ Objectives: Did you learn to ...

- Describe presenting symptoms of common variable immunodeficiency?
- Recognize treatment options for CVID?

QUICK QUIZ: IGA DEFICIENCY

A 37-year-old female is incidentally found to have an IgA level of 3 mg/dL (below the normal range).

What is the most likely clinical picture in this patient?

- A) Pyogenic infections
- B) Thrush
- C) Cold abscesses
- D) Aphthous ulcers
- E) No clinical abnormalities

The correct answer is “E.” IgA deficiency is present in approximately 1 in 700 Caucasians in the United States and is the second most common immunodeficiency described. Most of these patients are asymptomatic, but some IgA-deficient patients may present with an increased rate of respiratory tract infections.

HELPFUL TIP:

The evaluation of immunodeficiency should NOT stop when IgA deficiency is discovered since IgA deficiency is often asymptomatic and may be accompanied by a more serious form of immunodeficiency.

QUICK QUIZ: IVIG

Which of the following patients is most likely to develop an anaphylactic reaction in response to the administration of IVIG?

- A) A patient with IgA deficiency
- B) A patient with IgG deficiency
- C) A patient with sickle cell anemia
- D) A patient with graft-versus-host disease
- E) A pregnant patient

The correct answer is “A.” Patients with IgA deficiency have pre-formed IgG or IgE antibodies against IgA, and thus may develop an anaphylactic reaction in response to IVIG (as well as blood and FFP, for that matter). Patients with IgG deficiency may have a similar problem, but it is much less common. Not all patients with IgA deficiency will develop anaphylaxis, but the risk is high enough to be prepared and to reduce the risk by using IgA-depleted IVIG and giving the IVIG slowly.

Clinical Pearls

- An extensive evaluation for an underlying cause of chronic urticaria is very low yield and should not be done. Target the evaluation to the patient.
- Beta-blockers should be used with caution in patients with a history of a severe anaphylactic reaction (e.g., requiring epinephrine). Beta-blockers increase the incidence and severity of anaphylaxis and blunt the response to therapeutic doses of epinephrine.
- Do not use non-targeted IgE testing in the evaluation of asthma. Do testing for specific antigens as indicated based on the patient's history.
- IgA immunodeficiency is often asymptomatic and should not be considered the cause of immunodeficiency unless no other cause is found.
- Intranasal steroids are first line for allergic rhinitis and will also improve allergic eye symptoms (when given intranasally).
- It is generally safe to use third-generation cephalosporins in a patient with penicillin allergy—as long as the reaction was not anaphylaxis.

- RAST testing for allergy has a 25% false-negative rate. Skin testing remains the gold standard.
- The great majority of patients who are reportedly “allergic” to penicillin do not have a true penicillin allergy.
- There is no cross-reactivity between shellfish and iodinated radiocontrast.
- Vocal cord dysfunction is an asthma mimic. Patients usually have inspiratory stridor.

Nephrology

5

Melissa L. Swee

► CASE 5.1

A 49-year-old female with a 5-year history of type 2 diabetes mellitus presents for an initial visit. She has no known complications of diabetes. She takes metformin, glyburide, and aspirin. On examination, you find a pleasant, obese female in no distress. Her blood pressure is 136/86 mm Hg. As you discuss monitoring her diabetes, you recommend screening for early kidney disease.

Question 5.1.1 Which of the following approaches is the recommended way to screen for diabetic kidney disease?

- A) Obtain a 24-hour urine collection for albumin now and again in 3 years
- B) Obtain a spot urine albumin every year
- C) Obtain a spot urine albumin/creatinine ratio every year
- D) Obtain a urinalysis every year
- E) Obtain a serum creatinine every year

Answer 5.1.1 The correct answer is “C.” Moderately increased albuminuria (previously known by the misnomer “microalbuminuria”) is a marker for increased risk of future kidney disease in diabetic patients. The best test to evaluate for moderately increased albuminuria is the urine albumin/creatinine ratio. Its advantages include ease of use, relatively low cost, and good correlation with 24-hour urine collections. Some of you may have chosen “B.” A “spot microalbumin” (now a spot albumin) is a common but less accurate way to provide screening and may still be in use in some areas. As a practical matter, many physicians use urine albumin alone as a method of screening, but this method does not allow for corrections for variations in urine volume and dilution. A random spot urine albumin/creatinine ratio is normally less than 30 mg/g. Values above 30 mg/g are consistent with 24-hour measures showing abnormal amounts of albumin in the urine. Answers “D” and “E” offer measures of kidney function that simply are not sensitive enough to use for screening purposes.

HELPFUL TIP:

Note on terminology. The term “microalbuminuria” has been replaced with “moderately increased albuminuria,” but the definition remains the same (30–300 mg protein in the urine per 24 hours). Compare this to “severely increased albuminuria,” defined as greater than 300 mg of protein in the urine per 24 hours.

Question 5.1.2 Her albumin/creatinine ratio is 42 mg/g. The next step to confirm moderately increased albuminuria is:

- A) Repeat urine albumin/creatinine ratio
- B) Urine dipstick for protein
- C) 24-hour urine collection for total protein excretion
- D) Serum creatinine
- E) Referral to a nephrologist

Answer 5.1.2 The correct answer is “A.” Verification by repeat urine albumin/creatinine ratio is sufficient for a diagnosis of moderately increased albuminuria, so 24-hour urine collection (“C”) need not be performed for confirmation. Of note, the diagnosis of moderately increased albuminuria requires 2 of 3 urine specimens showing >30 mg/g albumin/creatinine over a 6-month period. Since protein excretion must exceed 300 to 500 mg/day for a urine dipstick to detect proteinuria, urinalysis (“B”) is not sensitive enough to be diagnostic. Serum creatinine (“D”) elevation may be a marker for diabetic kidney disease, but it would develop late in the process. Nephrology referral (“E”) is premature—you went to medical school; you can do this!

Question 5.1.3 Which of the following can cause a false-negative albumin/creatinine ratio?

- A) Vigorous exercise
- B) Fever
- C) Cachexia
- D) Poor glycemic control
- E) Large muscle mass

Answer 5.1.3 The correct answer is “E.” Patients with a large muscle mass have a high rate of creatinine excretion, which may decrease the albumin/creatinine ratio. Cachectic patients have the opposite problem, with low amounts of creatinine excretion, resulting in false-positive albumin/creatinine ratio. Fever, vigorous exercise, heart failure, and poor glycemic control can also cause transient increases in albuminuria, potentially resulting in false-positive albumin/creatinine ratios.

Your patient’s other laboratory studies reveal the following: hemoglobin A_{1c} 6.4%, serum creatinine 1.4 mg/dL, and normal electrolytes. A month later, your patient returns. Her blood pressure is 138/84 mm Hg. Her urine albumin/creatinine remains elevated on a second measurement. According to an eye examination yesterday, she has nonproliferative diabetic retinopathy.

Question 5.1.4 Because your patient has type 2 diabetes mellitus and moderately increased albuminuria, you realize that her likelihood of progressing to overt nephropathy is:

- A) Almost zero
- B) About half that of a similar patient with type 1 diabetes
- C) Nearly equal to that of a similar patient with type 1 diabetes
- D) More than twice that of a similar patient with type 1 diabetes
- E) Absolutely certain (100% chance)

Answer 5.1.4 The correct answer is “C.” Although earlier studies showed a greater progression to overt nephropathy in type 1 diabetics, more recent studies demonstrate a nearly equal rate of progression in types 1 and 2. About 20% to 40% of Caucasian patients with diabetes type 2 and moderately increased albuminuria will progress to diabetic nephropathy. The rate of progression to nephropathy in non-Caucasian populations is even higher.

Question 5.1.5 What is the most appropriate next step in the evaluation and management of this patient’s moderately increased albuminuria?

- A) Start an angiotensin-converting enzyme (ACE) inhibitor
- B) Start an angiotensin receptor blocker (ARB)
- C) Order renal ultrasound with Doppler of the renal arteries
- D) Start insulin
- E) Order a 24-hour urine collection for total protein

Answer 5.1.5 The correct answer is “A.” ACE inhibitors should be the first-choice drugs unless there is a contraindication to their use. “B,” ARBs, are considered second-line choice if the patient cannot tolerate an ACE inhibitor. “C,” a renal ultrasound, is not indicated at this point in time since it is unlikely to change therapy. The choice to start insulin, “D,” is also not necessarily dependent on albuminuria. Your patient already has good glucose control (HbA_{1c} of 6.4%). As previously stated, a 24-hour urine collection is not necessary for diagnosis.

HELPFUL (AND VERY IMPORTANT) TIP:

An ARB is *not* just an ACE inhibitor without the cough. A large meta-analysis showed that ARBs, while lowering blood pressure, *have no appreciable effect on MI or cardiovascular mortality versus placebo* (BMJ. 2011;342:d2234; JAMA Intern Med. 2014;174:773). But that’s heart disease in diabetics (which is kind of important). Back to renal disease . . . The only study (to date) to directly compare an ACE inhibitor (enalapril) to an ARB (telmisartan) for renal protection in diabetes did not demonstrate a statistically significant difference between the two, although there was a trend in favor of the ACE inhibitor (N Engl J Med. 2004;351(19):1952). However, this was a small study (250 individuals) with a high dropout rate. Another study of 4,000 subjects showed that while ARBs *do reduce proteinuria, they have no benefit on mortality* (N Engl J Med. 2011;364:907-917), which is what we really care about.

The patient has a full urinalysis to rule out renal inflammation (e.g., nephritis) and overt proteinuria (nephrotic syndrome). The urinalysis is entirely negative.

Question 5.1.6 What further investigations must your patient undergo to eliminate other potential causes of proteinuria?

- A) Renal biopsy
- B) Renal ultrasound with Doppler of the renal arteries
- C) ANA, ESR, CRP
- D) All of the above
- E) None of the above

Answer 5.1.6 The correct answer is “E.” No further evaluation is necessary in this patient with moderately increased albuminuria. The combination of diabetic retinopathy (a marker for diabetic renal disease), hypertension (BP >140/90 mm Hg in a diabetic patient), and abnormal protein in the urine as measured by the urine albumin/creatinine ratio is sufficient to make the diagnosis of early diabetic nephropathy. Renal biopsy (“A”) is quite invasive and unlikely to change management. ANA, ESR, CRP (“C”), and ultrasound (“B”) are unlikely to offer new information. If things do change (e.g., nephritic urine and gross proteinuria), then further evaluation may be indicated.

You continue to follow this patient for several years. She ultimately is admitted for chest pain, rules out for myocardial infarction, but has a positive stress test. She will need to have a cardiac catheterization. Her creatinine is now 1.5 mg/dL, and her glomerular filtration rate is in the range of stage 3 chronic kidney disease.

Question 5.1.7 In addition to holding her metformin, which of the following interventions would be most

likely to reduce her risk of developing contrast-induced nephropathy?

- A) *N*-acetylcysteine and IV saline
- B) *N*-acetylcysteine and mannitol
- C) IV saline
- D) Sodium bicarbonate and mannitol
- E) Mannitol and IV saline

Answer 5.1.7 The correct answer is “C.” For patients at risk of contrast-induced nephropathy, contrast studies should be avoided *if possible* (see helpful tip below). If a contrast study must be done, stop aggravating medications like nonsteroidal anti-inflammatory drugs (NSAIDs—this patient shouldn’t be on these anyway since she has CKD!). Hydration, usually with IV saline, should be given if there are no contraindications (e.g., heart failure). Nonionic lower osmolality (or even iso-osmolar) contrast agents should be used. Additionally, we recommend discussing these cases individually with your radiologist, cardiologist, or whomever is performing the procedure. Sodium bicarbonate and *N*-acetylcysteine do not have good evidence for effectiveness, but they also do not appear to do harm. The diuretics (mannitol, furosemide, etc.) may be associated with an *increased* risk of nephropathy, and mannitol in particular has an undesirable side effect profile.

HELPFUL TIP:

The old teaching about renal toxicity and iodinated contrast has recently been called into question (*Radiology*. 2014;273(3):714–725; *Radiology*. 2014;271(1):65–73). These studies have suggested that the risk of renal injury is low. However, few patients in these studies had a creatinine of >3 mg/dL. In short, don’t go hog wild; try to avoid using contrast in renal disease, but it may not be as doom-and-gloom as once thought. If you really need to rule out that PE or aortic dissection, go for it. See also *N Engl J Med* 2019; 380: 2146–2155 DOI: 10.1056/NEJMra1805256

HELPFUL TIP:

Hemofiltration and hemodialysis have been studied in the prevention of contrast-induced nephropathy for patients at risk. There does not appear to be a benefit over more conservative approaches. Also, there is a move to dialyze patients who are already on dialysis within 24 hours of a contrast study. There is no good data, however, and studies show potential harm.

HELPFUL (AND VERY IMPORTANT) TIP:

The use of MRI contrast (gadolinium) in patients with renal disease has been associated with a scleroderma-like syndrome (nephrogenic systemic fibrosis). Gadolinium should be avoided in those with a CrCl of <30 mL/min. The data are less compelling in those with a CrCl of 30 to 60 mL/min. Since nephrogenic

systemic fibrosis can affect more than just the kidneys, early dialysis may help prevent this disease by reducing the half-life of the gadolinium. Further, gadolinium may remain in the CNS and form deposits. What affect this has on cognition is unknown but is being investigated. For these reasons, the FDA suggests minimizing repeated gadolinium-enhanced MRIs, especially closely spaced MRIs. Patient-specific characteristics, such as pregnancy and anticipated lifetime exposure to gadolinium, should be weighed when deciding on imaging.

Upon cardiac catheterization, she is found to have several lesions. She undergoes coronary artery bypass grafting and is discharged. Her creatinine remains stable at 1.5 mg/dL.

A few months later, she presents with gradually increasing dyspnea and cough. Her urine output is reported to be normal. Her vitals show temperature 37°C, pulse 76 bpm, respiratory rate 24, and blood pressure 92/46 mm Hg. You note crackles at both lung bases. Her heart rhythm is regular and an S4 is audible. She has JVD of 9 cm and 2+ pitting pretibial edema.

The ECG shows sinus tachycardia but no evidence of potassium toxicity (peaked T-waves, prolonged QT). Laboratory results: troponin-T and CK normal, BUN 70 mg/dL, Cr 2.0 mg/dL (her baseline was 1.5 mg/dL), Na 128 mEq/L (reference range 135–145), K 5.5 mEq/L (reference range 3.5–5.0), HCO₃ 19 mEq/L, WBC 14,500 per mm³, remainder of the CBC is normal. Urinalysis shows protein and glucose with a specific gravity >1.030 , but there are few cells and no casts. Cultures and a chest x-ray are pending.

Question 5.1.8 You suspect that her elevated creatinine is primarily due to which of the following processes?

- A) Adverse toxic effects of drugs on the kidney
- B) Heart failure or other prerenal cause of renal failure such as dehydration
- C) Sudden progression of diabetic nephropathy
- D) Urinary obstruction
- E) Urinary tract infection

Answer 5.1.8 The correct answer is “B.” Your patient has clinical evidence of heart failure (HF), including edema and rales. With a BUN/Cr ratio greater than 20 and an elevated urine-specific gravity, she appears to have a prerenal azotemia, likely secondary to insufficient cardiac output. Drugs (“A”) may play a role in her volume depletion, but the BUN/Cr ratio of >20 argues against a renal cause of her elevated creatinine. Therefore, the most likely culprit is HF. Diabetes should not cause a sudden worsening of renal disease. Although it has not been eliminated as a cause, urinary obstruction (“D”) is less likely since she has good urine output. Answer “E” is incorrect since the urinalysis does not support diagnosis of infection, and heart failure explains the overall clinical picture much better.

**HELPFUL TIP:**

Remember that a BUN/Cr ratio >20 generally (but not always!) indicates a prerenal cause of azotemia. These causes include dehydration and poor renal perfusion (shock such as sepsis, HF, and hypotension). A BUN/Cr ratio <20 is suggestive of intrinsic renal disease or urinary outlet obstruction. These broad generalizations apply to adults only. There are plenty of exceptions, so please, always use clinical judgment.

Question 5.1.9 Given her diabetes and renal disease, which of the following is the most likely cause of her hyperkalemia?

- A) Renal tubular acidosis (RTA) type 1
- B) RTA type 2
- C) RTA type 3
- D) RTA type 4
- E) RTA type 5

Answer 5.1.9 The correct answer is “D.” RTA type 4 is due to aldosterone deficiency or the kidney’s resistance to the activity of aldosterone. (Does the kidney truly possess free will and choose to exercise it to resist aldosterone? Sure... if it helps to think of it that way.) The most common cause of RTA type 4 is hyporeninemic hypoaldosteronism, which is often seen in diabetic nephropathy. The disorder is recognized by hyperkalemia and mild acidosis. RTA types 1 and 2 usually are *hypokalemic* and these forms of RTA are not associated with diabetes. RTA type 3 is very rare and is a combination of types 1 and 2. RTA type 5 does not exist.

Question 5.1.10 In an effort to *reduce* her serum potassium level (not temporize), you should do which of the following?

- A) Temporarily hold her furosemide and ACE inhibitor
- B) Increase her furosemide and temporarily hold her ACE inhibitor
- C) Administer IV calcium gluconate
- D) Bolus IV normal saline 1 to 2 L
- E) Give albuterol by nebulizer

Answer 5.1.10 The correct answer is “B.” Ah, test-taking—clearly not real life! The best answer here is to increase renal clearance of potassium with furosemide while holding the ACEI. Because ACE inhibitors can increase serum potassium, you should stop hers. “But what about her heart failure?” you ask. Well, good question. Given that her potassium is only slightly elevated, the ACEI could be continued while monitoring her serum potassium. “A” is incorrect; stopping the furosemide may lead to worsening HF symptoms and worsening hyperkalemia. In hyperkalemia, calcium gluconate (“C”) is used to protect cardiac conduction, but it is not effective for reducing potassium concentrations. A bolus of normal saline (“D”) is contraindicated in a patient with an acute HF exacerbation. Albuterol (“E”) is a temporizing measure, reducing serum potassium by forcing potassium into the intracellular space.

**HELPFUL TIP:**

A patient with hyperkalemia and ECG changes (or a potassium of 7.5 mg/dL) should give **you** palpitations. It’s time for a full court press—throw everything that you’ve got: calcium, insulin, glucose, sodium polystyrene sulfonate (Kayexalate), nebulized albuterol, etc. Note the absence of bicarbonate. It likely doesn’t work short-term, and its use has fallen out of favor. Finally, don’t use Kayexalate with sorbitol and be careful using even plain Kayexalate in individuals with GI dysfunction. Kayexalate has been associated with, and is likely the cause of, bowel perforation (*J Am Soc Nephrol*. 2010;21:733). Patiromere (Veltassa) is a newer potassium binder, *but does not remove potassium acutely* and is meant for chronic use. Note that there is an FDA black box warning that patiromere binds other medications. Turns out the same is true for Kayexalate. Separate other oral drugs by at least 6 hours. Even newer: Sodium zirconium cyclosilicate (ZS-9), Lokelma. Indicated for chronic hyperkalemia. Causes edema (like Kayexalate) but does not bind magnesium.

You administer intravenous furosemide. The night after admission she starts vomiting, and your partner inserts a nasogastric tube, which is inadvertently left to continuous suction overnight (don’t do this . . . there is almost no indication for an NG tube—especially on continuous suction). The next morning, your patient’s laboratory results are as follows: BUN 49 mg/dL, Cr 2.0 mg/dL, Na 132 mEq/L, K 3.5 mEq/L, and HCO₃ 38 mEq/L (reference 23–29 mEq/L).

Question 5.1.11 On the basis of history and laboratory data provided, you strongly suspect:

- A) Metabolic acidosis
- B) Respiratory acidosis
- C) Metabolic alkalosis
- D) Respiratory alkalosis

Answer 5.1.11 The correct answer is “C.” Loss of gastric acid, through emesis or gastric suction, can result in a metabolic alkalosis. Although no pH is available to confirm alkalosis, you are able to infer the diagnosis based on the elevation in serum HCO₃. This is one of the many reasons that you should avoid nasogastric tubes unless there is a compelling reason, such as bowel obstruction. Even there, the usefulness is limited unless they are vomiting.

**HELPFUL TIP:**

Diuretics will often cause a hypochloremic, “contraction,” alkalosis from volume contraction. Watch for this in your patients on a diuretic.

Your patient recovers surprisingly well from her heart failure. Her creatinine returns to baseline (1.5 mg/dL). You try to re-challenge the patient with an ACE inhibitor. However,

her hyperkalemia recurs and she is unable to tolerate either ACEI or ARB. With beta-blocker and loop diuretic therapy, her average blood pressure is 130/80 mm Hg. At a follow-up visit, you find no signs or symptoms of HF.

Question 5.1.12 You want to lower your patient's risk of progressing to end-stage renal disease. To reduce proteinuria, which of the following strategies is best?

- A) Add isosorbide dinitrate
- B) Add a nondihydropyridine calcium channel blocker (e.g., diltiazem, verapamil)
- C) Add a dihydropyridine calcium channel blocker (e.g., amlodipine, nifedipine)
- D) Restrict protein in the diet
- E) Aim for a higher A1C target, around 8%

Answer 5.1.12 The correct answer is "B." Nondihydropyridine calcium channel blockers reduce protein excretion in diabetic patients with nephropathy and slow down the progression of renal disease—but not to the degree of ACE inhibitors. "A," a long-acting nitrate, would be effective for angina and will lower blood pressure but does not demonstrate an effect on diabetic nephropathy. The dihydropyridine calcium channel blockers ("C") do **not** slow down progression to nephropathy to the same degree as some other antihypertensive drugs. The effect of protein restriction ("D") on nephropathy is controversial and not clearly beneficial; therefore, more effective therapies should be initiated first. Finally, "E" is incorrect since better glycemic control is associated with renal protection.

HELPFUL TIP:

For diabetic nephropathy, always start with an ACE inhibitor and try to maximize the dose. Full-dose ACE inhibitor treatment is associated with improved survival in diabetic nephropathy compared with low-dose therapy. The dose of ACE inhibitor may be limited by serum potassium level or the patient's blood pressure. Sodium restriction added to an ACE inhibitor is actually more effective than adding an ARB for proteinuria and blood pressure control (*BMJ*. 2011;343:d4366). In this study, the actual sodium in the diet was 2,500 mg (although the goal was 1,200 mg). Despite initial enthusiasm (or drug company marketing), an ARB plus an ACE is **not** useful in essentially any patient and results in increased side effects; this combination should be avoided.

Question 5.1.13 At a follow-up visit, you find that her estimated glomerular filtration rate (GFR) has declined to 40 mL/min/1.73 m² (from a previous baseline of 50 mL/min/1.73 m²). With this new information, you should discontinue which of the following medications?

- A) Insulin
- B) Metoprolol
- C) Metformin
- D) Aspirin
- E) None of the above

Answer 5.1.13 The correct answer is "E." Per the FDA, as long as the GFR is greater than or equal to 30 mL/min/1.73 m², metformin is safe—with the following caveat. If a patient's GFR declines below 45 during treatment with metformin, the dose should be reduced by 50%. Additionally, do **not start** metformin unless the GFR is greater than 45 mL/min/1.73 m². Metformin actually seems to improve outcomes in those with renal disease and compensated heart failure even when the GFR (or creatinine clearance) is low.

HELPFUL TIP:

A rough estimate of the creatinine clearance can be calculated using the Cockcroft–Gault formula:

$$\text{Estimated creatinine clearance} = (140 - \text{age}[\text{year}])(\text{body weight}[\text{kg}]) / (72 \times (\text{serum creatinine} [\text{mg/dL}]))$$

For women, multiply this figure by 0.85. One caveat is that this formula may not reflect early renal injury because of compensatory hypertrophy of the remaining glomeruli. **Normal** for healthy adult is 94 to 140 mL/min for men and 72 to 110 mL/min for women.

HELPFUL TIP:

There is no perfect equation for calculating the GFR. The abbreviated modified diet in renal disease (MDRD) calculation is increasingly used because it seems to be an accurate representation of kidney function in adults with renal disease. Unlike the Cockcroft–Gault equation, the MDRD makes an adjustment for African-American race but does not take weight into account. Both equations adjust for gender. Although the equation is a little complicated, many labs now calculate the MDRD GFR. If you want to calculate it yourself, there are multiple free sites and apps that you can access (e.g., www.mdcalc.com, www.niddk.nih.gov, etc.). From the authors' perspective, any of these are OK. We just want you to think about GFR!

Over the next year, your patient experiences increasing difficulties with glycemic control. Despite your efforts, her proteinuria and serum creatinine increase. As you discuss referral to a nephrologist, she asks about dialysis.

Question 5.1.14 Which of the following is NOT an indication for dialysis?

- A) Severe hyperkalemia due to renal failure
- B) Accelerated hypertension
- C) Weight loss
- D) Persistent nausea and vomiting despite treatment
- E) Bleeding secondary to uremia

Answer 5.1.14 The correct answer is "C." In chronic renal failure due to any cause, **absolute clinical indications for initiating dialysis include** pericarditis, pleuritis, uremic encephalopathy, or other life-threatening situations such as severe

volume overload, drug toxicities (e.g., lithium), severe electrolyte disturbances (such as hyperkalemia), and refractory metabolic acidosis. “C,” weight loss, is not an indication in and of itself. However, declining nutritional status may improve with dialysis. Persistent nausea and vomiting may be due to uremia.

HELPFUL (AND VERY IMPORTANT) TIP:

Counter to what you might expect, early dialysis increases mortality (or at least is of no benefit). Do not initiate dialysis until the GFR is 5 to 7 mL/min/1.73 m² or the patient is having clinical problems that cannot be otherwise managed (*N Engl J Med.* 2010;363(7):609–619). Patients on early dialysis die from infection, complications from dialysis (hypotension), problems with their grafts (again leading to infection), etc. This does not mean avoid nephrologists. Dialysis planning should start when dialysis is anticipated to be needed in the future.

► Objectives: Did you learn to ...

- Screen for moderately increased albuminuria in diabetic patients?
- Evaluate and treat moderately increased albuminuria and overt proteinuria in diabetic patients?
- Identify prerenal acute kidney injury?
- Describe the features of RTA type 4?
- Identify gastric suctioning as a cause of metabolic alkalosis in the hospital?
- Discuss when to initiate dialysis in a patient with chronic renal failure?

► CASE 5.2

A 49-year-old African-American female with type 2 diabetes mellitus, hypertension, and hyperlipidemia returns for a follow-up visit. She's had diabetes for 15 years, and her control has been variable over that time. Now, her glycosylated hemoglobin is 8%. She has developed moderately increased albuminuria and diabetic retinopathy. You tell her that her renal function has progressively declined, which alarms her since her mother is on hemodialysis. Her creatinine was 1.2 mg/dL 3 years ago, and now it is 1.9 mg/dL. Her GFR is 36 mL/min/1.73 m². She weighs 100 kg, and her blood pressure is 120/76 mm Hg.

Question 5.2.1 Which of the following is the most appropriate description of her renal function?

- Stage 1 chronic kidney disease (CKD)
- Stage 2 CKD
- Stage 3 CKD
- Stage 4 CKD
- Stage 5 CKD

Answer 5.2.1 The correct answer is “C.” She has stage 3 CKD. Table 5-1 defines the various stages of CKD. Not all patients will

progress through all of the stages of CKD. On the basis of age alone, many elderly patients may be classified as having stage 1 or 2 CKD, and they may never progress. Knowledge of a patient's CKD stage is useful in determining how to treat, what drugs to avoid, etc.

HELPFUL TIP:

Patients with CKD, with or without diabetes, are at increased risk of coronary artery disease, so other risk factors for heart disease should be treated aggressively. In fact, many experts believe that CKD should be treated as a “coronary artery disease equivalent.” At the least, CKD is an independent risk factor for CAD.

You increase the patient's insulin and lisinopril doses, confirm that she is taking aspirin, and convince her to quit smoking (you are very persuasive—not to mention good looking and strong . . . and humble). One month later, your patient returns with typical symptoms of a urinary tract infection (UTI) without systemic symptoms (e.g., fever, nausea). Her urine culture grows *Escherichia coli* resistant to trimethoprim/sulfamethoxazole but susceptible to all other antibiotics tested.

Question 5.2.2 Out of the following, the most appropriate antibiotic regimen for this patient's UTI is:

- Ciprofloxacin 250 mg PO every other day for two doses
- Ciprofloxacin 250 mg PO once
- Ciprofloxacin 250 mg PO BID for 3 days
- Levofloxacin 750 mg PO daily for 7 days

Answer 5.2.2 The correct answer is “C.” This patient's GFR is 36 mL/min/1.73 m² and her creatinine clearance is 56 mL/min (using the Cockcroft–Gault equation). Therefore, the usual

TABLE 5-1 STAGES OF CHRONIC KIDNEY DISEASE

Stage	GFR (mL/min/1.73 m ²)	Comments
1	≥90	Stage 1 defined by evidence of kidney damage (e.g., structural damage, albuminuria) with normal GFR
2	60–89	Mild decline in renal function; about 5.4% of US population
3	30–59	Moderate decline in renal function; about 5.4% of US population (yes, same percentage as stage 2)
4	15–29	Severe decline in renal function; approaching need for dialysis
5	<15	End-stage disease

GFR, glomerular filtration rate.

ciprofloxacin dose of 250 mg PO BID for UTI is safe and appropriate. Less frequent dosing may be required for a lesser GFR. The important thing here is to recall that CKD may require dosage adjustments for many medications. Numerous drugs are renally cleared, so it's always prudent to know the GFR or creatinine clearance and check for dosage adjustments before prescribing. Remember, however, that fluoroquinolones are not indicated for cystitis so other choices would be better if they were an option.

You assume the UTI cleared because you do not hear from her for a few months. Then her sister brings her in for an acute illness including nausea, emesis, confusion, and generalized weakness. These symptoms began yesterday. The only other thing new with her health is heartburn which she has been self-treating with increasingly larger amounts of Tums® (calcium carbonate), taking “handfuls” over the past few days. Her laboratory results now include creatinine 2.5 mg/dL, calcium 14 mg/dL (reference 8.9–10.5 mg/dL), and HCO_3^- 37 mEq/L (reference 22–28 mEq/L).

Question 5.2.3 The most appropriate treatment for her now includes:

- A) Hydrochlorothiazide (HCTZ)
- B) Furosemide
- C) Normal saline IV
- D) A and C
- E) B and C

Answer 5.2.3 The correct answer is “C.” Your patient is now presenting with milk-alkali syndrome. The diagnosis should be recognized by the triad of hypercalcemia, metabolic alkalosis, and renal insufficiency in combination with the history of typical symptoms (described in the case) and excessive calcium carbonate ingestion. Treatment includes removal of the offending agent and treatment of the hypercalcemia with IV saline (to improve renal perfusion and metabolic alkalosis). “A,” thiazide diuretics, results in reabsorption of calcium—the opposite of what you want to achieve in a patient with hypercalcemia. “B,” furosemide, has fallen out of favor and may worsen hypovolemia further.

HELPFUL TIP:

Compared with loop diuretics, thiazide diuretics are generally better at lowering blood pressure. However, at a GFR < 30 mL/min/1.73 m², thiazides are less effective as antihypertensive agents. For patients with CKD stage 4 or stage 5, especially those with hypervolemia, consider using a loop diuretic or metolazone (which acts at multiple renal sites) instead of a thiazide.

You get the patient through her episode of hypercalcemia and advise her to lay off the calcium-based antacids, favoring an H₂-antagonist instead. As your patient's renal disease progresses over the years, you find that she has become anemic with a hemoglobin of 9.9 g/dL. She takes a multivitamin. Her iron studies are consistent with anemia of chronic disease

and her screening colonoscopy last year was normal. The anemia is normocytic and normochromic.

Question 5.2.4 If you were to treat her with an erythropoietic agent (e.g., erythropoietin or darbepoetin), her target hemoglobin would be:

- A) 8 to 9 g/dL
- B) 10 to 11 g/dL
- C) 13 to 14 g/dL
- D) >15 g/dL

Answer 5.2.4 The correct answer is “B.” For patients with CKD and anemia of chronic disease (when other causes of anemia have been ruled out and/or treated), erythropoietic agents should **not** be used to achieve “near normal” hemoglobin levels. Target levels are determined on an individual basis but in general will be between 9 and 11 g/dL. Higher hemoglobin levels—in particular, attempts to “normalize” the hemoglobin concentration—are associated with a greater risk of adverse events, including increased risk of mortality, need for dialysis, heart failure, graft thrombosis, uncontrolled hypertension, etc. These findings are consistent with a similar finding in cancer patients. If the patient is an appropriate candidate, the initial erythropoietin dose is approximately 50 to 100 U/kg per week. Because of the need to preserve veins for future hemodialysis access, experts recommend that erythropoietin be administered subcutaneously (and avoid PICC lines for the same reason). The FDA suggests withholding erythropoietin for hemoglobin >12 g/dL or if the hemoglobin increases by >1 g/dL in any 2-week period.

► Objectives: Did you learn to ...

- Stage CKD?
- Adjust medication doses based on renal function?
- Recognize and treat milk-alkali syndrome?
- Recognize appropriate targets for the treatment with erythropoietic agents?

► CASE 5.3

A 55-year-old male presents to your office for evaluation of blood in his urine discovered incidentally during a life insurance physical. The urinalysis showed 2+ blood on urine dipstick and 2 RBC/hpf. The remainder of the urinalysis and microscopic examination was normal.

Question 5.3.1 After an appropriate history and physical examination, your first step in the evaluation of this urine abnormality is to:

- A) Repeat the urinalysis and microscopic examination
- B) Obtain urine for culture
- C) Order a renal ultrasound
- D) Order a CT scan of the abdomen
- E) Order an intravenous pyelogram (IVP)

Answer 5.3.1 The correct answer is “A.” According to the urinalysis, there is a small amount of blood in your patient's urine,

but the number of RBCs is actually normal (<3 RBC/hpf). Your first step should be to repeat the urinalysis and urine microscopic examination to determine if this patient actually meets the criteria for microscopic hematuria (≥ 3 RBC/hpf on 2 of 3 properly collected urine specimens, according to the American Urological Association [AUA]). A urine culture may prove useful later in the evaluation process but is not necessary now. Likewise, ordering imaging studies is premature because the diagnosis of microscopic hematuria has not been made.

HELPFUL TIP:

Kidney stones are a very common cause of gross and microscopic hematuria. However, recall that 20% of patients with kidney stones will have no blood in their urine and have a normal urinalysis. IgA nephropathy is one of the most common intrinsic renal diseases to cause microscopic hematuria; kidney cysts, including polycystic kidney disease, are common causes as well. Neoplastic diseases, in particular, bladder cancer and renal cell carcinoma, may also be discovered during the investigation of microscopic hematuria.

HELPFUL TIP:

Compared with microscopic hematuria, **gross hematuria** is more commonly associated with malignancy and, once confirmed, should prompt a thorough evaluation. Benign causes of **microscopic hematuria** in adults include: vigorous exercise, menstruation, sexual activity, viral illness, and trauma.

Further history reveals that he smokes one to two packs of cigarettes per day. He has a normal blood pressure and the remainder of the physical examination is unrevealing. Two urine samples reveal microscopic hematuria, with 5 RBC/hpf on each sample. The rest of the urinalysis is normal, and there are no red cell casts.

Question 5.3.2 In your evaluation of this patient, you include all of the following tests EXCEPT:

- A) Urine cytology
- B) CBC
- C) Serum creatinine
- D) CT scan of the abdomen and pelvis with particular note of the kidneys
- E) Renal biopsy

Answer 5.3.2 The correct answer is “E.” In most cases of microscopic hematuria, renal biopsy is not indicated. However, if an intrinsic renal cause of hematuria is suspected, renal biopsy may prove necessary. Intrinsic renal disease is more likely if there is proteinuria, hypertension, elevated serum creatinine, or an active urinary sediment (e.g., nephritic, dysmorphic red cells, red cell casts).

There is no evidence-based approach to evaluate microscopic hematuria in a standardized manner, and recommendations vary depending on the organization. Most experts, including the AUA guidelines, recommend a serum creatinine and usually include CBC, coagulation studies, and serum chemistries. Depending on the patient's age and risk factors, further studies may be indicated. For patients older than 35 years, you should consider studies to evaluate for urinary tract cancers. Urine cytology has low sensitivity but high specificity for bladder cancer and may be quite useful in conjunction with cystoscopy. Imaging of the urinary system is an absolute requirement in the workup of microscopic hematuria in older patients (generally, those over age 35 years). CT scan appears to have the greatest sensitivity for detecting masses, but ultrasound, IVP, or the combination of the two may also be employed. Cystoscopy should be considered in addition to CT, since CT is poor at visualizing bladder abnormalities. See Table 5-2 for a suggested workup for microscopic hematuria.

Question 5.3.3 The US Preventive Services Task Force recommends which of the following screening strategies for detecting microscopic hematuria?

- A) Annual urinalysis after age 50
- B) Urinalysis every 2 years after age 50
- C) Annual urinalysis after age 65
- D) Annual urinalysis in all high-risk patients older than 65 years
- E) No screening at any age

Answer 5.3.3 The correct answer is “E.” The USPSTF recommends *against* routine screening for microscopic hematuria to detect urinary tract cancers. In one-time urine specimens in healthy adults, the presence of abnormal numbers of RBCs (≥ 3 RBCs/hpf) can be as high as 39%. In up to 70% of patients, even after imaging of the upper and lower urinary tract, the source of microscopic hematuria cannot be found. In a low-risk population, the false-positive rate of microscopic hematuria found on urinalysis would be unacceptably high. Also, there is no evidence that early detection of urinary tract cancers through screening urinalysis improves prognosis.

TABLE 5-2 EVALUATION OF MICROSCOPIC HEMATURIA

After microscopic hematuria has been identified (2 of 3 urine samples with 3 or more RBC/hpf), the American Urological Association (AUA) recommends the following evaluation:

- Infection identified → treat with antibiotics and repeat urinalysis
- RBC casts, proteinuria, or elevated creatinine → begin evaluation for glomerulonephritis and consider referral to a nephrologist
- No infection or primary renal disease identified in first 2 steps → urine cytology, bladder cystoscopy (if at risk for bladder cancer based on environmental exposures and/or age >40), and CT scan (helical CT if stones suspected, contrast-enhanced CT if stones not suspected)
- If entire thorough diagnostic evaluation negative → follow-up urinalysis, urine cytology, blood pressure, and serum creatinine every 6–12 months

Your patient returns to discuss his laboratory and radiology results. His serum creatinine is 1.1 mg/dL, and his CBC, chemistries, and coagulation studies are normal. His urine cytology was negative, as was cystoscopy performed by your friendly neighborhood urologist. CT scan of the abdomen and pelvis reveals normal size kidneys and no masses, but three stones, measuring 2 to 3 mm in diameter, are noted in the left renal pelvis. There does not appear to be any obstruction. Your patient denies any history of renal colic.

Question 5.3.4 Regarding the finding of stones in the left renal pelvis, which of the following interventions is warranted at this time?

- A) Observation
- B) Lithotripsy
- C) Ureteral stent placement
- D) Ketorolac and fluids by IV
- E) Prophylactic nephrectomy

Answer 5.3.4 The correct answer is “A.” The incidental finding of stones during the evaluation of microscopic hematuria is common. The stones may be the reason for your patient’s hematuria. Since the stones are small, they may pass without intervention. Stones less than 5 mm in diameter are likely to pass spontaneously. No further intervention is warranted in asymptomatic patients. “D” is of particular note. Ketorolac and other NSAIDs are effective in treating the pain of urolithiasis. However, fluid is not helpful in treating acute ureteral colic (unless the patient is dehydrated). Fluid does nothing to “push” the stone out: fluid increases pain by further dilating the renal pelvis and the body simply shifts the excess fluid to the non-obstructed kidney.

HELPFUL TIP:

Desmopressin (DDAVP), which decreases urine production and thus stretch on the renal pelvis, can be used to control pain in those with urolithiasis although we don’t recommend it for routine use—there are plenty of good analgesics out there.

Your patient does well for a year. When you see him next, he presents to your office as a late afternoon add-on and complains of severe abdominal pain that woke him from sleep at 3 AM. He describes the pain as “sharp” or “crampy,” occurring in his left lower quadrant and radiating to the left testicle. Although the pain has waxed and waned, it has never resolved completely. He is also nauseated and has been vomiting. On examination, he is afebrile and tachycardic and has a blood pressure of 110/56 mm Hg. He appears uncomfortable and is writhing in pain. There is left lower quadrant, flank, and costovertebral angle tenderness.

Question 5.3.5 Your next action is to:

- A) Prescribe oral ibuprofen and morphine and arrange follow-up tomorrow
- B) Give IM ketorolac and arrange follow-up tomorrow

- C) Bolus 1 L IV saline, administer IV ceftriaxone, and arrange follow-up tomorrow
- D) Send him to the emergency department (ED) for pain management, fluids, and possible admission

Answer 5.3.5 The correct answer is “D.” In a patient with known kidney stones presenting with classic findings of urolithiasis, the most likely diagnosis is renal colic due to stones. This patient is nauseated and vomiting frequently and may not do well at home overnight. He is unlikely to tolerate oral medications and could become dehydrated. In addition, we don’t have a urinalysis, and a postobstructive UTI is an indication for admission and possibly stenting. For these reasons, the most appropriate action is aggressive pain management and further workup, which can be accomplished in the ED. If the patient is unable to tolerate oral pain medications after treatment in the ED, admission to the hospital is warranted. Narcotic analgesics, IV NSAIDs (e.g., ketorolac), and IV fluids to maintain euvolemia are all appropriate. The role of antibiotics will depend on urinalysis findings, but most cases of acute renal colic do not require antibiotics.

HELPFUL (AND VERY IMPORTANT) TIP:

Urolithiasis and abdominal aortic aneurysm can have the same presenting symptoms and signs (including hematuria). For that reason, imaging is mandatory in the older individual in whom an abdominal aortic aneurysm is a consideration. Also, keep testicular torsion on the differential for younger male patients presenting with renal colic symptoms—these patients need a genital examination (but you knew that, right?).

You admit the patient to the ED and start IV saline to maintain hydration; and administer narcotics, NSAIDs (ketorolac), and antiemetics. CT scan shows a 5-mm stone in the proximal ureter. There is no hydronephrosis. Serum electrolytes, BUN, creatinine, and CBC are all normal. Urinalysis reveals 2+ blood, 1+ leukocyte esterase, trace protein, pH 6, specific gravity 1.025, 20 RBC/hpf, few calcium oxalate crystals, and otherwise normal.

Question 5.3.6 Which of the following is the most appropriate management at this point in time?

- A) Add antibiotics to the current therapy
- B) Continue the current therapy and observe
- C) Refer for extracorporeal shock wave lithotripsy
- D) Refer for endoscopic lithotripsy

Answer 5.3.6 The correct answer is “B.” There is no reason to change management at this point in time. Many 5 mm stones will pass spontaneously. Although leukocyte esterase is detected on the urine dipstick, there is no compelling evidence of infection (e.g., fever, elevated WBC count, and WBCs on microscopic examination), so antibiotics are not necessary. But culturing the urine would be prudent.

**HELPFUL TIP:**

Stones of 6 mm or greater will pass spontaneously only 10% of the time and those 4 to 6 mm 50% of the time. Those less than 4 mm pass the great majority of the time. If pain persists or the stone does not pass within 72 hours, consider urologic intervention such as nephrostomy, stent placement, and/or lithotripsy. Renal injury from obstruction generally does not occur for at least 72 hours (and, amazingly enough, there is only a 20% chance of complications if a non-obstructing stone remains for 4 weeks).

**HELPFUL TIP:**

Patients discharged from the ED with urolithiasis should be placed on an NSAID in addition to a narcotic. This reduces pain and “bounce back” visits.

Question 5.3.7 Your patient—a man possessing incredible foresight—asks how he can avoid kidney stones in the future. Which of the following tests will be most useful in determining the treatments that may prevent future stone formation?

- A) Urine culture
- B) Stone recovery and analysis
- C) Urinary calcium excretion
- D) Urinary oxalate excretion
- E) Serum uric acid

Answer 5.3.7 The correct answer is “B.” The prevention of further stone formation is aided by knowledge of the stone type. Always attempt to recover the stone and send it for analysis—unless the patient is a well-known stone former and the composition of the stones is already known. The other studies listed may have value. Struvite stones form during bacterial infections of the urinary tract and a urine culture (“A”) will help direct therapy when these stones are identified. Calcium oxalate stones are the most common and 24-hour urine collection to determine calcium and oxalate excretion (“C”) can lead to diagnoses of metabolic disturbances (hyperoxaluria and hypercalciuria). Patients with uric acid stones (“D”) should be evaluated for symptoms of gout and undergo serum uric acid measurements (“E”).

Your patient passes the stone, his pain completely resolves, and he is discharged from the hospital within 24 hours of his admission. The stone is pure calcium oxalate. Studies of his 24-hour urine collection are pending.

Question 5.3.8 In order to reduce his risk of forming more stones, you tell him to incorporate all of the following lifestyle changes EXCEPT:

- A) Restrict calcium intake
- B) Restrict oxalate intake (e.g., leafy green vegetables, chocolate)
- C) Increase daily water intake

- D) Add a glass of orange juice daily
- E) Decrease sodium intake

Answer 5.3.8 The correct answer is “A.” To prevent recurrent urolithiasis, restricted calcium intake was encouraged in the past. Moderate calcium intake (1 g/day) is recognized as beneficial and should be encouraged. Patients should take calcium with meals, which will bind oxalate and prevent its absorption. A low-calcium diet actually leads to an *increased* risk of urolithiasis. Increase in urine oxalate greatly increases the risk of stone formation. Restriction of oxalate (“B”) in the diet may help to reduce the risk of recurrent urolithiasis. Foods high in oxalate include spinach, rhubarb, nuts, chocolate and legumes. Unfortunately, oxalate is also the end product of numerous metabolic pathways, and significant reduction in urinary oxalate levels often proves difficult (good news for you rhubarb fans! We like rhubarb pie *and* chocolate . . . say, I feel a stone coming on).

Increased fluid intake (“C”) to achieve a urine volume >2 L/day reduces stone formation. Water and citrus juices (“D”) are traditionally recommended (hypocitraturia is associated with stone formation), but most fluids consumed are associated with a positive effect, including drinks with caffeine.

Decreasing sodium intake (“E”) is always a good piece of advice to patients with kidney disease. With stones in particular, increased sodium intake increases calcium excretion and decreases citrate excretion. Both of these increase the risk of recurrent stones.

Question 5.3.9 Your patient is wondering if he should have his urolithiasis worked up to determine an etiology. All of the following are reasons to pursue a further evaluation in this patient EXCEPT:

- A) A strong family history of stones
- B) African ancestry
- C) Chronic diarrhea
- D) Hypertension
- E) Bariatric surgery

Answer 5.3.9 The correct answer is “D.” Simply having hypertension is not a reason to work up a patient for renal stones. All of the other choices are correct. Of note is “B.” Patients of African ancestry are *less likely* to have stones. Therefore, the workup is more likely to reveal a pathologic process in these patients. “C” and “E” are also of note. Anything that can cause malabsorption including bowel surgery, history of inflammatory bowel disease, etc., can increase the risk of stones. Thus, evaluation is indicated in these patients.

Because of his strong family history, you decide to proceed with evaluation. Results of your patient’s 24-hour urine have returned and are as follows (reference ranges):

Volume 1.6 L.

pH 6.5.

Creatinine clearance normal.

Calcium 410 mg (100–300 mg).

Uric acid 410 mEq (250–750 mEq).
 Oxalate 42 mg (7–44 mg).
 Citrate 560 mg (100–800 mg).
 Magnesium 3.1 mEq (3–5 mEq).

Question 5.3.10 Which of the following medications is most likely to reduce his risk of developing kidney stones in the future?

- A) Allopurinol
- B) Potassium citrate
- C) Hydrochlorothiazide
- D) Sodium bicarbonate
- E) Furosemide

Answer 5.3.10 The correct answer is “C.” According to the 24-hour urine studies, your patient has hypercalciuria, sub-optimal urine volumes (the goal for urine output in urolithiasis should be 2 L/day or more), and no other abnormalities. Patients with urolithiasis and hypercalciuria may benefit from the long-term treatment with thiazide diuretics, such as hydrochlorothiazide, which decrease calcium excretion and therefore stone formation. Furosemide increases calcium excretion and has the potential to increase stone formation.

Even though it seems counterintuitive, patients with **calcium** stones and **hyperuricosuria** (not this patient) may benefit from allopurinol. It is thought that hyperuricosuria predisposes to calcium stones. Also, allopurinol is useful in the treatment of patients with uric acid stones. Patients with uric acid stones and hyperuricosuria may benefit from alkalinization of the urine with sodium bicarbonate or potassium citrate. In general, dietary citrate should be maximized. Oral potassium citrate is indicated for patients with hypocitraturia.

The patient is wondering whether he can expect to get another stone.

Question 5.3.11 All of the following are true EXCEPT:

- A) The peak incidence of kidney stones occurs at age 30
- B) Kidney stones are more common in men than in women
- C) The probability of a second kidney stone is 60% to 80%
- D) Only people who become dehydrated can expect to have a second stone
- E) Living in a hot climate can predispose to a second stone

Answer 5.3.11 The correct answer is “D.” While dehydration predisposes patients to a second stone (and thus “E”), maintaining optimal hydration lowers the risk but is not a foolproof remedy. Kidney stones are more common in men and have a peak incidence at age 30. About 60% to 80% of patients with a kidney stone will suffer a recurrence.

Question 5.3.12 Which of these patients with urolithiasis requires hospitalization?

- A) A patient with a high-grade obstruction
- B) A patient with intractable pain or vomiting
- C) A patient with an associated urinary tract infection

- D) A patient with a solitary kidney or transplanted kidney
- E) All of the above

Answer 5.3.12 The correct answer is “E.” All of the patients listed above should be admitted. Obviously, patients having uncontrollable pain or vomiting will do poorly as outpatients. Urolithiasis with a coexistent UTI is a significant problem due to the risk of abscess formation, bacteremia, and renal parenchymal destruction. These patients require IV antibiotics and immediate urologic consultation, particularly in the presence of comorbidity. Patients with solitary or transplanted kidneys or in whom the diagnosis of renal colic is unclear should be admitted for monitoring of renal function and further evaluation.

HELPFUL TIP:

Recent high-quality data suggest that alpha-blockers (e.g., tamsulosin, doxazosin) are not helpful if the stone is <5 mm (most pass anyway). In stones 5 to 10 mm, there seems to be a benefit (*Cochrane Database Syst Rev.* 2018;4: CD008509; *JAMA Intern Med.* 2018;178(8):1051–1057). This recommendation seems to change yearly...

HELPFUL TIP:

Remember that multiple drugs can form radiolucent stones that will not show up on a CT scan. Among these are indinavir, acyclovir, and triamterene. Ultrasound should be the first modality, anyway. It detects hydronephrosis which is what we care about acutely and avoids radiation.

► Objectives: Did you learn to ...

- Define microscopic hematuria?
- Evaluate a patient with microscopic hematuria based on risk and differential diagnosis?
- Describe the difficulties inherent in employing urine studies to screen for urinary tract cancers?
- Evaluate a patient with urolithiasis?
- Identify causes of urolithiasis based on the characteristics of the stone?
- Manage a patient with symptomatic urolithiasis?
- Use strategies to prevent stone formation based on the characteristics of the stone?

► CASE 5.4

A 19-year-old female presents to your office concerned about protein in her urine. As a college student, she has a part-time job in a medical laboratory. She “repurposed” a few urine dipsticks from the laboratory—you know, “just checking her urine”—and found that she had 2+ protein on urine dipstick. She has no urinary symptoms and denies fever, weight changes, and edema. She is afebrile with a blood pressure of 118/68 mm Hg. Examination is otherwise unremarkable. Repeat urinalysis in the office confirms 2+ protein, specific

gravity 1.020, pH 6.5, and no blood. The urine microscopic examination is normal.

Question 5.4.1 Which of the following is the most appropriate next action in evaluating this patient?

- A) Repeat urinalysis and urine culture
- B) Ultrasound of the kidneys
- C) 24-hour urine collection for protein and creatinine
- D) Random urine protein/creatinine ratio

Answer 5.4.1 The correct answer is “D.” Did you go for “C”? A random urine is much easier than collecting a 24-hour urine and correlates well with 24-hour collections. You *could* ask the patient to collect urine for 24 hours for protein and creatinine measurements, but why? Who wants to lug around a jug of their own urine all day? What will she tell her friends and coworkers?

Your patient already has protein on urinalysis twice. Another urinalysis (“A”) will not help to determine if this is truly a worrisome finding or not. There is no evidence of a UTI (no leukocyte esterase, nitrites, etc., and no symptoms); thus, culture would be very low yield. There is no indication for renal ultrasound (“B”) at this point.

HELPFUL TIP:

Concentrated or alkaline urine can result in overestimation of urine protein on dipstick. Note that this patient’s urine specific gravity was normal.

Question 5.4.2 Which type(s) of protein are detected on a urine dipstick?

- A) Albumin
- B) Amino acids
- C) Immunoglobulin light chains
- D) A and B
- E) A and C

Answer 5.4.2 The correct answer is “A.” The urine dipstick only detects large-molecular-weight proteins—generally this means albumin. Amino acids are not detected. Immunoglobulin light chains, such as Bence Jones proteins, are also not detected on urine dipstick.

Her urine protein/creatinine ratio is equivalent to 1 g of urine protein per day. Creatinine clearance is normal. Serum creatinine, BUN, albumin, glucose, and electrolytes are normal.

Question 5.4.3 Which of the following is the best next step in your evaluation and management?

- A) Start her on a low-protein diet
- B) Order CT scan of abdomen and pelvis
- C) Measure recumbent urine protein level
- D) Refer for renal biopsy

Answer 5.4.3 The correct answer is “C.” Proteinuria may be either transient or persistent. Transient proteinuria is often due

to fever, exercise, or other causes and is not associated with significant kidney disease. Transient proteinuria is found in 7% of women and 4% of men. It often resolves spontaneously, and subsequent urine tests will probably be negative. However, at this point you don’t know if this case will be transient or persistent proteinuria.

Orthostatic proteinuria is a common type of transient proteinuria seen in young, healthy persons. Up to 5% of adolescents have orthostatic proteinuria, and young adults may present with it as well. Protein is spilled in the urine when the patient is upright, but not when recumbent. There are two ways to determine recumbent urine protein: an easy way and a hard way. The easy way is to have the patient void before going to bed, stay supine all night (8 hours), and collect urine immediately upon waking. This urine is checked for protein/creatinine ratio. Another urine sample must be checked for protein/creatinine ratio after the patient has been upright. If the upright is abnormal and the recumbent is normal, you have diagnosed orthostatic proteinuria (and impressed your colleagues). The “hard way” involves splitting a 24-hour urine collection—two jugs of urine and the required arithmetic. Orthostatic proteinuria is a benign condition that usually resolves as the patient ages, requiring no additional evaluation.

A finding of 1 g of protein in a 24-hour urine collection is abnormal (normal <0.15 g/day), but it does not yet reach the nephrotic range (>3 g/day). Regardless, a low-protein diet (“A”) is not helpful. CT scan of the abdomen and pelvis (“B”) is unlikely to add any new information. Referring for renal biopsy (“D”) is premature.

The patient collects urine in upright and recumbent positions, and both have abnormal amounts of protein. You refer the patient to a nephrologist who recommends follow-up rather than biopsy. Annual follow-up will include blood pressure, serum creatinine, and spot urine protein/creatinine ratio.

Question 5.4.4 In order to prevent worsening proteinuria, the nephrologist also recommends which of the following medications?

- A) Amlodipine
- B) Diltiazem
- C) Furosemide
- D) Benazepril
- E) Aspirin

Answer 5.4.4 The correct answer is “D.” Patients with proteinuria tend to respond well to ACE inhibitors. ACE inhibitors have been shown to reduce proteinuria by 35% to 40%. This effect is true in nondiabetic patients with proteinuria as well as in diabetic patients. ACE inhibitors appear to be superior to other antihypertensives, including calcium channel blockers (“A” and “B”). Furosemide (“C”) would be indicated if your patient develops edema, but loop diuretics should not be used primarily for the treatment of hypertension or proteinuria. Aspirin (“E”) may be indicated for protection against coronary artery disease

in patients with risk factors, including CKD, but it is not a primary treatment of proteinuria or hypertension. Remember that NSAIDs can adversely affect renal function.

HELPFUL (AND IMPORTANT) TIP:

While ACE inhibitors are first-line treatments for proteinuria, they also can cause effects on the fetus during pregnancy. Use is not contraindicated within women of child-bearing age, but should be undertaken with caution. Ensure she is on a reliable source of contraception (perhaps long-acting reversible contraception such as IUD or Nexplanon) and that she is counseled on the risks to the fetus if she were to get pregnant. If she does become pregnant, she must discontinue the ACE inhibitor right away.

Unfortunately, over the next few years, your patient develops hypertension. You maximize the dose of benazepril and need to add another drug to control her pressure. Her proteinuria increases to 3.5 g/day, and her plasma creatinine increases to 2 mg/dL. She develops edema, and her serum albumin is 2.8 g/dL. The urine shows only protein and no inflammatory components.

Question 5.4.5 This patient's current clinical condition is most appropriately described as:

- A) Hypertensive nephropathy
- B) Acute renal failure
- C) Focal nephritic glomerulonephritis
- D) Nephrotic syndrome
- E) Floating kidney

Answer 5.4.5 The correct answer is "D." While identifying no specific disease state, the term "nephrotic syndrome" refers to a constellation of signs and laboratory abnormalities. A number of diseases may lead to nephrotic syndrome (keep reading for more on this). When urine protein exceeds 3 to 3.5 g/day, it is often referred to as "nephrotic range" proteinuria. "Complete" nephrotic syndrome consists of edema, heavy proteinuria (>3 g/day or 3.5 g/day) and hypoalbuminemia (<3 g/dL). Please note that we are not writing "3 or 3.5 g/day" to confuse you. That's just what the experts say. Basically, there's way more albumin in the urine than there should be. Additional associated abnormalities include hyperlipidemia and thrombosis (Table 5-3).

TABLE 5-3 CRITERIA FOR NEPHROTIC SYNDROME

Required for the diagnosis of nephrotic syndrome

- Albuminuria >3 g/day
- Hypoalbuminemia (serum albumin of <3 g/dL)
- Peripheral edema

Other (nondiagnostic but supportive) findings

- Hyperlipidemia
- Thrombotic events

Question 5.4.6 Which of the following findings in urine sediment is associated with nephrotic syndrome?

- A) Red cell casts
- B) White cell casts
- C) Oval fat bodies
- D) Uric acid crystals
- E) Granular casts

Answer 5.4.6 The correct answer is "C." Urine sediment in nephrotic syndrome is typically bland. There is little cellular matter. Oval fat bodies and fatty casts occur in the urine of patients with heavy proteinuria and hyperlipidemia. Fat bodies reflect the increased permeability of the glomeruli and suggest some type of glomerular disease (including nephrotic syndrome) albeit not necessarily active disease. However, fat can also be seen in patients with polycystic kidney disease and fat embolism syndrome.

Red cell casts ("A"), the hallmark of nephritic syndrome, are absent in nephrotic urine. White cell casts ("B") are associated with interstitial nephritis and pyelonephritis. Uric acid crystals ("D") are sometimes seen in gout, hyperuricemia, and urate stone disease. Granular casts ("E") are not specific to any particular pathologic process and may be found in acute tubular necrosis, glomerulonephritis, and other renal diseases. See Table 5-4 for more details on urine sediment.

Question 5.4.7 Nephrotic syndrome is not a specific disease entity, but can be the end result of a number of processes. Which of the following cause(s) nephrotic syndrome?

- A) Diabetes
- B) Minimal change disease
- C) Amyloidosis
- D) Systemic lupus erythematosus
- E) All of the above

TABLE 5-4 URINE SEDIMENT FINDINGS AND ASSOCIATED CONDITIONS

Sediment Finding	Associated Condition
Epithelial cell casts	ATN, acute glomerulonephritis
Fat bodies, fatty casts	Massive proteinuria (nephrotic syndrome), fat emboli, polycystic kidney disease, glomerular disease (may not be active as in nephrotic syndrome)
Granular casts	Nonspecific—many renal disorders
Hyaline casts	Concentrated urine, diuretic use, normal finding
Red cell casts	Glomerulonephritis, vasculitis (very specific to these)
Waxy casts	Advanced renal failure
White cell casts	Pyelonephritis, acute interstitial nephritis, various glomerular diseases

ATN, acute tubular necrosis.

Answer 5.4.7 The correct answer is “E.” All of the above can be a cause of **nephrotic** syndrome. Remember that many causes of nephrotic syndrome can present initially with **nephritic** urine. Causes of nephrotic syndrome are summarized in Table 5-5.

Question 5.4.8 Which of the following tests is NOT indicated in most patients with nephrotic syndrome?

- A) Hepatitis B and C serology
- B) ANA
- C) Serum and urine protein electrophoresis
- D) HbA1c
- E) CA-125 antigen

Answer 5.4.8 The correct answer is “E.” Evaluation for cancer should be done if there is a specific reason to believe the patient has a malignancy (weight loss, mass on examination, etc.). CA-125 is a marker for ovarian cancer (among others . . . colon, pancreatic, etc.) and need not be done routinely. Plus, it’s not a useful screening test for ovarian cancer. In addition to a thorough history and physical examination, consider obtaining the following in patients with nephrotic syndrome (as well as those with nephritic urine):

- Hepatitis B and C serology
- ANA
- Serum and urine protein electrophoresis
- ASO titer
- Cryoglobulins
- Serum complement levels
- ANCA
- Serum calcium (to rule out sarcoid)
- Antiglomerular basement membrane antibodies

Use clinical judgment to guide your workup. However, this evaluation will find the cause in many cases of nephritis and/or nephrotic syndrome.

The diagnosis in your patient is unclear despite the workup noted above. It is time to consider a renal biopsy.

TABLE 5-5 CAUSES OF NEPHROTIC SYNDROME

- Diabetes
- Amyloidosis
- Systemic lupus erythematosus
- Minimal change disease (“Nil” disease)
- Diffuse glomerulonephritis
- Membranous nephropathy
- IgA nephropathy
- Postinfectious glomerulonephritis (e.g., post-streptococcal GN)
- Membranoproliferative glomerulonephritis
- Various neoplastic diseases (lymphoma, multiple myeloma, lung cancer, etc.)
- Preeclampsia
- Familial kidney disease (Alport disease, Fabry disease)
- Focal and segmental glomerulosclerosis
- Medications (NSAIDs)
- Miscellaneous

Question 5.4.9 Absolute contraindications to renal biopsy include which of the following?

- A) Hypertension
- B) Use of an anticoagulant for atrial fibrillation
- C) Perinephric abscess
- D) Solitary renal cyst
- E) All of the above

Answer 5.4.9 The correct answer is “C.” The presence of renal or perirenal infection is a contraindication to renal biopsy. None of the others are absolute contraindications. However, **uncontrollable** hypertension, **irreversible coagulopathy**, **multiple bilateral cysts**, hydronephrosis, small kidneys (indicative of chronic, irreversible disease), known renal tumor, and lack of consent **are** additional contraindications to renal biopsy. Simply being on warfarin or another anticoagulant, which can be stopped or reversed, is not a contraindication to biopsy.

Question 5.4.10 Which of the following is an indication for renal biopsy?

- A) Persistent hematuria in a patient with normal renal function and an otherwise negative workup
- B) Persistent low-grade proteinuria (1–2 g/day range) with normal blood pressure and creatinine
- C) Suspected case of IgA nephropathy
- D) Nephrotic syndrome likely from diabetes mellitus
- E) Persistent low-grade proteinuria with elevated blood pressure and/or elevated creatinine

Answer 5.4.10 The correct answer is “E.” Patients with low-grade proteinuria and elevated serum creatinine and/or hypertension should have a renal biopsy in order to determine the etiology of their disease. Indications for biopsy are listed in Table 5-6.

► **Objectives: Did you learn to ...**

- Evaluate and follow a healthy-appearing patient with proteinuria?
- Define and diagnose orthostatic proteinuria and understand its significance?
- Manage a patient with progressive proteinuria?
- Define and evaluate nephrotic syndrome?
- Identify causes of nephrotic syndrome?

TABLE 5-6 INDICATIONS FOR RENAL BIOPSY

- Nephrotic syndrome **without** a systemic etiology found on other testing
- Hematuria from a glomerular source **with** hypertension or increasing creatinine
- Persistent low grade proteinuria **with** hypertension or increasing creatinine
- Nephritis **without** a systemic explanation (e.g., no lupus, drug exposure)
- Suspicion of granulomatosis with polyangiitis (formerly Wegener disease) or polyarteritis nodosum where other tissue is not available
- Acute or subacute renal failure without another explanation (although history will usually result in a presumptive diagnosis)

CASE 5.5

While covering the ED, a 62-year-old female you have known for several years presents with her husband. She appears lethargic and is unable to give a coherent history. Her husband tells you that she began having stomach pain, nausea, and diarrhea 2 days ago. Although she has not been vomiting, she has been unable to drink or eat much due to nausea. She takes furosemide for edema and albuterol/ipratropium (Combivent) for chronic obstructive pulmonary disease (COPD). She smokes a pack of cigarettes per day.

On physical examination, her respiratory rate is 30, pulse 104 bpm, blood pressure 112/64 mm Hg, and temperature 37.9°C. She is somnolent and disoriented. Oral mucosa is dry. Lung examination demonstrates diminished air movement bilaterally. Her abdomen is diffusely tender, but there is no rebound. Rectal examination is negative for occult blood.

The first laboratory test you have available is a room air arterial blood gas (although venous would have been fine, right?): pH 7.12, PaCO₂ 33 mm Hg, PaO₂ 80 mm Hg, HCO₃ 10 mEq/L, and oxygen saturation 92%.

Question 5.5.1 This blood gas is most consistent with which of the following processes?

- A) Compensated metabolic acidosis
- B) Compensated respiratory acidosis
- C) Poorly compensated metabolic acidosis
- D) Poorly compensated respiratory acidosis
- E) Pure respiratory alkalosis

Answer 5.5.1 The correct answer is “C.” This patient is clearly acidotic, as her pH is well below the normal range of 7.35 to 7.45. So, whatever she has, it will be poorly compensated, ruling out “A” and “B.” Based on the bicarbonate (HCO₃) level and the history of gastrointestinal losses due to diarrhea, you would suspect a metabolic acidosis. In order to have appropriate respiratory compensation, the PaCO₂ should fall 12 points for every 10-point drop in the HCO₃ below the normal level (normal HCO₃ is around 24 mEq/L).

In this case, the HCO₃ is 10 mEq/L (14 points below normal); therefore, the PaCO₂ is expected to drop by about $(1.2 \times 14 = 16.8)$ or approximately 17. However, the PaCO₂ is not 23 mm Hg; it is 33 mm Hg (close to the normal range of 35–45). The patient's PaCO₂ is too high to appropriately compensate for her metabolic acidosis, and she thus has a poorly compensated metabolic acidosis.

There is another way to do this:

The pH should change by 0.08 for every 10 change in CO₂. So, if a patient's CO₂ is 50, the pH should be 7.32 if it is an uncompensated respiratory acidosis. If they are more acidotic (e.g., 7.24), they have a mixed respiratory and metabolic acidosis. If they are less acidotic (e.g., 7.39), they have a compensated respiratory acidosis.

HELPFUL TIP:

The results of a venous and arterial blood gas are essentially the same except for the oxygen, which you can read off of the transcutaneous oxygen saturation monitor. And, a venous gas hurts less. We rarely do arterial blood gases.

While you are providing supportive care, the patient's laboratory results are completed: Na 134 mEq/L (reference range 135–145 mEq/L), K 2.1 mEq/L (3.5–5.0 mEq/L), Cl 112 mEq/L (98–107 mEq/L), HCO₃ 10 mEq/L (23–29 mEq/L), BUN 29 mg/dL (5–20 mg/dL), Cr 1.1 mg/dL (0.6–1.2 mg/dL), Ca 9.1 mg/dL (8.5–10.2 mg/dL); CBC: WBC 16,100 cells/mm³, Hgb 13.9 g/dL, platelets 167,000 cells/mm³; urinalysis: specific gravity 1.030, remainder normal. Troponin-T, CK, and liver enzymes are normal.

Question 5.5.2 All of the following may be contributing to hypokalemia in this patient EXCEPT:

- A) Hypomagnesemia
- B) Furosemide
- C) Acidosis
- D) Beta-agonists such as albuterol
- E) Diarrhea

Answer 5.5.2 The correct answer is “C.” Acidosis should cause a spurious elevation in potassium—not hypokalemia. Magnesium (“A”) depletion promotes potassium loss. Thus, hypomagnesemia can contribute to hypokalemia. “B,” furosemide and other loop diuretics, causes renal potassium wasting. “D,” beta-agonists transiently shift potassium into cells, thereby lowering the serum potassium. Diarrhea (“E”) causes direct gastrointestinal losses of potassium.

Other causes of hypokalemia include thiazide diuretics, metabolic alkalosis (often from protracted emesis—although this represents a shift of potassium intracellularly and not a true hypokalemia), hyperaldosteronism, and RTA types 1 and 2.

INTERESTING (BUT USELESS) TIP:

Until 1970, “light salt” contained lithium chloride. You could help grandma's hypertension and mania at the same time! Areas in Japan with higher lithium content in the soil have lower rates of depression and suicide.

HELPFUL TIP:

Acidosis will spuriously elevate a patient's potassium. The serum potassium goes up by about 1 mEq/L for every decrease in pH of 0.1. Alkalosis will cause an equivalent hypokalemia. So, if the pH is 7.3, 1 mEq/L of the elevated potassium is due to the acidosis.

Question 5.5.3 Since your administration likes to keep the hospital at 99% capacity, there are currently no cardiac-monitored beds available for this patient. The most appropriate initial therapy to correct her hypokalemia (2.1 mEq/L) is to give your patient:

- A) KCl 40 mEq orally
- B) KCl 80 mEq orally
- C) KCl 20 mEq per hour IV
- D) KCl 20 mEq *push* IV
- E) KCl 60 mEq per hour IV

Answer 5.5.3 The correct answer is “C.” Remember that this patient is nauseated and lethargic and has been unable to eat. Thus, oral potassium replacement is unlikely to work. Couple this with the fact that she is profoundly hypokalemic, and IV replacement becomes the treatment of choice. One should not give more than 20 mEq KCl IV per hour without a cardiac monitor. It should be given through a large bore peripheral IV or a central line due to venous irritation. If you chose “D,” you just failed your test. IV push KCl is fatal.

Most commonly, the chloride salt of potassium (KCl) is administered to replete potassium stores. In the conscious patient with a functional gastrointestinal tract, oral KCl should be administered. Oral and intravenous bioavailability is very similar, but oral doses greater than 40 to 60 mEq may not be well tolerated.

HELPFUL TIP:

There are no reliably reproducible ways to gauge potassium depletion and amount needed to make a patient eukalemic. The best thing to do is start replacing with KCl and monitor serum potassium levels, adjusting the KCl dose as you go. Be careful when ordering potassium replacement: *hyperkalemia* is most commonly iatrogenic.

Question 5.5.4 In addition to KCl repletion, which of the following interventions do you initiate now in an attempt to correct the acidosis?

- A) Bolus normal saline
- B) Sodium bicarbonate
- C) Bolus 5% dextrose
- D) Intubation and mechanical ventilation

Answer 5.5.4 The correct answer is “A.” On the basis of history, physical examination, and BUN/creatinine ratio, your patient is dehydrated. The first step is to correct the dehydration with intravenous fluids. Normal saline is preferred over dextrose (“C”), which might lead to further hyponatremia and hypokalemia. In addition, dextrose will not stay intravascular and will actually precipitate a diuresis by making the serum hypotonic. “B” is incorrect. There is no evidence that bicarbonate improves outcomes in metabolic acidosis (though some will try it if the patient’s pH is 6.9–7.0). The best initial approach is to correct the underlying problem. In most cases, volume replacement

will lead to improvement in acidosis without needing to resort to bicarbonate. Although she is oxygenating well now, if your patient’s respiratory condition deteriorates, she may require intubation (“D”) and ventilator settings could be adjusted to aid in correcting the acid/base disorder.

► **Objectives: Did you learn to ...**

- Define acidosis and distinguish compensated from poorly compensated acidosis?
- Discuss causes of hypokalemia?
- Manage a patient with metabolic acidosis and hypokalemia?

QUICK QUIZ: RHABDOMYOLYSIS

The primary mechanism by which renal failure occurs in rhabdomyolysis is:

- A) Glomerular destruction
- B) Acute tubular necrosis (ATN)
- C) Interstitial nephritis
- D) None of the above

The correct answer is “B.” Myoglobin deposits in the renal tubules, causing local damage and ischemia, which results in acute tubular necrosis. Findings in the urinary sediment that support acute tubular necrosis include renal tubular epithelial cells and dark brown casts of granular material (“muddy” brown casts).

HELPFUL TIP:

Patients with rhabdomyolysis with creatine kinase (CK) <5,000 U/L and clear urine are unlikely to develop acute tubular necrosis, but should be monitored to assure dropping CK and adequate renal function.

QUICK QUIZ: LUMPY KIDNEYS

Which of the following is/are associated with autosomal-dominant polycystic kidney disease (ADPKD)?

- A) Liver cysts
- B) Cerebral aneurysms
- C) Colonic diverticula
- D) Cardiac valvular disease
- E) All of the above

The correct answer is “E.” All of the above are associated with polycystic kidney disease. Of particular importance is the possibility of cerebral aneurysms (5–20%) leading to subarachnoid hemorrhage. However, aneurysm rupture remains fairly rare, but it does seem to run in families—and seems to result in a really bad day for your patient. Currently, screening for subarachnoid aneurysms in asymptomatic, low-risk patients with ADPKD is not recommended. ADPKD occurs in 1 in every 400 to 2,000 live births and is, as the name implies, autosomal dominant. Common extrarenal manifestations of ADPKD include

cerebral aneurysms, hepatic cysts, cardiac valve disease, colonic diverticula, and abdominal and inguinal hernias.

QUICK QUIZ: TOO SALTY

A 79-year-old female nursing home resident with moderate dementia presents for worsening confusion over the last 2 days. She just finished antibiotics for a urinary tract infection. Her temperature is 37.1°C, pulse 110 bpm, respiratory rate 18 breaths/minute, and blood pressure 108/56 mm Hg. She is disoriented and lethargic. Examination of the heart, lungs, and abdomen is unremarkable.

Laboratory studies are as follows: Na 165 mEq/L, K 4.6 mEq/L, Cl 118 mEq/L, HCO₃ 28 mEq/L, BUN 31 mg/dL, Cr 1.1 mg/dL. Urine specific gravity is >1.030 and urine osmolality is 700 mmol/kg (elevated, reflecting reabsorption of free water). Her CBC is normal.

Initial treatment for this patient should be:

- A) Normal saline IV bolus
- B) Dextrose 5% IV bolus
- C) Sterile water IV bolus
- D) Furosemide 40 mg IV.
- E) DDAVP

The correct answer is “A.” Demented or delirious patients with an acute febrile illness may not be able to consume enough free water to avoid hypernatremia. Several mechanisms may be at work: free water loss due to illness, impaired thirst, and inability to respond to thirst due to cognitive or physical impairments.

Just as with hyponatremia, the hypernatremic patient should not be corrected too quickly. Sudden changes in plasma sodium may result in cerebral edema. Although there are no standardized guidelines to direct the correction of hypernatremia, most authorities recommend a maximal correction of 0.5 to 1 mEq/L/hr. In this patient who appears hypovolemic, the primary concern is to give volume. The administration of normal saline will allow you to administer volume while lowering her plasma sodium. Dextrose 5% solution will likely lower the sodium too quickly. Sterile water should never be administered IV because it will cause massive local hemolysis.

“D” is incorrect since she is dehydrated, based on history and lab findings. “E” is incorrect. This patient’s kidney function is appropriate for her hypernatremia. She is concentrating her urine, as evidenced by her high urine specific gravity and urine osmolality. Therefore, she does not have diabetes insipidus, which is characterized by large volumes of dilute urine. DDAVP is an appropriate treatment for central diabetes insipidus. See Table 5-7 for more on causes of hypernatremia.

HELPFUL TIP:

Generally, regulatory mechanisms will maintain a normal serum sodium. However, this requires access to free water. Immobile patients (especially the elderly) are particularly prone to problems because of their limited mobility and inability to independently access water.

TABLE 5-7 CAUSES OF HYPERNATREMIA

- GI loss of water
- Osmotic diuresis
- Excess exercise and sweating
- Diabetes insipidus
- Decreased access to free water

HELPFUL TIP:

Calculators are available to estimate free water deficit in hypovolemic hypernatremic patients. There are several equations and it’s not clear which one is superior to another. However, these must be viewed as rough guides. As fluids are replaced, reassess the patient frequently using clinical and laboratory measures.

CASE 5.6

A surgical colleague asks you to consult on a patient because of increasing creatinine (yes, we know this will never happen with a surgeon—just consider this a thought experiment). A 63-year-old woman was admitted for an elective cholecystectomy. She is on postoperative day 3 and has fever with delirium. Her current medications are morphine, cefotetan, and acetaminophen as needed. She takes nothing by mouth, but has intravenous fluids (5% dextrose/0.45% saline) running at 100 cc/hr . . . continuously . . . since surgery. Plasma studies from the day of surgery and this morning are available:

Laboratory Test	Day Before Surgery	Day of Consultation
Sodium (mEq/L)	138	130
Potassium (mEq/L)	4.5	5.8
Chloride (mEq/L)	103	105
HCO ₃ (mEq/L)	24	18
BUN (mg/dL)	15	30
Creatinine (mg/dL)	1.1	2.0

Question 5.6.1 The BUN/Cr ratio on the day of consultation suggests that:

- A) She is hypovolemic
- B) She has a prerenal cause of her increased creatinine, such as heart failure
- C) Intrinsic kidney disease is more likely than a prerenal cause of her increased creatinine
- D) Pyelonephritis is the most likely cause of her increased creatinine

Answer 5.6.1 The correct answer is “C.” A BUN/Cr ratio <20 generally indicates an intrinsic renal cause of renal failure (increasing Cr) while a BUN/Cr ratio >20 indicates a prerenal

cause such as hypoperfusion (e.g., heart failure, volume depletion, liver failure). In this patient, the BUN/Cr ratio is 15, suggesting—but not confirming—intrinsic renal disease.

Question 5.6.2 Which of the following is the most appropriate first step in determining the nature of this patient's elevated creatinine?

- A) Give a trial bolus of normal saline
- B) CT scan of the abdomen
- C) Determine volume of urine output
- D) Obtain urine for culture
- E) Give a trial dose of furosemide

Answer 5.6.2 The correct answer is "C." Currently, all you know about this patient's kidney function is that it has declined since her admission and that it is not likely from a prerenal cause. It is important to know if this patient is oliguric/anuric or has adequate urine output. This is important because it can affect the treatment. For example, oliguric or anuric patients may become volume overloaded easily in response to IV fluids. Although hospital measurements of intake and output are often plagued by errors, you should start this evaluation by analyzing the patient's urine output, as well as fluid intake. Urine culture and CT scan may eventually play a role in your evaluation. The decision to give fluids or diuretics cannot be made until more information is gathered.

HELPFUL TIP:

Relatively small changes in serum creatinine may reflect acute kidney injury (previously termed "acute renal failure"). A patient with a baseline creatinine of 0.7 mg/dL has lost **half** her renal function when her creatinine increases to 1.4 mg/dL, even though this number may still be in the normal range for a particular lab—thus, the need to calculate a creatinine clearance and/or MDRD GFR. There are a number of definitions of acute kidney injury (e.g., RIFLE, AKIN, and KDIGO criteria), but the basic premise is that by some objective measure (e.g., creatinine, urine output), kidney function has rapidly declined.

HELPFUL TIP:

Like acute kidney injury, there is no single number that defines oliguria. However, one commonly used definition of oliguria is: less than 1 mL/kg/hr in infants, less than 0.5 mL/kg/hr in children, and less than 500 mL/day for adults. Of course, anuria is defined as no urine output (or less than 50 mL/day for adults).

Vital signs, intake, and output have been recorded by the nurses for each shift since admission and are provided in Table 5-8.

Question 5.6.3 You have now determined that your patient has become oliguric. Which of the following is most likely

to help you narrow the differential diagnosis of renal failure?

- A) Calculation of creatinine clearance
- B) Arterial blood gases
- C) CT scan of the abdomen
- D) Fractional excretion of sodium (FENa)
- E) Furosemide challenge

Answer 5.6.3 The correct answer is "D." In this patient, you know that her BUN/Cr ratio is <20, pointing you toward intrinsic renal disease. But this ratio is not specific enough to rely upon. In oliguric renal failure, the FENa is a useful tool to help differentiate prerenal causes of renal failure from intrinsic renal causes. If the FENa is less than 1%, the kidney is functioning appropriately to conserve sodium and water to better perfuse the kidney, and a prerenal cause of failure is more likely such as hypoperfusion from shock, dehydration, heart failure, etc.

If the FENa is greater than 1%, salt and water losses are excessive, suggesting intrinsic kidney dysfunction. This calculation is **most meaningful** in oliguric renal failure (urine output <500 cc/day), but can also be used with any acute kidney injury in order to help determine the possible underlying cause. Also, FENa may be inaccurate in the elderly, patients receiving diuretics, and in chronic renal failure. The equation used to calculate FENa is:

$$\text{FENa}(\%) = [(\text{urine Na/plasma Na})/(\text{urine Cl/plasma Cr})] \times 100$$

HELPFUL TIP:

What if the patient is on a diuretic and you cannot make use of the FENa? Use the FEUrea, as urea excretion is not affected by diuretics. Here's the equation:

$$\text{FEUrea}(\%) = [(\text{urine urea/plasma urea})/(\text{urine Cr/plasma Cr})] \times 100$$

If the FEUrea is <35%, a prerenal cause is more likely. If FEUrea is >50%, acute tubular necrosis is more likely. Caveat: hyperglycemic diuresis increases excretion of urea even in hypovolemic states (e.g., 3 + glucose in the urine can give you a falsely high FEUrea).

On examination, you find a mildly disoriented female in no acute distress. She has lower extremity and sacral edema. You obtain urine studies, showing a specific gravity of 1.020, pH 6, 3 RBCs/hpf, 2 WBCs/hpf, and muddy brown granular casts. The urine creatinine is 6.5 mg/dL and the urine sodium is 45 mEq/L. You calculate the FENa at 10.65%.

Question 5.6.4 Given the clinical course and urine findings, which of the following is the best diagnosis?

- A) Acute tubular necrosis (ATN)
- B) Acute interstitial nephritis (AIN)
- C) Vasculitis
- D) Heart failure (HF)
- E) Lactic acidosis

Answer 5.6.4 The correct answer is "A." ATN is a major cause of acute kidney injury in hospitalized patients. ATN is the result

TABLE 5-8 VITAL SIGNS, INTAKE, AND OUTPUT

	Day 1	Day 1	Day 1	Day 2	Day 2	Day 2	Day 3	Day 3	Day 3
	Shift 1	Shift 2	Shift 3	Shift 1	Shift 2	Shift 3	Shift 1	Shift 2	Shift 3
BP (mmHg)	118/60	117/63	102/57	80/42	92/48	102/67	105/60	102/61	102/79
Pulse (bpm)	84	82	92	124	117	106	100	102	93
Temp (°C)	37.3	37.0	37.7	40.0	39.1	37.1	38.0	36.9	36.8

of toxic and/or ischemic effects on the kidney tubules. Metabolic derangements in ATN include progressive hyponatremia, hyperkalemia, and metabolic acidosis with a high anion gap, all of which are present in this case. Typically patients with ATN have a FENa >1% (or FEUrea >50%) and a urine sodium >40 mEq/L. Remember, the functioning kidney should be retaining sodium to increase its perfusion if the source of the problem is extrinsic to the kidney or “prerenal.” This is not happening here, so it is an intrinsic renal problem. In this case, FENa is 10.65%. In addition, “muddy” brown casts (renal tubular cell casts) are often found in the urinary sediment of patients with ATN. All of these findings point to ATN as the cause of renal failure in this patient.

Question 5.6.5 Based on the available data (including the vital signs in Table 5-8 and urine values), you suspect that ATN in this patient is the result of:

- A) Acetaminophen
- B) Hypotension
- C) Intrinsic renal infection
- D) Cefotetan
- E) Any of the above is equally likely

Answer 5.6.5 The correct answer is “B.” As you review the vital signs, intake, and output, you will notice that the patient had a hypotensive period associated with tachycardia and fever (day 2, shifts 1 and 2). She then developed progressively lower urine output despite stable IV intake. It is likely that she has had an ischemic insult to her kidneys as a result of hypotension and decreased perfusion. While many medications can cause ATN, cefotetan and acetaminophen are relatively safe. However, cephalosporins may cause acute interstitial nephritis (fever, rash, white cell casts, and perhaps eosinophils in the urine and peripheral blood).

**HELPFUL TIP:**

In addition to hypoxic insult (shock, hypoperfusion, HF, etc.), common causes of ATN include medications such as tacrolimus, NSAIDs, ACE inhibitors, gentamicin, tobramycin, cyclosporine, and more.

Question 5.6.6 Which of the following recommendations do you make for this patient’s continuing care?

- A) Administer “renal dose” dopamine
- B) Increase IV fluids to 200 cc/hr, using 5% dextrose/0.45% saline
- C) Consult nephrology for hemodialysis
- D) Administer hydrochlorothiazide
- E) Administer furosemide

Answer 5.6.6 The correct answer is “E.” The treatment of acute kidney injury due to ATN is largely supportive. In this oliguric patient with signs of volume overload, a trial of a loop diuretic is appropriate. Intravenous furosemide dosed at 40 to 100 mg every 6 to 12 hours is a reasonable way to start. Of note, furosemide will often improve the symptoms of volume overload even if there is no diuresis; it has some direct vasodilating effect which decreases pulmonary artery pressure. “A,” dopamine, is not effective in the treatment of ATN (it is not “renal sparing” and does not increase GFR). “B,” more fluid, is clearly not indicated in this patient who is already fluid overloaded. Why not dialysis you ask (“C”)? Early dialysis in ATN has been associated with greater mortality and increased kidney damage from hypotension, infection, and complement activation in the kidney. “D,” hydrochlorothiazide, is also a diuretic but less effective than furosemide in the setting of a low GFR.

**HELPFUL TIP:**

While traditionally taught, trying to “convert” oliguric to nonoliguric renal failure (by flogging the kidneys with diuretics) is not helpful and is possibly harmful. There is a trend toward greater mortality in patients who are treated this way. There’s more: loop diuretics can cause deafness (eh?), vertigo, and tinnitus. Remember, it doesn’t help to flog a dead horse or ailing kidneys. Why did we think it worked in the past? Probably the people who were able to produce urine in response to diuretics were less sick to begin with.

When you go to check on the patient later in the afternoon, she has become more tachypneic and has rales on examination.

Your patient has very little response to furosemide, but you match her input and output and she has enough insensible loss to resolve her rales. She begins to eat, and you monitor her fluid intake carefully. You match her fluid intake with output, giving normal saline to match her urine output and suspected insensible losses. You treat her hyperkalemia with sodium polystyrene sulfonate *without sorbitol* (Kayexalate), which is effective. Her BUN and creatinine continue to rise over the next 2 days and reach 60 and 4 mg/dL, respectively. The plasma HCO_3^- is 18 mEq/L.

Question 5.6.7 You now recommend:

- A) Hemodialysis
- B) Sodium bicarbonate
- C) Strict protein restriction
- D) Continuing to match intake and output
- E) All of the above

Answer 5.6.7 The correct answer is “D.” At this point, there is no reason to change your therapeutic approach. In particular, hemodialysis is not necessary. Indications for hemodialysis in this patient might include symptomatic uremia (e.g., coma, pericarditis), severe hyperkalemia or acidosis unresponsive to other therapies, and complications of volume overload (e.g., pulmonary edema). Dialysis (“A”) is actually associated with worse outcomes and prolonged renal disease (complement fixation in the kidney produces additional injury, episodic hypotension from dialysis increases kidney injury). Sodium bicarbonate (“B”) is used orally in patients with significant chronic acidosis in end-stage renal disease, but many patients can tolerate the temporary mild acidosis associated with acute kidney injury. Dramatic protein restriction (“C”) will probably lower BUN but this should not be your primary goal. Your patient is recovering from surgery and was probably septic. She requires good nutrition to continue to heal.

HELPFUL TIP:

Acute kidney injury due to ATN typically lasts 7 to 21 days, with renal function returning as the tubular cells regenerate. However, the course is highly variable and depends on the patient’s general health and the length and degree of the initial injury.

Question 5.6.8 In patients with acute tubular necrosis, the most common cause of death is:

- A) Hemorrhage
- B) Adverse event of hemodialysis
- C) Infection
- D) Transfusion reaction
- E) Heart failure secondary to fluid overload

Answer 5.6.8 The correct answer is “C.” In patients with ATN who die, infection is the usual culprit. Unfortunately, serious infection resulting in sepsis is one of the most common causes of ATN. It’s the circle of life . . . or death, in this instance.

Ten days after her surgery, your patient’s urine output increases markedly. Her BUN and creatinine return to their premorbid levels. The National Kidney Foundation makes you an honorary nephrologist and awards you the Bronze Nephron.

► **Objectives: Did you learn to ...**

- Evaluate a hospitalized patient for acute kidney injury?
- Use urine studies, including urine sodium and FENa, to assist in the diagnosis of acute kidney injury?
- Identify acute tubular necrosis?
- Describe common causes of acute tubular necrosis, its treatment, and its prognosis?

► CASE 5.7

While on call, you admit a 75-year-old female for confusion. One month ago, she started hydrochlorothiazide (HCTZ) for hypertension. Her medications include HCTZ 25 mg daily, levothyroxine 125 mcg daily, aspirin 81 mg daily, sertraline (Zoloft) 50 mg daily, and atorvastatin (Lipitor) 40 mg daily. She has a 50-pack-year history of tobacco use and continues to smoke.

On examination, you find an irritable and confused female in no acute distress. Her admission vitals are BP 100/60 mmHg, P 120 bpm, RR 12 breaths/minute, T 36.1°C, weight 50 kg. Her oral mucosa is dry and she has poor skin turgor. She has clear lungs, an S4 on heart examination, and no edema. Her neurological examination is nonfocal.

Laboratory results: Na 110 mEq/L (135–145 mEq/L), K 3.0 mEq/L (3.5–5.0 mEq/L), Cl 70 mEq/L (98–107 mEq/L), HCO_3^- 33 mEq/L (23–29 mEq/L), BUN 30 mg/dL (5–20 mg/dL), Cr 1.0 mg/dL (0.6–1.2 mg/dL), glucose 110 mg/dL. Plasma osmolality 220 mOsm/L (270–299 mOsm/L).

Question 5.7.1 Which of the following statements is true regarding the etiology of her hyponatremia?

- A) She has pseudohyponatremia
- B) She has isovolemic hyponatremia
- C) She has hypovolemic hyponatremia
- D) She has hypervolemic hyponatremia

Answer 5.7.1 The correct answer is “C.” The definition of hyponatremia is a plasma sodium concentration below 135 mEq/L. The evaluation of hyponatremia begins with the determination of the validity of the plasma sodium measurement. First question: is this pseudohyponatremia (“A”) ? Look at the measured serum osmolality. If it is low (as it is here), the patient does not have pseudohyponatremia. Pseudohyponatremia is caused by either hyperlipidemia or hyperproteinemia decreasing the water content of plasma. This distinction was more important in the past; newer laboratory techniques compensate for pseudohyponatremia.

Hyperglycemia and severe uremia can cause hyponatremia. In an instance where a patient’s measured sodium concentration is hyponatremic and his glucose is 800 mg/dL, the measured serum osmolality may be **normal or elevated** (due to

the elevated glucose, which “counts” as osmoles) and should be compared to the calculated osmolality using the equation:

$$\text{Osmolality} = 2(\text{sodium}) + \text{glucose}/18 + (\text{BUN}/2.8)$$

If the calculated osmolality approximates the measured osmolality, then much of the “hyponatremia” will autocorrect when the hyperglycemia is corrected. Therefore, you would not want to aggressively correct the serum sodium concentration without consideration of the patient’s hyperglycemia. When in doubt, frequent sodium monitoring is advisable.

The next step in the evaluation of hyponatremia is to determine the patient’s volume status. This patient has no signs of volume overload, such as edema or crackles, making hypervolemia (“D”) less likely. She is tachycardic with a low blood pressure, dry mucous membranes, and a BUN/Cr ratio greater than 20, suggesting she is hypovolemic. Most likely, she has a hypovolemic hyponatremia.

HELPFUL TIP:

Always consider “beer potomania” (one of our favorite disease names . . . not to mention one of our favorite food groups). Here is what happens: too much beer (or any alcohol) plus too little solute equal poor free water excretion and hyponatremia.

Question 5.7.2 What further information will help you narrow the differential diagnosis of hyponatremia in this patient?

- A) FENa
- B) Urine osmolality and urine sodium concentration
- C) Urine creatinine concentration
- D) Urine potassium and calcium concentration

Answer 5.7.2 The correct answer is “B.” Urine osmolality can be used to distinguish between impaired water excretion caused by SIADH (syndrome of inappropriate secretion of antidiuretic hormone), and pathologic water intake (polydipsia). In SIADH, the urine will be inappropriately concentrated with urine osmoles of >100 mosmol/kg (the patient is unable to retain sodium). FENa (“A”) is discussed earlier; although the word “sodium” is in it, FENa is not helpful for discovering the etiology of hyponatremia. Concentration of potassium and calcium (“D”) is not likely to add any useful information.

You order urine studies. Urinalysis: specific gravity 1.025, pH 5.0, trace protein, 0 to 1 RBC/hpf, 0 to 1 WBC/hpf, otherwise negative. Spot urine Na 70 mEq/L (elevated) and urine osmolality = 700 mmol/kg (elevated).

Question 5.7.3 Given the patient’s history, urine studies, and hypovolemic status, what is the most likely diagnosis?

- A) Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- B) Heart failure (HF)
- C) Diuretic-induced hyponatremia
- D) Hyponatremia due to reset osmostat
- E) Potato chip deficiency (hypopringlism)

Answer 5.7.3 The correct answer is “C.” In order to be useful in the diagnosis of hyponatremia, urine studies must be viewed in the context of volume status, plasma osmolality, and electrolyte levels. This patient’s laboratory results are consistent with SIADH. However, patients with SIADH should be euvolemic or slightly hypervolemic. In fact, if a patient is hypovolemic, ADH levels should be appropriately elevated. Thus, her laboratory results and clinical picture are most consistent with diuretic-induced hyponatremia. Note that she also has a chloride-depletion alkalosis (formerly called contraction alkalosis).

The appropriate response of the kidney to hypoosmolality is to make maximally dilute urine (retain sodium to correct the hypoosmolality). Thus, the urine should have a specific gravity less than 1.005 and osmolality less than 100 mmol/kg.

Inappropriately concentrated urine (osmolality >100 mmol/kg) occurs when there is limited excretion of fluid and may be observed in SIADH, HF, cirrhosis, and renal failure. This is also reflected in the urine sodium. If the kidneys respond to hyponatremia as expected, urine sodium concentration should be low, typically less than 20 mmol/L and often less than 10 mmol/L. In the setting of hypovolemia, if the urine sodium concentration is inappropriately high, something is inappropriately spurring the kidney to excrete sodium (e.g., diuretic use, hypoaldosteronism). In this patient, the elevated urine sodium is likely due to the diuretic. Diuretic use is the most common cause of hypovolemic hypoosmolality, and thiazides are more commonly associated with hyponatremia than are loop diuretics (furosemide, etc.). Your patient is hypovolemic and hyponatremic, with a high urine sodium concentration and the history of diuretic use: most likely, her hyponatremia is diuretic induced.

“D,” a reset osmostat, requires special mention. A reset osmostat, which is responsible for 20% to 30% of hyponatremia, occurs when the patient’s body “adapts” to hyponatremia and “gives up” trying to correct the problem: the kidneys just throw in the towel. Patients with a reset osmostat will present like SIADH (hyponatremia, euvolemia or slight hypervolemia, and inappropriately concentrated urine) but will be resistant to treatment. If a patient with apparent SIADH does not respond to the usual treatment, consider a reset osmostat. Patients with a reset osmostat generally have mild hyponatremia (125–130 mg/dL). Newer research suggests that these patients have higher rates of morbidity and mortality, and correction of their sodium levels is often very difficult.

HELPFUL TIP:

When you encounter a patient with hyponatremic hypoosmolality, also look at the plasma potassium concentration. Diuretic use is a common cause of hyponatremia, hypokalemia, hypochloremia, and hypoosmolality occurring simultaneously.

Question 5.7.4 In addition to discontinuing her diuretic, which of the following approaches is the best initial therapy for her hyponatremia?

- A) Saline 0.9% 1 L bolus followed by 150 cc/hr
- B) Fluid restriction to 1,500 cc/day
- C) Saline 3% 100 cc/hr for 24 hours

- D) Furosemide 20 mg IV
E) A large bag of potato chips with a tomato juice chaser

Answer 5.7.4 The correct answer is “A.” This patient is hypotensive and tachycardic and thus needs volume somewhat quickly to address her abnormal vital signs. If this patient was not hemodynamically compromised, you could forgo the fluid bolus. Excessively rapid correction of hyponatremia may lead to osmotic demyelination syndrome (formerly called central pontine myelinolysis).

Sodium concentrations less than 120 mEq/L are considered severe hyponatremia. Patients with acute, severe hyponatremia are almost always symptomatic as a result of the low sodium. By definition, acute hyponatremia has been present for 48 hours or less and chronic hyponatremia for more than 48 hours. As previously discussed, your patient’s hyponatremia is due to a diuretic, which she started 1 month ago. Therefore, her hyponatremia is more likely to be chronic.

As a general rule, hypovolemic hyponatremia should be corrected by volume infusion, usually with 0.9% (normal) saline. Fluid restriction (“B”), while good treatment for SIADH, is not appropriate in this patient who is already volume depleted. Likewise, a loop diuretic is not appropriate (“D”). Both “C” and “E” will provide more sodium but will not provide the necessary volume.

Your patient has chronic hyponatremia, which needs to be corrected more slowly than acute hyponatremia. Chronic hyponatremia should be corrected no faster than 0.5 mEq/hr or 10 to 12 mEq/day. For significantly symptomatic patients with acute hyponatremia, sodium can be corrected more quickly.

In order to determine how quickly sodium concentrations will rise, you must know the concentrations of the solution being infused and the patient’s plasma sodium. A liter of saline will affect the serum sodium by the following calculation:

$$\text{Na increase} = (\text{solution Na} - \text{plasma Na}) / (\text{total body water} + 1)$$

$$\text{Patient's Na} = 110 \text{ mEq} / \text{L}$$

$$\text{Na in 3\% saline} = 513 \text{ mEq} / \text{L}$$

$$\text{Na in 0.9\% saline} = 154 \text{ mEq} / \text{L}$$

$$\text{Total body water} = \text{weight (kg)} \times 0.5 (\text{females}) \text{ or } 0.6 (\text{males})$$

When using 3% saline solution, 1 L will increase the plasma sodium as follows:

$$\begin{aligned} \text{Na increase} &= (513 - 110) / [(50 \times 0.5) + 1] \\ &= 15.5 \text{ mEq} / \text{L} \end{aligned}$$

At 100 cc/hr, the plasma sodium will increase at a rate of 1.55 mEq/hr.

This correction is too rapid for chronic hyponatremia.

When using normal saline (0.9%), 1 L will increase the plasma sodium as follows:

$$\begin{aligned} \text{Na increase} &= (154 - 110) / [(50 \times 0.5) + 1] \\ &= 1.7 \text{ mEq} / \text{L} \end{aligned}$$

Therefore, it is expected that 1 L of normal saline will increase the plasma sodium by 1.7 mEq initially, and 150 cc/hr will increase the plasma sodium by 0.25 mEq/hr, well within the safe range.

HELPFUL TIP:

Whenever correcting sodium, whether with moderate-to-severe hyponatremia or hypernatremia, check serum sodium concentrations frequently—every 2 to 4 hours is reasonable in the initial treatment period.

Question 5.7.5 In addition to HCTZ, which medication should you discontinue because of its potential role in hyponatremia in this patient?

- A) Aspirin
B) Atorvastatin
C) Levothyroxine
D) Sertraline

Answer 5.7.5 The correct answer is “D.” Serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants, among other medications, can stimulate the release of ADH from the pituitary gland, ultimately causing hyponatremia with an SIADH-type presentation. The association between SSRIs and hyponatremia is strong enough to consider measuring plasma sodium levels in elderly patients before and after starting an SSRI. The other medications are not associated with hyponatremia to any significant degree.

Your patient does well, recovers from her hyponatremia, and is discharged. In place of HCTZ, you start an ACE inhibitor for hypertension. You next see her a few months later when she starts to have problems with mild confusion. Her family reports that she is definitely not taking any diuretics. Her vitals are normal. Clinically, she appears euvolemic, and her examination is nonfocal. Her plasma sodium is 120 mEq/L, creatinine 1.1 mg/dL, plasma osmolality 240 mmol/kg, and urine osmolality 320 mmol/kg. Urinalysis shows specific gravity of 1.030 but is normal otherwise.

Question 5.7.6 In addition to the laboratory tests already available to you, which of the following laboratory tests should be done in patients with hyponatremia?

- A) CBC
B) ESR
C) TSH
D) Liver enzymes
E) ADH

Answer 5.7.6 The correct answer is “C.” Hyponatremia with hypoosmolality and a normal volume status is often the result of SIADH. However, SIADH is a diagnosis of exclusion. Both hypothyroidism and glucocorticoid deficiency present with similar features and should be ruled out. Hypothyroidism is more common, and at a minimum you must check TSH. Of special note is option “E.” Most of the time, ADH levels are not helpful in the diagnosis of SIADH because up to 20% of patients with diagnosable SIADH do not have elevated plasma ADH levels. In fact you may see the designation change from SIADH to SIAD (syndrome of inappropriate diuresis) depending on what

you are reading. SIADH is diagnosed on clinical grounds, with characteristic laboratory data, and lack of a better explanation.

HELPFUL TIP:

In any given patient with hyponatremia, what makes SIADH likely? All of the following data are used to support the diagnosis of SIADH: decreased plasma osmolality; inappropriately concentrated urine (e.g., a urine osmolality of >100 mosmol/kg); clinical euvoolemia or mild hypervolemia; elevated urine sodium excretion (urine sodium >20 mEq/L); and the absence of diuretic use, hypothyroidism, and adrenal dysfunction.

You order a number of laboratory tests, including TSH, CBC, and electrolytes. In addition to the laboratory tests mentioned above, abnormal tests include plasma Cl 90 mEq/L (low), urine Na 50 mEq/L (high) (and urine osmoles, as noted above, are 320 mmol/kg). Thyroid function tests are normal. You diagnose SIADH.

Question 5.7.7 As initial treatment, you prescribe:

- A) Demeclocycline
- B) Lithium
- C) Saline 0.9% bolus
- D) Furosemide
- E) Water restriction

Answer 5.7.7 The correct answer is “E.” The laboratory results and clinical picture are consistent with SIADH (euvoolemia, elevated urine sodium excretion, elevated urine osmolality). Water restriction is the mainstay of therapy in SIADH. Free water should be restricted to 1 to 2 L/day. Demeclocycline (“A”) and lithium (“B”) interfere with the activity of ADH at the collecting tubules, but these drugs are reserved for SIADH patients with severe hyponatremia unresponsive to first- and second-line treatments. Saline infusion (“C”) corrects hypovolemic hyponatremia. Furosemide (“D”) is used in hypervolemic hyponatremia (e.g., CHF, renal insufficiency) and sometimes in more severe cases of SIADH in order to promote more dilute urine.

Question 5.7.8 The patient fails water restriction. The next step in the treatment of this patient is:

- A) Demeclocycline
- B) Lithium
- C) Sodium chloride tablets
- D) IV urea
- E) None of the above

Answer 5.7.8 The correct answer is “C.” Increasing salt intake and adding a loop diuretic are other ways to treat SIADH in patients who cannot or will not maintain fluid restriction. The aggressiveness of the intervention will depend on patient-specific factors, including symptoms and comorbidities. In an outpatient who is minimally symptomatic or asymptomatic, oral salt supplementation is most reasonable. IV urea (“D”), which

causes an osmotic diuresis, could be considered as the next step after sodium chloride tablets. Demeclocycline and lithium should be reserved for patients who fail the other treatments. In more severe hyponatremia and those with significant symptoms, admission for more aggressive therapy may be warranted.

HELPFUL TIP:

Conivaptan (Vaprisol[®]) and tolvaptan (Samsca[®]) both are ADH antagonists that can be used for SIADH. They are third-line agents. Potential problems include exacerbations of heart failure, orthostatic hypotension, and hypokalemia. *They must be started in the hospital because of the potential side effects and rapid serum sodium changes.*

► Objectives: Did you learn to ...

- Generate a differential diagnosis for hyponatremia?
- Identify medications that are commonly associated with hyponatremia?
- Use urine osmolality to identify impaired renal water handling?
- Calculate sodium correction using different concentrations of saline?
- Diagnose, evaluate, and treat a patient with SIADH?

► CASE 5.8

A 65-year-old male with a new diagnosis of heart failure returns to your office after starting several new medications within the last month. A cardiologist at Ivory Tower Academic Medical Center 100 miles away started these medications but never sent a note, and neither you nor your patient knows what drugs he’s taking (“Well, there’s a little white one and a pink one and . . .”). Over that same time period, he states that he has felt “worse than I did after my heart attack.” At first he was just fatigued, but in the last few days, he has developed nausea, vomiting, and body aches.

On examination, his vitals are T 37.1°C, P 70 bpm, RR 8 breaths/minute, BP 100/58 mm Hg. He has trace pedal edema. His lungs are clear, and his abdomen is diffusely tender. When you stand him up to check his blood pressure, he loses consciousness but quickly recovers when placed supine (fortunately, you are strong and possess quick reflexes and caught him on the way down).

Your nurse draws blood, starts an IV, and obtains a venous blood gas on room air. VBG: pH 7.52, PaCO₂ 49 mm Hg, PaO₂ 40 mm Hg, and HCO₃ 39 mEq/L. His oxygen saturation on monitor is 95%.

Question 5.8.1 The blood gas is consistent with the diagnosis of:

- A) Metabolic alkalosis with respiratory compensation
- B) Respiratory alkalosis with metabolic compensation
- C) Mixed metabolic/respiratory alkalosis
- D) Mixed metabolic alkalosis and respiratory acidosis

Answer 5.8.1 The correct answer is “A.” Your patient appears to have a pure metabolic alkalosis with respiratory compensation. His pH is above the upper limit of normal (range 7.35–7.45), and his plasma bicarbonate is elevated as well. In metabolic alkalosis, you can expect the PaCO_2 to rise in proportion to the rise in HCO_3^- . PaCO_2 should increase by 0.5 to 0.75 times the increase in HCO_3^- from baseline (about 24 mEq/L). In this case, the HCO_3^- has increased by 15 ($39 - 24 = 15$), and the PaCO_2 has appropriately increased by 9 ($9/15 = 0.6$). And remember, you cannot overcorrect your pH (although it is quite possible simultaneously to have two processes—an acidosis and an alkalosis resulting in a normal pH). Thus, the primary process has to be an alkalosis.

Question 5.8.2 Which of the following urine tests will aid in determining the cause of this patient’s metabolic alkalosis?

- A) Urine sodium
- B) Urine potassium
- C) Urine chloride
- D) Urine bicarbonate
- E) Urine creatinine

Answer 5.8.2 The correct answer is “C.” You can approach the differential diagnosis of metabolic alkalosis by measuring the urine chloride (see next question). The other urine studies are less useful in metabolic alkalosis. Of course, an appropriate history and physical as well as plasma tests are required to determine the correct diagnosis and treatment.

You have admitted the patient and are on your way to the hospital to see him when the laboratory tests return (you aren’t driving and talking on the phone at the same time, are you?). Plasma studies: Na 140 mEq/L (135–145 mEq/L), K 2.5 mEq/L (3.5–5.0 mEq/L), Cl 102 mEq/L (98–107 mEq/L), BUN 18 mg/dL (5–20 mg/dL), creatinine 0.9 mg/dL (0.6–1.2 mg/dL), Ca 9.5 mg/dL (8.5–10.5 mg/dL), Mg 1.4 mg/dL (1.7–2.2 mg/dL).

Urine studies: specific gravity 1.025, chloride 45 mEq/L (elevated).

Question 5.8.3 Of the following choices, which is NOT likely to contribute to metabolic alkalosis in this patient?

- A) Corticosteroids
- B) Diuretics
- C) Hypokalemia
- D) Vomiting

Answer 5.8.3 The correct answer is “D.” This makes intuitive sense. If there is vomiting (or NG suctioning), the patient will have low plasma chloride and thus will have little in the urine, where it is being reabsorbed. All of the rest of the answers will cause an **elevated** urine chloride and thus are consistent with this patient’s picture. With mineralocorticoid excess (aldosterone or extrinsic corticosteroids), “A,” one excretes potassium, causing hypokalemia. Hypokalemia prevents the kidneys from optimally reabsorbing chloride (“C”). See Table 5-9 for more on causes of metabolic alkalosis.

TABLE 5-9 CAUSES OF METABOLIC ALKALOSIS DIVIDED BY URINE CHLORIDE LEVELS

Low Urine Chloride (<25 mEq/L)	High Urine Chloride (>40 mEq/L)
Vomiting	Hypokalemia (severe)
Nasogastric suctioning	Diuretics (loop or thiazide; early effect)
Factitious diarrhea (laxative abuse)	Alkali load
Cystic fibrosis	Bartter/Gitelman syndromes
Low chloride intake	Primary mineralocorticoid excess (hyperaldosteronism, corticosteroids)
Posthypercapnia	
Diuretics (loop or thiazide; late effect)	

It only took your nurse 40 minutes, but now you have the cardiologist’s notes and the medication list. Your patient started taking atorvastatin, captopril, furosemide, isosorbide dinitrate, aspirin, and metoprolol in the last month—and you are not surprised he has orthostatic hypotension.

Question 5.8.4 All of the following are appropriate interventions in this patient EXCEPT:

- A) Discontinue furosemide
- B) Administer potassium chloride
- C) Administer hydrochloric acid through an NG tube
- D) Infuse normal (0.9%) saline
- E) Administer ranitidine

Answer 5.8.4 The correct answer is “C.” Chloride-responsive metabolic alkalosis is usually secondary to volume contraction. Your patient has renal salt and water losses due to a diuretic and has gastrointestinal volume losses due to emesis. Physical examination (except trace edema—but remember that he has heart failure) and laboratory findings support hypovolemia. The diuretic should be discontinued and volume should be replaced. An isotonic solution, such as normal saline, is an appropriate choice. However, you must monitor your patient’s volume status closely due to his heart failure. Because his potassium is low, he requires KCl. An H_2 -blocker, like ranitidine, is a good choice for a patient with alkalosis and gastrointestinal illness: it will reduce acid secretion in the stomach (and thus further acid loss) and may offer some symptomatic relief as well.

Hydrochloric acid is an option in severe metabolic alkalosis unresponsive to other therapies. However, it is not given by NG tube. HCl is very corrosive and should only be infused centrally.

Question 5.8.5 Your patient is not responding to the KCl you are administering. You give which of the following electrolytes to aid in repleting his potassium stores?

- A) Sodium
- B) Bicarbonate

- C) Calcium
- D) Phosphate
- E) Magnesium

Answer 5.8.5 The correct answer is “E.” Give magnesium before giving more potassium. Recall that his plasma magnesium level was slightly low at 1.7 mg/dL. Even if a patient’s magnesium is only slightly low or even low-normal, continued hypokalemia in the face of KCl repletion may indicate whole-body magnesium depletion. Serum magnesium levels may not accurately reflect whole-body magnesium stores, especially in patients with heart failure. Furosemide causes further magnesium wasting. None of the other electrolytes listed earlier is as important to potassium repletion.

With correction of fluid and electrolyte status, your patient recovers quickly. You try to convey to the cardiologist the importance of good communication. However, as noted by George Bernard Shaw, “The single biggest problem in communication is the illusion that it has taken place.”

► **Objectives: Did you learn to ...**

- Identify metabolic alkalosis?
- Utilize urine chloride in the evaluation of metabolic alkalosis?
- Recognize various causes of metabolic alkalosis?
- Recognize the role of hypomagnesemia in treating hypokalemia?

QUICK QUIZ: HEMATURIA

A 25-year-old male medical student presents with blood in his urine. When asked further about this finding, he admits that he was using urine dipsticks at home to check his urine. (Did you know that 20% of medical students meet the criteria for somatization disorder—now known as “somatic symptom disorder” in DSM V—at some time during medical school? It’s true.) He has no gross hematuria, just 1+ blood on his urine self-test. He has no symptoms otherwise. His major concern is that his father had a renal transplant at age 30 for Alport syndrome.

Given that his father had Alport syndrome, what is the probability that this student has it?

- A) Certain (100% chance)
- B) One in two
- C) One in four
- D) Less than 1 in 20

The correct answer is “D.” Alport syndrome, also known as hereditary nephritis, typically presents with microscopic hematuria and progresses to complete renal failure. Alport syndrome has a heterogeneous inheritance pattern: 80% of cases are due to X-linked disease, about 15% are autosomal recessive, and about 5% are autosomal dominant. Since most cases are X-linked, males are affected more severely and earlier than females. If

your medical student’s father had Alport syndrome, it was most likely X-linked, and the patient could not possibly have inherited it. However, there is a 5% chance that the father had autosomal-dominant disease and then a 50% chance that the trait was passed on to the patient; therefore, “D” is correct.

► CASE 5.9

A 33-year-old male presents to the ED complaining of shortness of breath and cough of 10 days duration. He now sleeps in a chair due to orthopnea. He has severe fatigue and a mild, diffuse headache. Four days ago, he was seen in an urgent care clinic and diagnosed with bronchitis. He reports no medical problems or surgeries. He quit smoking 1 year ago and denies alcohol and drug use. He has a strong family history of hypertension. The review of systems is otherwise negative.

On physical examination, his vitals are T 36.8°C, P 104 bpm, RR 16 breaths/minute, and BP 200/118 mm Hg. There are bibasilar crackles with dullness to percussion at the lung bases. The heart, abdomen, and extremities are otherwise unremarkable.

His chest x-ray shows cardiomegaly, cephalization of lung markings, and bilateral small pleural effusions. An ECG shows sinus tachycardia with left atrial enlargement and left ventricular hypertrophy. Laboratory results: troponin-T negative, hemoglobin 9.1 g/dL (low), WBC count and platelets normal, Na 136 mEq/L, K 4.4 mEq/L, Cl 96 mEq/L, HCO₃ 19 mEq/L (low), BUN 108 mg/dL (high), Cr 11.9 mg/dL (high), glucose 104 mg/dL, calcium 7.8 mg/dL (low), albumin 4 g/dL (normal).

Question 5.9.1 Which of the following is the most appropriate next step?

- A) Prescribe levofloxacin and discharge patient with follow-up the next day
- B) Prescribe furosemide and discharge patient with follow-up the next day
- C) Administer a bolus of normal saline intravenously and admit the patient
- D) Administer furosemide intravenously and admit the patient
- E) Perform thoracentesis for diagnostic purposes

Answer 5.9.1 The correct answer is “D.” The proper disposition of this patient is the hospital. His uremia is quite severe, and he is symptomatic from his renal failure. He needs further diagnostic tests and requires further monitoring. He has signs and symptoms of volume overload, and he may yet respond to loop diuretics. A trial of IV furosemide is reasonable. Even if it doesn’t cause a diuresis, furosemide can decrease pulmonary capillary wedge pressure. The initial diagnosis of bronchitis was most likely erroneous and switching to another antibiotic (“A”) will only perpetuate that error. As he is volume overloaded, you certainly do not want to administer more volume (“C”). If you are willing to attribute his pleural effusions to volume overload due to kidney failure, a thoracentesis (“E”) is not necessary.

Question 5.9.2 The patient's ECG is normal. How should the low calcium be approached in the ED?

- A) Administer calcium gluconate intravenously
- B) Obtain a serum parathyroid hormone level
- C) Monitor for signs and symptoms of hypocalcemia
- D) Obtain an ionized calcium level

Answer 5.9.2 The correct answer is "C." Currently, your patient does not have signs and symptoms of hypocalcemia; therefore, he does not need IV calcium replacement in the ED ("A"). He should be observed for the development of signs and symptoms. Symptoms are mostly neurological—generalized seizures, perioral paresthesias, and carpopedal spasms. The two best-known signs of hypocalcemia are Chvostek and Trousseau signs. Chvostek sign is present if a grimace occurs in response to tapping the facial nerve. Trousseau sign is evoked by inflating a blood pressure cuff above the systolic pressure for 3 minutes and observing for hand spasms.

Since you expect that the patient's hypocalcemia is secondary to renal disease and hyperphosphatemia and you will treat him symptomatically, serum PTH level ("B") is not required. It is not necessary to measure ionized calcium ("D"). Since you have access to both the total serum calcium level and the serum albumin, you can calculate the corrected calcium. In addition, no correction is required since the albumin level is normal.

HELPFUL TIP:

If the patient does not respond to furosemide, IV nitroglycerin will likely be successful at reducing this patient's pulmonary edema by decreasing preload and afterload.

Your patient is admitted. Initially, his urine output increases slightly with loop diuretics, but then he becomes oliguric. You ask for a nephrology consult to assist in management of this case. The nephrologist plans to place an IV catheter for dialysis and is considering a renal biopsy. If the patient develops bleeding with these procedures, hemostasis may be impaired because of his uremia.

Question 5.9.3 Which of the following treatments is LEAST likely to reduce the risk of bleeding in this patient?

- A) Hemodialysis
- B) DDAVP
- C) Cryoprecipitate
- D) Platelet transfusion
- E) Conjugated estrogens

Answer 5.9.3 The correct answer is "D." The cause of bleeding dysfunction in uremia appears to be the effect of uremic toxins on platelet function. Giving a uremic patient more platelets—especially when there is no thrombocytopenia—will not improve the situation, as the platelet dysfunction due to uremia will occur with the new platelets as well. "A," hemodialysis, will remove toxins related to uremia, improving platelet function. "B," DDAVP,

is often the first-line treatment in a bleeding patient with uremia. DDAVP is not generally toxic and quickly reduces bleeding time. It acts by causing the release of factor VIII:vWF multimers from endothelial storage sites. Unfortunately, patients rapidly develop tachyphylaxis to DDAVP; once the multimers are depleted from the endothelial cells, DDAVP will not work until these multimers are replaced (usually a process of several days). "C," cryoprecipitate, enhances platelet aggregation and will reduce bleeding time for about 24 hours after administration. Estrogen is another option for renal failure-related bleeding and has been used for short durations and seems to be effective and well tolerated.

Question 5.9.4 In order to reduce the risk of renal osteodystrophy (elevated serum parathyroid hormone with mobilization of calcium from bone), which of the following medications will you prescribe initially?

- A) Calcium carbonate
- B) Aluminum hydroxide
- C) Magnesium hydroxide
- D) Sevelamer (Renagel)
- E) Vitamin D

Answer 5.9.4 The correct answer is "A." Renal osteodystrophy occurs when parathyroid hormone levels are elevated and bone is mobilized. This occurs because patients with renal failure cannot clear phosphate. The body tries to compensate by increasing parathyroid hormone secretion, which reduces phosphate and increases serum calcium. However, it also is detrimental to bone and leads to demineralization.

Gastrointestinal binding of phosphate requires large doses of a cation such as calcium (2 g/day). Calcium carbonate is associated with the least potential toxicity; therefore, it is the initial choice for treating hyperphosphatemia to reduce the risk of renal osteodystrophy. Also, you may consider calcium acetate, which is as safe as calcium carbonate and is a more potent phosphate binder but more expensive. Avoid aluminum and magnesium products ("B" and "C") in renal failure as these ions accumulate and can cause toxicity.

Sevelamer ("D") is a cationic polymer that binds phosphate in the gastrointestinal tract and avoids the problems that can occur with the calcium, magnesium, and aluminum compounds. It is expensive so calcium products should be tried first in the setting of hypocalcemia. Newer studies suggest that Sevelamer may have better cardiovascular outcomes, so practices may change in the near future.

Patients with chronic renal failure or end-stage renal disease on dialysis should also receive vitamin D ("E"). However, vitamin D causes **increased** gastrointestinal absorption of phosphate, so it should be given only after hyperphosphatemia has been controlled.

HELPFUL TIP:

Whenever prescribing calcium for renal osteodystrophy, have patients take it with meals—otherwise it will not bind phosphate. Also, calcium is absorbed better when taken with food.

**HELPFUL TIP:**

Cinacalcet (Sensipar®) is another option for treating renal osteodystrophy. By mimicking calcium in the parathyroid, it “fools” the parathyroid into thinking that the serum calcium is normal and thus reduces the output of parathyroid hormone. It sounds cool, but there’s a price for being cool—in this case several thousand dollars per month (in 2018). There are several other new phosphate binders including ferric citrate (Auryxia®), which also increases serum iron levels, and lanthanum carbonate (Fosrenol®), which requires fewer pills than other options, but must be chewed completely (making it a less attractive option for your patients without teeth). Both of these are relatively expensive (approximately \$800/month).

► **Objective: Did you learn to ...**

- Anticipate complications of renal failure, including hypervolemia, hypocalcemia, platelet dysfunction, and renal osteodystrophy?

► **CASE 5.10**

A 10-year-old male presents with his mother, who appears very anxious. She reports several episodes of red-brown urine this morning. The patient reports feeling a bit tired, but otherwise has no complaints. His past medical history is unremarkable and he takes no medications. On review of systems, he reports about 10 days of a sore throat that completely resolved a few days ago.

On examination, you find a pleasant young male in no acute distress. He is afebrile. His blood pressure is 140/94 mm Hg, and he has trace pretibial edema. The remainder of the examination is unrevealing.

Question 5.10.1 All of the following tests are likely to be helpful in the workup of this patient EXCEPT:

- A) Urinalysis
- B) Abdominal X-ray
- C) CBC
- D) Plasma electrolytes
- E) BUN and creatinine

Answer 5.10.1 The correct answer is “B.” Abdominal plain films are not useful in almost any situation unless looking for bowel obstruction. X-ray is not indicated and can be misleading in constipation. (What did you say? Free air? An upright chest is the most sensitive film for free air—save for CT.) If this patient had a presentation consistent with urolithiasis, an abdominal CT scan may be indicated, although an ultrasound would be the preferred first study for urolithiasis in most patients. All of the other laboratory tests should be ordered.

Urinalysis shows 2+ blood, 2+ protein, specific gravity 1.015, and numerous red blood cells with red cell casts. BUN is 35 mg/dL and creatinine is 1.8 mg/dL. CBC, coagulation studies, and electrolytes are pending.

Question 5.10.2 At this point, all of the following should be considered in the differential diagnosis EXCEPT:

- A) Minimal change disease
- B) Henoch–Schönlein purpura
- C) Post-streptococcal glomerulonephritis
- D) IgA nephropathy
- E) Membranoproliferative glomerulonephritis

Answer 5.10.2 The correct answer is “A.” Minimal change disease usually presents with clinical signs and symptoms of nephrotic syndrome and not gross hematuria. All of the other diseases are associated with hematuria, either microscopic or gross. Henoch–Schönlein purpura, post-streptococcal glomerulonephritis, IgA nephropathy, and membranoproliferative glomerulonephritis all have more “nephritic” features with “active” urinary sediments (dysmorphic red cells, red cell casts, white cells, and protein in the urine). These diseases also have a similar pathologic process in which immune complexes deposit in the glomeruli, resulting in glomerulonephritis.

CBC, coagulation studies, and electrolytes are all normal. You are suspicious that he may have had streptococcal pharyngitis that was unrecognized.

Question 5.10.3 Which of the following statements best describes the usual course of post-streptococcal glomerulonephritis?

- A) Most patients progress to renal failure
- B) After resolution of the initial episode, recurrent episodes of gross hematuria are common
- C) In most cases, hypertension and uremia subside within 1 to 2 weeks after onset.
- D) In most cases, hypertension is persistent and requires treatment
- E) Adults tend to recover more quickly than children

Answer 5.10.3 The correct answer is “C.” Post-streptococcal glomerulonephritis, characterized by immune complex deposition in the glomeruli, is a self-limited disease in most patients. There is a latent period, averaging 10 days, between pharyngitis and the development of hematuria. Recovery is expected to start within 1 to 2 weeks. Recurrent episodes of gross hematuria are rare in post-streptococcal glomerulonephritis. Post-streptococcal glomerulonephritis is more common in children and tends to be more severe when it affects adults. Hypertension and uremia resolve relatively quickly, but microscopic hematuria may persist for 6 months.

**HELPFUL TIP:**

Renal biopsy is rarely indicated in children with nephritic urine and mild renal failure because the differential diagnosis can be narrowed by the clinical presentation and because many of the diseases are self-limited. In more severe cases, renal biopsy may be necessary to diagnose and treat appropriately. See Table 5-10 for a partial list of causes of hematuria in children.

TABLE 5-10 CAUSES OF GROSS HEMATURIA IN CHILDREN

Idiopathic (usually benign with resolution over time)
Urinary tract infection
Trauma
Congenital anomaly
Urethral irritation or trauma
Nephrolithiasis
Sickle cell disease/trait
Coagulopathy
Glomerular disease (e.g., post-streptococcal glomerulonephritis)
Malignancy (e.g., Wilms tumor)
Medications (e.g., hemorrhagic cystitis from cyclophosphamide)

► Objectives: Did you learn to ...

- Evaluate a child with gross hematuria?
- Generate a differential diagnosis for hematuria and proteinuria in a child?
- Describe the usual course of post-streptococcal glomerulonephritis?

► CASE 5.11

The parents of a 2-year-old female bring her in to your office for a week-long history of diarrhea. Initially, her stools were loose and watery, but over the last 2 days, they have become bloody. The patient has appeared to have abdominal pain on occasions, and her appetite is depressed. Despite bloody diarrhea, her parents attempted to care for her at home until she became more lethargic (well, that didn't work . . . probably the same parents who refused vaccines). They are also worried about some bruising on her extremities.

Vital signs: T 37.2°C, P 145 bpm, BP 88/47 mm Hg, RR 40 breaths/minute. The patient appears pale, with slight scleral icterus. You note petechiae and purpura on the extremities. Her abdomen is diffusely tender. She responds to commands but appears very lethargic.

While you are arranging her admission to the hospital, some laboratory tests return: Hgb 8 g/dL, Hct 24%, WBC 14,000/mm³, platelets 50,000/mm³, Na 128 mEq/L, K 3.9 mEq/L, HCO₃ 14 mEq/L, BUN 38 mg/dL, creatinine 2.1 mg/dL. The peripheral blood smear shows schistocytes, "Burr" cells, and grossly reduced number of platelets.

Question 5.11.1 Which of the following is the most appropriate initial management of this patient?

- A) Intravenous fluids
- B) Dialysis
- C) Platelet transfusion
- D) Corticosteroids
- E) Antibiotics

Answer 5.11.1 The correct answer is "A." The proper initial management consists of supportive therapy. This patient has signs of dehydration, which would be expected from the history

of prolonged diarrhea. She is hyponatremic, and isotonic (0.9%) saline is the IV fluid of choice. Use 20 cc/kg boluses until her blood pressure stabilizes. This patient may also require an RBC transfusion given her anemia. Although she has had diarrhea, her potassium is currently in the normal range, probably due to decreased glomerular filtration. Given her renal failure, potassium should not be in her IV fluids.

Consideration of dialysis ("B") is premature. A platelet count of 50,000 is adequate for hemostasis, so answer "C" is incorrect. The schistocytes suggest a microangiopathic hemolytic anemia. Steroids are not generally helpful for this, so "D" is incorrect. Finally, antibiotics ("E") may (or may not) be beneficial if the patient has bacterial enteritis, but IV fluids should be administered first.

Question 5.11.2 Based on the available information, which of the following is the most likely diagnosis?

- A) Thrombotic thrombocytopenic purpura
- B) Hemolytic uremic syndrome
- C) Postinfectious glomerulonephritis
- D) Henoch-Schönlein purpura
- E) Autosomal-recessive polycystic kidney disease

Answer 5.11.2 The correct answer is "B." Hemolytic uremic syndrome (HUS) is the most likely diagnosis. This patient presents with a classic history of uremia, hemolysis, and thrombocytopenia preceded by 5 to 7 days of diarrhea. Patients tend to become oliguric and sometimes anuric.

"A," thrombotic thrombocytopenic purpura (TTP), is related to HUS but is rare in children. The average age of a patient with TTP is 41 years with women making up about 70% of all cases. African-American ancestry is also a risk factor for TTP. In contrast to HUS, patients with TTP may present with the classic pentad: thrombocytopenia, fever, mental status changes, renal insufficiency, and hemolytic anemia. Usually, there is a prodrome viral illness with TTP but diarrhea occurs only rarely. See Chapter 6 for more details.

"C," postinfectious glomerulonephritis, usually occurs after pharyngitis or skin infection with group A beta-hemolytic streptococci. Common symptoms include edema and hematuria but not thrombocytopenia or diarrhea. "D," Henoch-Schönlein purpura (HSP), is a (usually) transient IgA vasculitis following upper respiratory infections in children and adolescents. HSP is not associated with a microangiopathic hemolytic anemia, thrombocytopenia or coagulopathy. Autosomal-recessive polycystic kidney disease ("E") is a rare disorder that presents early in childhood with abdominal masses, hypertension, urinary tract infections, and renal failure but not hemolytic anemia.

**HELPFUL TIP:**

HUS may occur without diarrhea. This atypical subtype of HUS occurs less frequently, is associated with *Streptococcus* infections or complement deficiencies, and carries a worse prognosis.

Question 5.11.3 From the blood culture, you expect to find:

- A) *Shigella* species
- B) *E. coli*
- C) *Streptococcus pneumoniae*
- D) *Haemophilus influenzae*
- E) None of the above

Answer 5.11.3 The correct answer is “E.” Although HUS is the result of bacterial enteritis, patients are not bacteremic. Instead, the endothelial damage and hemolysis are caused by Shiga toxin, released from *E. coli* or *Shigella dysenteriae*.

Question 5.11.4 All of the following are true regarding Shiga toxin HUS in children EXCEPT:

- A) If dialysis is needed, renal function rarely returns
- B) Half or more of the cases occur in the summer months
- C) Ingestion of contaminated meat is a common source of *E. coli* O157:H7 infection
- D) Cattle are the main vectors of *E. coli* O157:H7
- E) Antibiotics do not reduce the risk of HUS in patients with confirmed *E. coli* O157:H7 infections

Answer 5.11.4 The correct answer is “A.” All the other statements are true. The prognosis of Shiga toxin HUS in children is generally quite favorable, even if renal failure requires dialysis. While 50% will have some residual renal damage, only 4% go on to require long-term dialysis. HUS is more common in rural areas and in the summer. Cows are the culprits—they get the blame for everything. “E” is of special note. There is controversy over whether or not antibiotics may **increase** the risk of HUS developing in patients with *E. coli* O157:H7 infections; however, it is fairly clear that antibiotics do not reduce the risk. The idea is that bacterial death from antibiotics releases more Shiga toxin leading to HUS. Remember that most cases of bacterial gastroenteritis—*E. coli* O157:H7 included—will clear without antibiotic therapy.

HELPFUL TIP:

Other subtypes of *E. coli* as well as *Shigella* can be responsible for HUS. The absence of the O157:H7 subtype of *E. coli* does not rule out HUS.

► **Objectives: Did you learn to ...**

- Evaluate and manage a child with hypovolemia and renal failure?
- Recognize a clinical history and laboratory findings suggestive of hemolytic uremic syndrome?
- Identify causes of hemolytic uremic syndrome?

► **CASE 5.12**

A 45-year-old female presents to your clinic complaining of urinary frequency, “bladder” pain, and urinary urgency. There is no dysuria, however. She has had hematuria on dipstick several times with urinalysis showing microscopic

hematuria on more than three occasions. This has been going on for several months and other practitioners (less skilled than yourself) have treated with a number of antibiotics without any relief. On questioning, she also notes bladder pain during intercourse and some chronic, vague, lower pelvic pain distinct from the bladder pain. At this visit, urinalysis and pelvic examination are unremarkable except for tenderness over the bladder area.

Question 5.12.1 The MOST IMPORTANT next step is:

- A) Urine culture
- B) Trial of 4 weeks of antichlamydial therapy
- C) Pelvic ultrasound
- D) Psychiatry consult and/or SSRI therapy for somatization disorder (now called somatic symptom disorder)

Answer 5.12.1 The correct answer is “C.” This patient is describing typical symptoms of “painful bladder syndrome,” the disease formerly known as “interstitial cystitis.” Painful bladder syndrome does not involve inflammation. Therefore, “interstitial cystitis” is, and always has been, a misnomer. Painful bladder syndrome consists, appropriately enough, of pain referable to the bladder that cannot be attributed to another cause. Patients generally note pain with filling of the bladder and relief of symptoms after urination. The pain may be described as urethral, as a suprapubic pressure, as a pressure or a burning pain. Painful bladder syndrome is a diagnosis of exclusion and now treated as a chronic pain syndrome. It is critical to rule out other pelvic pathology that might cause the same symptoms such as an enlarged uterus sitting on the bladder, fibroids, or ovarian cancer. Other causes of similar symptoms could be bladder irritants (caffeine, alcohol), a urethral diverticulum, a sexually transmitted infection, etc. While less common, painful bladder syndrome can be seen in men. In such cases, prostate pathology must be ruled out.

Question 5.12.2 All of the following are mandatory at this point EXCEPT:

- A) Urine cytology in a high-risk patient (smoker, etc.)
- B) Postvoid residual
- C) Cystoscopy and hyperdistention of the bladder
- D) Ruling out a bladder stone

Answer 5.12.2 The correct answer is “C.” Cystoscopy and hyperdistention are NOT required in order to make the diagnosis of painful bladder syndrome. As noted above, painful bladder syndrome is a clinical diagnosis of exclusion: Is there anything else causing the symptoms? If not, as Sherlock Holmes said, “Once you eliminate the impossible, whatever remains, no matter how improbable, must be the truth.” It is important to rule out tumor (if indicated), stones, and neurogenic bladder (thus the postvoid residual).

HELPFUL TIP:

Treatment of painful bladder syndrome may include referral to a pain clinic, support groups, treatment of any other underlying problems (inflammatory bowel

disease, etc.), tricyclics, gabapentin, intravesicular DMSO, recurrent hydrodistention of the bladder, etc. What about pentosan polysulfate sodium (Elmiron®)? It is very expensive, may take up to 6 months to work, and the benefit is modest at best.

HELPFUL TIP:

Why not chronic phenazopyridine (e.g., Pyridium) for painful bladder syndrome? Well, you can consider it. But there is a danger of methemoglobinemia.

► Objectives: Did you learn to ...

- Evaluate and manage a patient with painful bladder syndrome?

QUICK QUIZ: ACID-BASE DISORDER

While covering your local ED, a 15-year-old female presents with her father. He reports that he came home from work, found her asleep on the couch, and had difficulty in waking her up. She is lethargic and complains of nausea, dizziness, and abdominal pain. Apparently, she had muscle aches after gymnastics practice and then took “handfuls” of aspirin to relieve her pain. She was taking three to four tablets every hour today but is not sure about her total ingestion. She denies other ingestions.

On physical examination, her vitals are: T 39°C, P 110 bpm, RR 18 breaths/minute, BP 104/68 mm Hg. She is diaphoretic. The neurological examination is nonfocal, but she becomes progressively more lethargic during the examination. A venous blood gas on room air shows pH 7.38 (normal), PaCO₂ 23 mm Hg (low), PaO₂ 40 mm Hg (low, but her oxygen saturation is 98% on transcutaneous monitoring), and HCO₃ 15 mEq/L (low). Other laboratory data: Na 140 mEq/L, K 3.1 mEq/L, Cl 101 mEq/L, HCO₃ 15 mEq/L (low), BUN 19 mg/dL, creatinine 1.1 mg/dL.

The venous blood gas results are best described as:

- Metabolic acidosis
- Metabolic acidosis and metabolic alkalosis
- Metabolic acidosis and respiratory alkalosis
- Metabolic alkalosis and respiratory acidosis
- Just dandy! Look at the pH, professor

The correct answer is “C.” Although the pH is in the normal range, there is an acid–base disorder present. First, there appears to be a metabolic acidosis with an elevated anion gap. The measured HCO₃ is 15 mEq/L, consistent with an acidosis, and the anion gap is 24 (based on the calculation of Na – (Cl + HCO₃), in this case: 140 – (101 + 15) = 24). This patient has taken an inadvertent overdose of aspirin. In salicylate overdoses, a high anion gap metabolic acidosis is often observed. Since salicylates directly stimulate the CNS respiratory center, there is usually a concurrent respiratory alkalosis.

In a compensated metabolic acidosis, the PaCO₂ should drop by 1.25 mm Hg for every 1 mEq/L drop in HCO₃. In this case,

the serum HCO₃ is 9 mEq/L below normal (if the normal is counted as 24), so PaCO₂ should be about 29 mm Hg (40 – (9 × 1.25)). However, the measured PaCO₂ is 23 mm Hg, indicating the presence of a respiratory alkalosis. Also, the pH is nearly normal despite the presence of a disturbance in measured HCO₃, **which only occurs when a mixed disorder is present.**

HELPFUL TIP:

It is impossible to overcorrect a metabolic abnormality. Thus, a patient with a metabolic acidosis will not become alkalotic or normal unless there is another primary process present (e.g., respiratory alkalosis). Likewise, a patient with a respiratory acidosis from the retention of CO₂ will not become alkalotic or normal unless there is a secondary primary process going on (e.g., metabolic alkalosis).

Proper treatment of salicylate overdoses includes supportive therapy, urine alkalinization with sodium bicarbonate, and possibly hemodialysis.

QUICK QUIZ: DYSURIA

Your nurse comes to you with a patient request. A 25-year-old female called in complaining of 2 days of burning with urination, urgency to urinate, and increased frequency. She has no fever, nausea, abdominal pain, flank pain, or vaginal discharge. The patient wants to know, “Can’t I just get some antibiotics?” She’s sure this is a bladder infection, just like the one she had last year. Oh, by the way, she’s leaving for Europe tomorrow for her honeymoon.

Your response is to:

- Prescribe ciprofloxacin 500 mg BID for 3 days
- Prescribe trimethoprim/sulfamethoxazole BID for 14 days
- Ask her to come in for a urinalysis
- Ask her to come in for a urine culture
- Prescribe nitrofurantoin 100 mg BID x 5 days

The correct answer is “E.” Although you could argue that the diagnosis of UTI should be confirmed by urinalysis, there is plenty of evidence that history alone is sufficiently accurate in the right population (in this case, women of child-bearing years—but **not** children, pregnant women, men, or the elderly). If a woman complains of dysuria and increased frequency without vaginal discharge, the likelihood ratio of UTI is about 25 and “pretest” probability is greater than 90% that she has a urinary tract infection (*JAMA*. 2002;287(20):2701–2710). If her urinalysis were completely normal, she may still have an infection and likely has a false-negative dipstick urine (only 70% sensitive). Thus, symptoms and historical elements are more useful than urinalysis (“C”). For this patient, empiric antibiotic therapy with an appropriate antibiotic (nitrofurantoin for 5 days or trimethoprim/sulfamethoxazole for 3 days

are reasonable options). Fourteen days of trimethoprim/sulfamethoxazole (“B”) is overkill. Why not “A”? The FDA has issued several warnings about fluoroquinolones including hypoglycemia, *permanent* neurologic/CNS problems, psychiatric disturbances, etc. So, fluoroquinolones should not be used for cystitis unless there is an overwhelming reason to do so. Plus, the dose is wrong. For simple cystitis, the dose of ciprofloxacin is 250 mg BID for 3 days. Of course, urine culture is the gold standard for diagnosing UTI, but she will be in Europe by the time you get the results—and we’re pretty sure your medical license does not extend to Paris (though maybe she needs someone to carry her bags). Additionally, increasing fluid intake may be helpful. Adding 1.5 L/day reduces the risk of UTI recurrence (*JAMA Intern Med.* 2018;178(11):1509–1515). The benefit of cranberry juice beyond just adding fluid is questionable. Finally, other options for cystitis include amoxicillin/clavulanate, cephalexin (for pregnancy), fosfomycin, cefixime, and cefpodoxime. Amoxicillin alone is not recommended because of resistance.

HELPFUL TIP:

With typical UTI symptoms (e.g., dysuria, frequency) and a negative urine culture or no response to antibiotics, consider other causes: painful bladder syndrome, chlamydia urethritis, prostatitis (in men), pelvic inflammatory disease (in women), pelvic mass, herpes genitalis, and drugs (e.g., diuretics, caffeine, and theophylline).

CASE 5.13

You are asked to consult on a patient who is hospitalized by an orthopedic surgeon (consulted by a surgeon twice in a chapter—congratulations!). The patient is a 25-year-old female who has a history of osteomyelitis from an open fracture sustained in a skiing accident. She has recently begun to spike a fever to 38.5°C and have a rapid increase in her creatinine.

Medications: nafcillin, ibuprofen, morphine, lactated Ringer solution IV 100 cc/hr.

Labs: Cr 3.5 mg/dL, BUN 25 mg/dL.

CBC shows mild WBC count of 12,500/mm³ and differential shows eosinophilia.

Question 5.13.1 Considering prerenal versus renal causes, you calculate the FENa, and what would you expect to find?

- A) FENa >2%, urine sodium <20 mg/dL
- B) FENa <1%, urine sodium <20 mg/dL
- C) FENa >2%, urine sodium >40 mg/dL
- D) FENa <1%, urine sodium >40 mg/dL

Answer 5.13.1 The correct answer is “C.” Remember . . . her BUN/Cr <20; therefore, it is likely **not** prerenal disease (and she’s receiving volume and has no history of heart failure). Thus, the patient likely has intrinsic kidney disease. This means that the FENa should be >2% and the urine sodium >40 mg/dL. In this scenario, the kidney is not trying to hold on to sodium in an attempt to correct a prerenal cause of increasing creatinine.

TABLE 5-11 COMMON DRUGS ASSOCIATED WITH ACUTE INTERSTITIAL NEPHRITIS

- Penicillins
- Aspirin
- Ciprofloxacin (and likely other fluoroquinolones)
- Allopurinol
- NSAIDs
- Some ACE inhibitors
- Proton Pump Inhibitors
- Erythromycin

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 5-12 SYMPTOMS/SIGNS/LABORATORY FINDINGS IN ACUTE INTERSTITIAL NEPHRITIS

- Fever
- Rash (variable, may not be seen in all)
- Acute rise in plasma creatinine
- Active urine sediment that includes white cell casts
- Peripheral eosinophilia and urine eosinophils (in most cases)
- Renal tubular acidosis

Note: Interstitial nephritis secondary to NSAIDs may occur without fever, rash, or eosinophilia.

The patient’s examination shows a diffuse rash and the urine contains white cell casts. There are no red cells in the urine.

Question 5.13.2 The most likely diagnosis is:

- A) Acute tubular necrosis (ATN)
- B) Acute interstitial nephritis
- C) Renal infarction
- D) Glomerulonephritis
- E) Nephrotic syndrome

Answer 5.13.2 The correct answer is “B.” The combination of fever, rash, mild eosinophilia, exposure to a new drug (nafcillin), and white cell casts in the urine essentially makes the diagnosis of acute interstitial nephritis. “A” is incorrect. The patient with ATN may have the same FENa and urine sodium as this patient, but should have renal tubular cells and/or granular casts in the urine. Also, ATN **does not cause fever, eosinophilia, or rash**. “C,” renal infarction, is unlikely in a young patient and the rest of the clinical picture is more consistent with acute interstitial nephritis. “D,” glomerulonephritis, is a possibility (e.g., lupus could cause a rash and fever). However, glomerulonephritis is associated with **red cell casts** and not white cell casts. Finally, as you already learned above, nephrotic syndrome presents with a bland urinary sediment. See Tables 5-11 and 5-12 for more details.

Question 5.13.3 How long after drug exposure does acute interstitial nephritis generally begin?

- A) 2 to 3 days
- B) 10 to 14 days
- C) Several months
- D) A and B
- E) Any of the above

Answer 5.13.3 The correct answer is “E.” Patients can develop acute interstitial nephritis anywhere from 1 day to several months after beginning a drug. Rifampin can cause acute interstitial nephritis on day 1. Interstitial nephritis can begin within 2 to 5 days if there has been a prior exposure to the drug, will typically begin within 10 to 14 days on **first** exposure to a drug, and may be delayed for months in the case of NSAID exposure.

HELPFUL TIP:

Patients with acute interstitial nephritis will often have eosinophils in the urine and peripheral smear, but eosinophils may be absent especially in those with NSAID-induced acute interstitial nephritis. Treatment is to stop the offending drug. If this doesn't work, steroids or cytotoxic drugs may be needed.

► Objectives: Did you learn to ...

- Recognize the presenting symptoms of acute interstitial nephritis?
- Describe causes and prognosis of acute interstitial nephritis?

HELPFUL TIP:

ACE inhibitors have been shown to be useful in reducing progression of renal disease even when the patient's creatinine is 5.0 mg/dL. But be very careful in this group. Start low, go slow, and check potassium and creatinine. In patients with CKD stage 3 or 4 started on an ACE inhibitor, a mild increase in creatinine is typical and expected and should not result in discontinuation of the ACE inhibitor.

Clinical Pearls

- ACE inhibitors are the drugs of choice for renal protection. ARBs and nondihydropyridine CCBs such as verapamil or diltiazem are other options.
- Avoid NSAIDs in patients with chronic renal disease from any cause, as well as in patients with heart failure or hypertension.
- BUN/Cr ratio >20 generally indicates that an acute kidney injury is secondary to extrarenal causes (poor perfusion from dehydration or CHF, etc.). This rule does not apply to children, those with GI bleeds, patients on high-dose steroids, and other exceptions.
- Calcium (dietary or supplemental) taken with meals reduces the risk of calcium oxalate stones by binding oxalate in the GI track.
- Gadolinium can cause a scleroderma-like disease in those with a creatinine clearance <30 mg/mL/min.
- In an otherwise healthy female without a vaginal discharge, the symptoms of dysuria, frequency, and urgency have a 90% positive predictive value for UTI, better than that of a UA.
- Patients with urolithiasis should have an NSAID as part of their pain control regimen unless it is contraindicated.

- Replace magnesium in the hypokalemic patient who is not responding as expected to treatment. The same is true in the patient with hypocalcemia.
- Sodium bicarbonate and *N*-acetylcysteine do not protect the kidneys from iodinated contrast. However, the risk of renal injury with contrast is small; hydrate the patient with normal saline.
- The early initiation of dialysis in patients with chronic kidney disease leads to worse outcomes. Start dialysis only when indicated.

Hematology and Oncology

Maresi Berry-Stoelzle and Jason K. Wilbur

▶ CASE 6.1

A 6-month-old boy presents to your office after his mother notices swelling and ecchymosis over his anterior right thigh. She does not recall any trauma to the area. The mother denies any history of bleeding problems, including during his circumcision. On physical examination the child has a large hematoma over his thigh. There are no obvious bony deformities and the child otherwise looks well. You suspect the child may have an inherited coagulation disorder.

Question 6.1.1 Which of the following statements is NOT correct?

- A) Child abuse should be included in the differential diagnosis
- B) The child did not bleed during circumcision, so the possibility of hemophilia need not be considered
- C) A careful family history is important in the workup
- D) Coagulation studies (PT, PTT) and CBC should be obtained

Answer 6.1.1 The correct answer (and untrue statement) is “B.” The absence of bleeding during circumcision in no way rules out hemophilia. Up to half of patients with hemophilia do not bleed with circumcision. Depending on the severity of factor deficiency, the diagnosis may not be made until the child is very active or even in adulthood, after surgery, etc. Whenever you encounter unexplained bruising in a child or dependent adult—especially in locations that would be unusual for accidental trauma, such as the posterior thighs or back—child abuse (“A”) should be included on your differential diagnosis. Since bleeding disorders in children are often inherited rather than acquired, a thorough family history (“C”) is important. The initial workup for this patient would include blood counts and coagulation studies (“D”).

Question 6.1.2 Which of the following is NOT TRUE about hemophilia A?

- A) It is an X-linked disorder
- B) It is the result of factor VIII deficiency

- C) It generally leads to mucosal bleeding
- D) It occurs most often in males
- E) It can be treated with factor VIIa

Answer 6.1.2 The correct answer (and untrue statement) is “C.” Hemophilia A is an X-linked deficiency of factor VIII, which presents with hematomas, bleeding, and hemarthrosis (and not generally mucosal bleeding or petechiae). Deficiency of factor IX, or hemophilia B, also known as “Christmas Disease,” is also X-linked but is much less common. “D” deserves special mention. Hemophilia rarely occurs in females but can occur in three situations: (1) the female patient is a heterozygote who has early inactivation of the second X chromosome during embryogenesis; (2) both parents are carriers, in which case the father would have the disease overtly; (3) acquired factor VIII deficiency. This is generally found in individuals over 50 or those who are pregnant or postpartum. The most common underlying conditions include pregnancy, postpartum, malignancy, rheumatoid arthritis, medications, and connective tissue disorders. Some have no identifiable trigger. It is caused by factor VIII antibodies. “E” is true—and not a typo. Factor VIIa can be used in most cases of hemophilia A and B to stop bleeding. It is mostly used in patients who have factor inhibitors in the blood (developed as a response to repeated exposure to factor VIII or factor IX).

HELPFUL TIP:

Generally speaking, petechiae and mucosal bleeding result from platelet problems (e.g., mild von Willebrand disease [VWD] and thrombocytopenia), while hemarthrosis and hematomas result from factor deficiency. Severe VWD may present with hemarthrosis and hematomas.

HELPFUL TIP:

Von Willebrand disease (VWD) may be autosomal dominant (Type I), variable (Type II), or autosomal recessive (Type III). There is often a family history of Von

Willebrand factor (vWF) deficiency or bleeding, but a percentage of cases occur spontaneously.

Question 6.1.3 Which of the following is indicated when evaluating for a suspected inherited coagulopathy?

- A) Prothrombin time (PT)
- B) Partial thromboplastin time (PTT)
- C) Platelet count
- D) PFA-100
- E) All of the above

Answer 6.1.3 The correct answer is “E.” The PTT is actually the most sensitive test for hemophilia. “D” deserves special mention. The PFA-100 (Platelet Function Analyzer) tests for (appropriately enough) platelet functioning and will be abnormal in diseases of platelet dysfunction, such as VWD. While the PFA-100 can help make a diagnosis of VWD, it does not correlate directly with the risk of clinically meaningful bleeding.

You diagnose this patient with hemophilia A, and he grows up under your excellent tutelage (along with some guidance from your friendly neighborhood hemophilia treatment center, since overall outcomes are better with multidisciplinary care through a hemophilia center). As a junior high school student, he attends summer camp for hemophiliacs in Transylvania. For some bizarre reason, the counselors decide to have the kids play tackle football (crazy, but a true story that happened to one of your authors). The patient presents to the ED with bleeding into his right knee and left elbow.

Question 6.1.4 What is the initial step in the management of this patient’s hemarthroses?

- A) Joint aspiration
- B) Desmopressin
- C) Factor VIII infusion
- D) Heparin infusion
- E) Leeches

Answer 6.1.4 The correct answer is “C.” While joint aspiration and desmopressin may be helpful, this patient needs to be treated with factor VIII in order to stop the bleeding. Joint aspiration (“A”) may play a role in preventing blood-induced arthritis, a risk with recurrent joint bleeds. Desmopressin (“B”) is useful in some cases of VWD and in some mild cases of hemophilia. Desmopressin releases vWF from platelets transiently increasing circulating vWF, which may be helpful in VWD but will not accomplish anything in this case. Antifibrinolytic therapy may also be of use: tranexamic acid or aminocaproic acid is commonly used to prevent clot breakdown. Heparin infusions (“D”) would lead to prolonged bleeding and would be counterintuitive. Leeches (“E”) are not indicated to treat hemarthroses.

Question 6.1.5 What factor level target is appropriate when treating this patient?

- A) 5% to 10%
- B) 40% to 50%

- C) 75% to 80%
- D) 100%

Answer 6.1.5 The correct answer is “B.” For a hemarthrosis (except for the hip joint, which is a special case) or other “minor” bleeding, maintain a factor level of 40% to 50% for 72 hours. For more serious bleeding (e.g., intracranial), maintain a level of 80% to 100% for 10 days. If planning a procedure, such as joint aspiration, raise the factor level to 80% to 100%.

HELPFUL TIP:

Von Willebrand disease Type I will respond to desmopressin (as noted above). Type II has variable response to desmopressin. A trial at the time of diagnosis is recommended. Type III VWD requires infusion of factor VIII and vWF (e.g., Humate-P, Alphanate). Remember that factor VIII is not enough, you need a preparation that also includes vWF. If you do not have a VIII + vWF factor available, or if the bleeding continues after replacement therapy, you can always transfuse normal platelets as a last option. These will have adequate vWF.

Question 6.1.6 As your patient grows and enters adulthood, he is likely to encounter which of the following?

- A) Hemarthrosis with significant arthritis and joint dysfunction
- B) A historically low risk of HIV/AIDS from multiple transfusions, as compared to the 1990s
- C) Maturation delay if antifactor antibodies are present
- D) Reduced risk of coronary artery disease (CAD)
- E) All of the above are found with hemophilia

Answer 6.1.6 The correct answer is “E.” “A” is true. Patients still get recurrent hemarthroses leading to arthritis and joint dysfunction. “B” is true. Screening and the use of recombinant factor VIII has led to a marked reduction in HIV in hemophiliacs from a high of 50% in the 1990s. Patients with hemophilia do have delayed maturation (“C”), especially if antifactor antibodies are present. And finally, they do have a **reduced risk** of CAD (“D”). This is also seen in carriers of hemophilia genes.

► **Objectives: Did you learn to ...**

- Suspect and test for a bleeding disorder in the appropriate setting?
- Use laboratory testing to assist in the diagnosis of a bleeding disorder?
- Identify and treat hemophilia A?

► **CASE 6.2**

A 4-year-old girl is brought to you after she is noted to have small pink spots on her lower extremities and bleeding from her gums. She had a URI a couple of weeks ago. She also recently received her second dose of her MMR vaccine (mom particularly wants to make sure she is protected from the recent resurgence in measles and mumps—thank you, anti-vaxers).

You note petechiae on her lower extremities and purpura in her oropharynx. The mother and patient deny any other bleeding. You obtain a CBC, which is normal except for a platelet count of $15,000/\text{mm}^3$. You suspect immune thrombocytopenic purpura (ITP, also known as idiopathic thrombocytopenic purpura).

Question 6.2.1 Which of the following may have led to this patient's ITP?

- A) MMR vaccine
- B) Infection
- C) Food allergy
- D) A and B
- E) All of the above

Answer 6.2.1 The correct answer is "D." Both infections ("B") and the MMR ("A") vaccine have been linked to ITP (not autism . . . got that? . . . **NOT** autism). Food allergy ("C") does not cause ITP.

Question 6.2.2 Which of the following is NOT likely to lead to a sustained (let's say at least 2 days) increase in the patient's platelet count?

- A) IVIG
- B) Steroids (e.g., prednisone)
- C) Platelet transfusion
- D) Splenectomy

Answer 6.2.2 The correct answer (and what will not yield a sustained increase in platelet count) is "C." Transfused platelets will just be "chomped up" by "Mr. Spleen." However, platelets can be used to temporize if a patient must go to the OR, etc. **Most children can simply be observed. The only indication for treatment is bleeding.**

All of the treatments have a downside. Splenectomy ("D") is associated with a risk of sepsis. If possible, delay splenectomy until after the child is over 5 years old. Of note, failure of ITP to respond to splenectomy may be due to the presence of an accessory spleen, which can often be identified by a liver-spleen radionuclide study. Steroids ("B") may cause behavioral problems and long-term problems such as avascular necrosis. IVIG ("A") leads to a temporary increase in platelets that may last several weeks, but can be associated with renal injury and anaphylaxis among other possible adverse effects.

HELPFUL TIP:

If a child suspected of having ITP looks sick, you need to expand your differential diagnosis. Sepsis with disseminated intravascular coagulopathy (DIC) and thrombotic thrombocytopenic purpura—hemolytic uremic syndrome (TTP-HUS) is also in the differential. ITP is most common in children between the ages of 2 and 4 years, with a small peak incidence in adolescence. ITP often resolves without specific therapy; 80% to 90% of pediatric patients are back to normal within a few months, and fewer than 20% of children will remain thrombocytopenic for greater than 12 months. Only 0.1% to 0.5% develop intracranial bleeding.

HELPFUL TIP:

Do not bother checking for antiplatelet antibodies in those with ITP. Patients **without** ITP may have antiplatelet antibodies and the presence of these antibodies is not predictive of outcome.

HELPFUL TIP:

For **adults** with ITP, treatment is generally indicated. Treatment includes (in order) steroids, Rho(D) immunoglobulin **for Rh-positive patients**, IVIG (which causes a transient rise in platelet numbers), and splenectomy. Other treatment options for refractory cases include rituximab or various immunosuppressive agents. The thrombopoietin-receptor agonists, romiplostim (Nplate) and eltrombopag (Promacta) (real names and not Icelandic vocabulary words), stimulate platelet production and can also be used in ITP.

► **Objectives: Did you learn to ...**

- Describe the natural history of ITP?
- Describe the treatments available to treat ITP?
- Understand the benefits and risks of the treatments for ITP?

► **CASE 6.3**

A 24-year-old female G1 P0 at 39 weeks of gestation presents to your office with a bruise on her anterior tibia, which she noticed after bumping into a coffee table. She has been healthy before and during her pregnancy and takes only prenatal vitamins. Her physical examination is unremarkable with the exception of an 8-cm bruise over her right anterior tibia. Her vital signs are normal. Her physical examination is remarkable for a gravid abdomen consistent with 39 weeks of gestation, fetal heart tones auscultated at 140 bpm, absence of right upper quadrant pain, and absence of peripheral edema. You obtain the following laboratory tests: CBC, which demonstrates white blood cell (WBC) $9,000/\text{mm}^3$, hemoglobin (Hgb) 11.8 g/dL, and platelet count $95,000/\text{mm}^3$; normal PTT and PT/INR; negative urinalysis; and normal liver enzymes.

Question 6.3.1 What is your next step?

- A) Recommend immediate delivery by cesarean section as the infant likely has thrombocytopenia as well and is at high risk for intracranial hemorrhage
- B) Recommend immediate delivery by cesarean section as this disorder will likely progress to eclampsia
- C) Recommend close observation and reassure the patient that this is typically a self-limited condition
- D) Start prednisone, 1 mg/kg daily, and taper slowly over the next 6 weeks
- E) Recommend splenectomy as soon as possible after delivery

Answer 6.3.1 The correct answer is “C.” This patient likely has gestational thrombocytopenia, a condition that occurs in up to 5% of pregnant women. It is characterized by mild thrombocytopenia occurring in late gestation, without other CBC abnormalities or physical findings; the platelet count is usually $>70,000/\text{mm}^3$ (two-thirds are between $130,000/\text{mm}^3$ and $150,000/\text{mm}^3$). The condition resolves after delivery and is not associated with severe neonatal thrombocytopenia. No specific change in routine obstetrical care is warranted, although the anesthesiologist placing an epidural may want a follow-up platelet count closer to the time of delivery.

Question 6.3.2 You can reassure this patient that an adequate platelet count for clotting is typically as low as:

- A) Minimum of $150,000/\text{mm}^3$
- B) Minimum of $100,000\text{--}110,000/\text{mm}^3$
- C) Minimum of $20,000\text{--}50,000/\text{mm}^3$
- D) Minimum of $5,000/\text{mm}^3$
- E) Minimum of 1. One platelet—that’s it. It’s just gotta be a big one.

Answer 6.3.2 The correct answer is “C.” A platelet count of $>20,000$ to $50,000/\text{mm}^3$ is generally considered adequate for achieving clotting.

► **Objectives: Did you learn to ...**

- Recognize gestational thrombocytopenia?
- Define the lower limit of platelet count appropriate for clotting?

QUICK QUIZ: COAGULATION STUDIES

Which of the following conditions should be considered if both the PT and PTT are prolonged in a patient noted to be oozing from a surgical incision?

- A) Severe liver disease, DIC, factor X deficiency
- B) Heparin effect, VWD, factor XII deficiency
- C) Warfarin effect, factor VII deficiency, vitamin K deficiency
- D) All of the above

The correct answer is “A.” The three factor deficiencies that may prolong both PT and PTT are II, V, and X. Both PTT and PT may be prolonged due to both **severe liver disease** and DIC. Mild vitamin K deficiency or **mild liver disease** generally affects the PT only. Generally, heparin affects PTT, and warfarin affects PT. Remember that the direct oral anticoagulants (rivaroxaban, dabigatran, etc.) cause bleeding without prolonging the PT or PTT.

HELPFUL TIP:

Why does vitamin K work to improve the PT in liver disease? Because most alcoholics and others with liver failure are vitamin K deficient (poor absorption, poor nutritional intake, antibiotic use—recall that vitamin K is made in the gut by bacteria). Paradoxically, those with *liver failure* are often hypercoagulable even in the face of an elevated PT leading to thrombotic complications such as hepatic vein thrombosis. See the GI chapter for more details.

► **CASE 6.4**

A 42-year-old male presents to the ED with a gastrointestinal (GI) bleeding due to ibuprofen use. His Hgb is 6.8 g/dL and he is hemodynamically unstable at this point. You are confident that this patient should receive a transfusion, but you remember that blood transfusions actually increase mortality if used incorrectly.

Question 6.4.1 Which of the following is an indication for transfusion?

- A) Hemodynamic instability in a trauma patient due to bleeding unresponsive to no less than 3 L of saline
- B) Preoperative Hgb of 7 to 8 g/dL with expected intraoperative blood loss
- C) Hemoglobin of 9.5 g/dL in a patient with angina
- D) A stable ICU patient with an Hgb of 8.7 g/dL
- E) All of the above

Answer 6.4.1 The correct answer is “B.” In general, a restrictive policy for blood transfusion has been shown to improve outcomes. “A” is incorrect because blood should be given to the hemodynamically unstable trauma patient after at most 2 L of saline (and per the ATLS recommendations after 1 L of saline). “B” is correct. A restrictive preoperative transfusion policy which limited transfusions to those with an Hb of <8 g/dL has shown survival benefit. “C” is incorrect. Transfusion should be considered in the patient with CAD only when the hemoglobin reaches 7 to 8 g/dL. Finally, “D” is incorrect. Transfusions should be withheld from a nonbleeding, hemodynamically stable ICU patient until the hemoglobin reaches 7 g/dL. A more liberal transfusion policy is associated with higher mortality. As an aside, some would transfuse postoperative patients with a hemoglobin of less than 10 g/dL if they are at high risk for ischemic disease (ischemic bowel, CAD, etc.). **Transfusion for indications other than these is not beneficial and has been proven harmful.** See Table 6-1 for a list of transfusion indications.

You decide to transfuse one unit of packed red blood cells (PRBCs). After 30 minutes, the patient complains of dyspnea and back pain. Repeat examination of this patient reveals a diaphoretic man with a pulse of 130 bpm and BP of 88/50 mm Hg. His lung fields are clear. Initial vitals before the transfusion were a pulse of 110 bpm and BP of 94/52 mm Hg.

Question 6.4.2 What is your next step?

- A) Stop the blood transfusion and begin normal saline through the IV
- B) Increase the rate of transfusion
- C) Administer acetaminophen 650 mg PO
- D) Administer furosemide 40 mg IV
- E) Place a nasogastric tube for lavage

Answer 6.4.2 The correct answer is “A.” *The transfusion must be stopped.* The patient is exhibiting signs and symptoms of a hemolytic transfusion reaction, which is generally the result of

TABLE 6-1 BLOOD TRANSFUSION INDICATIONS

Indication	Transfusion Threshold
Otherwise stable adult and pediatric intensive care patients	Hgb ≤ 7 g/dL
Hemodynamically stable postoperative patients	Hgb ≤ 8 g/dL OR for symptoms of chest pain, orthostatic hypotension, tachycardia unresponsive to IVF boluses, or CHF
Hemodynamically stable patients with preexisting cardiovascular disease	Hgb ≤ 8 g/dL OR for symptoms of chest pain, orthostatic hypotension, tachycardia unresponsive to IVF boluses, or CHF
Hemodynamically stable patients with acute coronary syndrome (ACS)	Unable to make a recommendation against liberal or restrictive transfusion.

Adapted from Carson JL, Grossman BJ, Kleinman S, et al. Red blood cell transfusion: a clinical practice guideline from the AABB. *Ann Intern Med*. 2012;157(1):49–58.

an ABO incompatibility. Patients may exhibit nausea, flushing, dyspnea, oliguria, back pain, and hypotension. Other findings include markers of hemolysis: hemoglobinuria, elevated serum-free hemoglobin, reduced haptoglobin, and elevated bilirubin. Patients are positive for direct antiglobulin test (i.e., Coombs). Therapy includes IV saline at a high enough rate to initiate a brisk diuresis to prevent hemoglobin from precipitating in the kidneys causing acute tubular necrosis. In evaluating the dyspnea, it is important to distinguish between transfusion-associated circulatory overload (TACO) and transfusion-related acute lung injury (TRALI). This may require a chest x-ray and assessment of oxygenation status (pulse oximetry or arterial blood gas measurement). TACO is more likely in patients who have received high volumes of fluids or are more sensitive to high fluid volume, such as those with underlying cardiac disease. Hypertension, hypoxemia, and pulmonary edema support the diagnosis of TACO. These patients should be treated with diuresis. TRALI may have a more sudden onset and will present with symptoms out of proportion to the volume of fluid or volume of transfusion. They will also require supportive care and consult to the transfusion service for further workup.

**HELPFUL TIP:**

Additional transfusion reactions include:

- Anaphylaxis (especially in those with IgA deficiency)
- Febrile, nonhemolytic reactions (which respond to meperidine and acetaminophen—"Finally, a use for meperidine!" you exclaim)
- Don't forget that fluid overload from transfusions may cause dyspnea

**HELPFUL TIP:**

Why did we always order "2 units of packed red cells?" In a non-bleeding patient, the transfusion of one unit of

PRBCs can be expected to raise the hematocrit by 3% to 4% (1 g/dL for Hb). Current guidelines recommend giving one unit and reassessing the patient. Every unit of blood has its own risk of mismatch, contagion, adverse reaction, etc.

► **Objectives: Did you learn to ...**

- Decide when blood transfusion is appropriate?
- Recognize hemolytic transfusion reactions?

► **CASE 6.5**

A 56-year-old male presents to the ED with an acute abdomen, likely from a perforated diverticulum. He is taking warfarin for a DVT that occurred after a total knee arthroplasty. He weighs 65 kg. You are evaluating him for surgery and find the following laboratory results: Hgb 14.3 g/dL, platelet count 478,000/mm³, INR 3.5, and PTT 28 seconds.

Question 6.5.1 Which of the following statements about his preoperative management is correct?

- Platelet transfusion perioperatively will produce the most immediate reduction in risk of bleeding from warfarin
- Fresh frozen plasma (FFP) transfusion will produce the most immediate reduction in risk of bleeding from warfarin
- Vitamin K administration orally (PO) will produce the most immediate reduction in risk of bleeding from warfarin
- Vitamin K administration subcutaneously (SC) will produce the most immediate reduction in risk of bleeding from warfarin
- Cryoprecipitate transfusion will produce the most immediate reduction in risk of bleeding from warfarin

Answer 6.5.1 The correct answer is "B." The patient above would benefit most immediately from the administration of FFP. FFP contains all the soluble plasma proteins found in whole blood, including the vitamin K-dependent factors that are depleted by warfarin. If a more sustained reversal is desired, the simultaneous administration of vitamin K is effective. **The preferred route of administration of vitamin K is oral.** Giving vitamin K IV is second best—this lowers the INR the same degree as oral vitamin K at 24 hours; the IV route may be preferred in instances where GI absorption is questionable. Avoid vitamin K SC or IM, which are less effective than PO and IV routes. The effects of FFP rarely last 24 hours; the effects of vitamin K are usually not apparent for 12 to 24 hours. The use of cryoprecipitate will not provide the appropriate factors depleted by warfarin. Cryoprecipitate contains vWF, factor VIII, factor XIII, and fibrinogen. Platelet transfusion would not benefit this patient since warfarin does not affect platelet function.

**HELPFUL TIP: REVERSING WARFARIN**

The most recent recommendations suggest using a 4-factor prothrombin complex concentrate (e.g., Kcentra) for reversing life-threatening bleeding

secondary to warfarin. A 3-factor prothrombin complex concentrate **plus** FFP is an alternative; 3-factor prothrombin complex concentrates lack factor VII. If these are not available, FFP is still an option.

HELPFUL TIP:

The INR of FFP is 1.5. No matter how hard you try, you cannot reduce the INR to less than 1.5 with FFP. Tell your surgeon to chill. Giving more FFP won't help.

► Objectives: Did you learn to ...

- Treat warfarin-induced hypocoagulability?

► CASE 6.6

A 20-year-old female with acute myeloid leukemia completed her second cycle of consolidation chemotherapy 5 days ago. She presents to the ED complaining of fatigue and fever. She denies cough, dysuria, abdominal pain, sinus drainage, or redness around her Hickman catheter. Her physical examination reveals a temperature of 38.4°C, pulse 100 bpm, BP 120/58 mm Hg, and respirations 14 breaths per minute. Her examination is otherwise unremarkable, including no redness or tenderness at the Hickman site. Your magic crystal ball tells you she does not have a line infection. Her laboratory results reveal the following: WBC 1300/mm³ (absolute neutrophil count 500 cells/mm³), Hgb 9 g/dL, hematocrit 27%, and platelet count 47,000/mm³. Blood cultures have been drawn.

Question 6.6.1 What is your next step, and what is your rationale?

- Administer IV amphotericin B; a Candida urinary tract infection is most likely
- Administer IV cefepime; she requires empiric coverage for both Gram-negative and Gram-positive organisms
- Administer IV nafcillin; a Gram-positive bacterial infection is most likely and broader antibiotic coverage will encourage growth of resistant bacteria
- Administer IV vancomycin; she most likely has an MRSA sinus infection
- Close observation; there is no focus of infection and she looks well

Answer 6.6.1 The correct answer is “B.” This patient has a neutropenic fever, which is a medical emergency. Prompt treatment with broad-spectrum antibiotics has drastically improved the survival of patients with neutropenic fever. Antimicrobial treatment should be started within 60 minutes of triage. Neutropenia is usually defined as neutrophils plus bands (absolute neutrophil count, ANC) <500/mm³ or <1,000/mm³ when the nadir has not been reached. Most myelosuppressive chemotherapeutic agents produce a reduction in WBCs 4 to 10 days after completion and nadir at 10 to 14 days. Fever is defined as

a **single** oral temperature >101°F (38.3°C) or a temperature >100.4°F (38°C) persisting for 1 hour or more. This patient does not need vancomycin since the absence of a line infection was stipulated in the history (via crystal ball that always works in our experience). Broad-spectrum coverage of Gram-positive and Gram-negative organisms, including *Pseudomonas*, is the cornerstone of therapy with specific therapy for any localizing symptoms or risk signs. See Table 6-2 for common antibiotic regimens.

TABLE 6-2 SUGGESTED ANTIBIOTIC REGIMENS FOR NEUTROPENIC FEVER

High-Risk Patients (ANC ≤ 100/mm³ or expected duration of neutropenia >7 days or significant comorbidity)

Comorbidities = hypotension, pneumonia, new onset abdominal pain or neurologic changes

Single Agents

Antipseudomonal β-lactam

- Cefepime
- Ceftazidime
- Piperacillin-tazobactam
- Carbapenem
- Imipenem-cilastatin
- Meropenem

Combination Agents

Add one of the following to the above regimen for management of complications or suspected/proven resistance:

- Aminoglycoside
- Fluoroquinolone (ciprofloxacin or levofloxacin)
- Vancomycin

Additional considerations:

- Add vancomycin if a line infection is suspected, MRSA is likely, skin or soft tissue infection, patient is clinically more ill (hypotension, hemodynamically unstable, etc.), or if no improvement after 3–5 days of empiric therapy.
- Add linezolid or daptomycin for VRE, or patient intolerance to vancomycin.
- Add metronidazole for abdominal symptoms or suspected *Clostridium difficile* infection.
- Add antifungal (fluconazole, voriconazole, amphotericin B) if still febrile 4–7 days after a broad-spectrum antibacterial regimen and no identified source of fever. The risk of fungal infection is increased by this point.
- Add acyclovir and/or fluconazole if there is oral ulceration.

Low-Risk Patients (anticipated neutropenia <7 days, able to take PO, hemodynamically stable, no comorbid conditions, able to comply with daily follow-up):

- PO ciprofloxacin and amoxicillin-clavulanate
- OR
- Hospital admission and any of the above regimens for persistent fever or worsening symptoms.

Data from Infectious Diseases Society of America. Freifeld AG, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;52(4):e56–e93.

**HELPFUL TIP:**

Patients with a neutropenic fever can have any infection seen in normal hosts, but you should also consider IV catheter infections, perirectal infections and abscesses, and necrotizing enteritis (aka “typhlitis”). Remember that they may not have an inflammatory reaction around a catheter site, abscess formation, infiltrate on chest x-ray, or WBCs in the urine because of the neutropenia. The absence of signs or symptoms should not dissuade you from starting empiric antibiotic therapy. Similarly, **the absence of fever in a neutropenic patient with focal infection should be approached as a high-risk situation.**

► **Objectives: Did you learn to ...**

- Identify and treat a neutropenic fever?

► **CASE 6.7**

A 63-year-old male with a diagnosis of non-small cell lung cancer, undergoing weekly chemotherapy and radiation to a left upper lobe mass, presents to your office. He complains of dull, non-radiating back pain in the lower thoracic/upper lumbar area. He denies trauma or any new activities. He has no associated weakness or paresthesias. He denies difficulties with bowel or bladder function but does notice he is tripping more.

Question 6.7.1 What is your initial diagnostic and/or therapeutic approach to this patient?

- MRI of thoracic and lumbar spine
- Plain films of the thoracic and lumbar spine and a COX-2 inhibitor with a 2-week follow-up
- Plain films of the thoracic spine and NSAIDs
- Prescription for physical therapy and NSAIDs
- Urinalysis with culture and antibiotics

Answer 6.7.1 The correct answer is “A.” This is not your average back pain. Any patient with active malignancy complaining of back pain should be investigated for metastasis. While a plain film of the spine may be useful, the gold standard is MRI. This patient gives a history of “tripping” which, beyond the reference to the 1960s, may indicate lower extremity weakness, foot drop, etc. The real emergency is spinal cord impingement. Spinal cord compression may occur from direct extension of metastatic disease from the vertebrae or extension from retroperitoneal or paravertebral disease. Frequently, the pain predates neurological symptoms, and because of the potential for severe, adverse outcomes, you want to catch the disease early to prevent chronic impairment.

The patient undergoes MRI of the spine, which demonstrates a lesion compressing the cord at L1.

Question 6.7.2 Which of the following is NOT an appropriate therapeutic modality?

- Decompression surgery
- Dexamethasone 10 mg bolus IV, followed by 6 mg every 6 hours
- Observation with pain control (e.g., with morphine PCA)
- Radiation therapy to the affected area

Answer 6.7.2 The correct answer is “C.” Patients with spinal cord compression who have aggressive interventions are more likely to retain function, including ambulation and bowel and bladder control. Steroids (“B”) will help reduce edema surrounding the tumor and hopefully will relieve pressure on the cord. Radiation (“D”) can often provide symptomatic relief and reduce the likelihood that the tumor will spread locally to impinge on the cord. Surgical decompression (“A”) is another option. Of course, if this patient opted for a palliative care approach and had decided upon hospice, “C” might be appropriate, but he is still getting active therapy, and his remaining time could be spent with less pain and better function if one of the other options were chosen. Additionally, radiation can be seen as symptom-directed palliative care.

► **Objectives: Did you learn to ...**

- Recognize and treat neoplastic spinal cord injury?

► **CASE 6.8**

A 32-year-old woman presents to your office with complaints of dyspnea, constipation, menorrhagia, and fatigue that are new over the past few weeks. She has a distant history of Hodgkin lymphoma treated with chemotherapy and radiation to the chest. Her physical examination reveals a well-developed woman, who appears comfortable at rest with normal vital signs. She has no adenopathy and the remainder of her examination is unremarkable. Her CBC with WBC differential is normal.

Question 6.8.1 Which of these diagnoses can be absolutely ruled out based on this patient’s history?

- Coronary ischemia
- Hypothyroidism
- Lung cancer
- Relapse of the Hodgkin lymphoma
- None of the above

Answer 6.8.1 The correct answer is “E.” The point here is that patients with a history of Hodgkin lymphoma and chest radiation are at risk for a wide range of complications—even years after the disease has been successfully treated. Even though 80% of Hodgkin lymphoma patients have long-term disease-free survival, one in six patients can be expected to die from late effects of therapy. The key late effects of radiation therapy for Hodgkin lymphoma include secondary malignancy (“C”), including breast cancer, lung cancer, leukemia, sarcoma, and non-Hodgkin lymphoma, and accelerated cardiac disease (“A”) at a younger age (5 to 10 times that of age-matched controls).

Other delayed complications that have been associated with radiation therapy include thyroid dysfunction, predominantly hypothyroidism ("B"), pulmonary fibrosis, non-coronary atherosclerotic disease, and muscle atrophy.

The patient has a normal chest radiograph and ECG. However, her TSH is markedly elevated, and you start her on levothyroxine. You plan to see her back in 8 weeks for re-evaluation and will provide additional counseling at that time.

Question 6.8.2 Which of the following preventative health issues is/are necessary to address at follow-up?

- A) Early intervention by a fertility specialist if the patient desires pregnancy
- B) Smoking cessation
- C) Yearly mammograms
- D) Yearly skin exams
- E) All of the above

Answer 6.8.2 The correct answer is "E." Female patients who were treated for Hodgkin lymphoma with chemotherapy and radiation prior to age 20 have up to a 35% incidence of breast cancer by the age of 40. The typical latency period is 15 years. National guidelines recommend that annual breast cancer screening of Hodgkin lymphoma survivors treated with chest irradiation should begin 5 years post-treatment (no earlier than age 25), or age 40, whichever comes first. Breast cancer screening for these high-risk patients includes breast MRI in addition to mammography, although the evidence for this approach is scant. Smokers with a history of Hodgkin lymphoma have a 20-fold increased chance of developing lung cancer when compared to nonsmokers with a history of Hodgkin lymphoma. At least yearly skin exams are recommended along with the routine physical examination. Also, female patients with Hodgkin lymphoma have a 69% incidence of premature ovarian failure if treated for their cancer before the age of 29 and up to 96% if treated after the age of 30. While these statistics are improving with newer chemotherapy regimens, a patient should seek early referral to a fertility specialist if she desires pregnancy but is unable to conceive.

► **Objectives: Did you learn to ...**

- List late complications of young adult lymphoma survivors?

► CASE 6.9

A 40-year-old male who has just received his first course of chemotherapy for non-Hodgkin lymphoma (NHL) presents to your ED complaining of weakness, cramps, and decreased urine output. He has no other medical problems and takes no medications except for prochlorperazine as needed for nausea. He has been eating and drinking well. His physical examination reveals a tired-appearing male, with normal vital signs. His head-and-neck examination reveals bilateral palpable cervical lymph nodes (2 cm). His lungs are clear in the upper lung fields with crackles bilaterally at the bases.

Muscle strength is normal, and reflexes are 3+ and symmetric. He exhibits 6 beats of clonus at the ankles. Chest radiograph shows evidence of early pulmonary edema.

Question 6.9.1 What is the most likely set of laboratory values you will find for this patient (reference ranges: potassium 3.5–5 mg/dL, phosphate 2.4–4.1 mg/dL, uric acid 3.5–7.2 mg/dL, calcium 8.5–10.2 mg/dL).

- A) Potassium 2.3 mEq/L, phosphorus 3.1 mg/dL, uric acid 4 mg/dL, calcium 9 mg/dL
- B) Potassium 2.6 mEq/L, phosphorus 6 mg/dL, uric acid 5 mg/dL, calcium 12 mg/dL
- C) Potassium 6.5 mEq/L, phosphorus 7 mg/dL, uric acid 18 mg/dL, calcium 6 mg/dL
- D) Potassium 6 mEq/L, phosphorus 6.8 mg/dL, uric acid 5 mg/dL, calcium 6.7 mg/dL
- E) Potassium 4.5 mEq/L, phosphorus 3.2 mg/dL, uric acid 9 mg/dL, calcium 8 mg/dL

Answer 6.9.1 The correct answer is "C." This patient most likely has tumor lysis syndrome, which can occur in a patient with a highly responsive leukemia or a bulky lymphoma being treated with chemotherapy (it rarely occurs without treatment). Tumor lysis syndrome occurs when there is rapid release of intracellular contents into the bloodstream. It is characterized by high potassium, high phosphorus, high uric acid, and low calcium. Patients may experience renal failure, arrhythmias, fatigue, muscle cramps, and tetany.

The patient is found to have a creatinine of 8 mg/dL.

Question 6.9.2 What is the most likely cause of this patient's renal failure?

- A) Dehydration
- B) Heart failure
- C) Hemoglobinuria
- D) Rhabdomyolysis related to chemotherapy
- E) Uric acid nephropathy

Answer 6.9.2 The correct answer is "E." Patients with tumor lysis syndrome may have renal failure secondary to uric acid nephropathy. This is caused by the precipitation of uric acid in the kidney. It can be prevented by starting allopurinol prior to the administration of chemotherapy. Although dehydration ("A") is not the cause of renal failure, it certainly will exacerbate the situation.

Question 6.9.3 Which of the following is MOST LIKELY to help this patient's current condition?

- A) Allopurinol 300 mg orally
- B) Calcium carbonate 500 mg orally
- C) Emergent hemodialysis
- D) IV D5W with 2 amps bicarbonate
- E) IV normal saline 200 mL/hr

Answer 6.9.3 The correct answer is "C." The horses are already out of the barn, and in fact they're probably over the hills and

through the woods. Allopurinol and oral calcium will not help this situation. The patient already has renal failure from his tumor lysis syndrome. While he may benefit from preventive measures, including aggressive hydration and allopurinol **prior to undergoing chemotherapy**, none of these measures are going to help his current renal failure. In addition, the patient may develop worsening pulmonary edema if given too much volume with IV fluids.

While awaiting hemodialysis, you should treat the patient's hyperkalemia. Treatment may include IV calcium gluconate, insulin and dextrose, and oral sodium polystyrene sulfonate (Kayexalate). Note that sodium bicarbonate for hyperkalemia has fallen out of favor.

HELPFUL TIP:

Rasburicase has also been approved for the prevention of tumor lysis syndrome. It converts uric acid into a nontoxic, excretable metabolite allantoin. It can also be used after tumor lysis syndrome has started. It has several black box warnings including: anaphylaxis, hemolysis, and methemoglobinemia. Its use is considered high risk in pregnancy. Except for the side effects noted above, it is well-tolerated, acts rapidly, and is effective. The need of dialysis secondary to tumor lysis syndrome has substantially declined since the introduction of rasburicase.

► Objectives: Did you learn to ...

- Diagnose and initiate treatment of tumor lysis syndrome?

QUICK QUIZ: TOO MUCH OF A GOOD THING

A 60-year-old gentleman presents to your office with complaints of fatigue. He has a history of alcoholic cirrhosis, diet-controlled diabetes, and hypertension. He currently takes hydrochlorothiazide, enalapril, and monthly testosterone injections. He smokes two packs of cigarettes daily and consumes 6 to 8 beers nightly. His physical examination reveals an obese, ruddy-faced man with a temperature of 37°C, pulse 90 bpm, BP 164/80 mm Hg, and respirations 14 bpm. He is found to have a hematocrit of 54%.

Which of the following items in his history is LEAST likely to explain the elevated hematocrit?

- A) Alcoholic cirrhosis
- B) Diabetes
- C) Antihypertensive medications
- D) Testosterone injections
- E) Smoking

The correct answer is "B." Diabetes should not cause an elevated hematocrit and often causes anemia secondary to renal disease and reduced responsiveness to erythropoietin. Approach an elevated hematocrit with two questions: (1) Is it due to increased RBC mass or decreased plasma volume? (2) Is it primary erythrocytosis or secondary?

This patient has many potential secondary causes of an elevated hematocrit. "A," alcoholic cirrhosis can lead to hepatocellular carcinoma which, along with other malignancies (e.g., renal cell carcinoma), can result in overproduction of erythropoietin, causing an elevated hematocrit. Diuretics ("C") decrease plasma volume, causing an elevation of hematocrit which is **not** a true polycythemia. Testosterone injections ("D") may cause polycythemia. Finally, he has a significant smoking history ("E") that may produce a secondary polycythemia due to hypoxia and cor pulmonale.

► CASE 6.10

A 30-year-old female presents to your office for a routine visit. She was hospitalized for an appendectomy and at the time of surgery, her platelet count was found to be 1,400,000/mm³, which her surgeon felt was most likely reactive. She has no other past medical history, is asymptomatic, and exercises three times per week. You repeat the CBC, showing WBC 5,000/mm³, Hgb 13 g/dL, and platelet count 800,000/mm³.

Question 6.10.1 What is your next step in managing this patient?

- A) Anticoagulation with warfarin to a goal INR of 2 to 3
- B) Counseling against becoming pregnant
- C) Initiation of hydroxyurea 500 mg BID
- D) No further evaluation or follow-up necessary
- E) Observation and periodic evaluation of her CBC

Answer 6.10.1 The correct answer is "E." This patient likely has essential thrombocythemia (ET), which is the most common myeloproliferative disorder in the United States. ET is more common in females. Patients are typically older when diagnosed with median age of 60. It is rare in children younger than 14 years of age. Patients with ET have a higher rate of mortality than matched controls due to risk of thrombosis (arterial > venous) and bleeding events. In order to diagnose ET, other causes of thrombocytosis (e.g., inflammation, iron deficiency, recent surgery, infection, bleeding, and malignancy) must be excluded. A bone marrow biopsy may be helpful in establishing the diagnosis by demonstrating adequate iron stores and ruling out chronic myelogenous leukemia (CML) or myelodysplasia.

"A" is incorrect. Warfarin would not be appropriate prophylactic therapy and would not be used unless the patient had a thromboembolic event. Aspirin *can* be used especially for the vasomotor symptoms associated with essential thrombocythemia (erythromelalgia [a burning pain in the hands and feet], acral paresthesias, headache, lightheadedness, etc.). Aspirin should also be considered if the platelet count is greater than 1,500,000/mm³. "B" is incorrect. Although patients with ET have a high rate of spontaneous abortion, many can have normal, healthy pregnancies. The patient should be counseled regarding pregnancy risks. "C" is also incorrect. The patient is at low risk for thromboembolic events (platelet count <1,500,000/mm³, young age, no comorbid illness, or prior events). Hydroxyurea

could be considered if the patient was at high risk for thromboembolic events or symptomatic.

HELPFUL TIP:

The most common cause of an abnormally high platelet count is reactive thrombocytosis, which can result from iron deficiency, infection, inflammation, or malignancy. There is no increase in bleeding or clotting risk in patients with reactive thrombocytosis. The diagnosis of ET can only be made once reactive thrombocytosis and the presence of other chronic myeloproliferative disorders are ruled out.

► Objectives: Did you learn to ...

- Recognize the presentation and implication of essential thrombocytosis?

► CASE 6.11

A 15-year-old female presents to your office complaining of fatigue. She reports menarche at age 13 and complains of heavy menses. Her physical examination reveals a well-developed, well-nourished, pale female. You find no hepatosplenomegaly. Her laboratory results reveal a WBC 6,000/mm³, Hgb 8.9 g/dL, hematocrit 27%, platelet count 400,000/mm³, MCV 72 fL (low), red blood cell distribution width (RDW) 16 (high). You order more laboratory tests.

Question 6.11.1 What are the expected findings in this patient?

- Increased iron, decreased ferritin, increased total iron binding capacity
- Decreased iron, decreased ferritin, decreased total iron binding capacity
- Increased iron, increased ferritin, increased total iron binding capacity
- Decreased iron, increased ferritin, decreased total iron binding capacity
- Decreased iron, decreased ferritin, increased total iron binding capacity

Answer 6.11.1 The correct answer is "E." This patient likely has iron deficiency anemia related to her heavy menses. Iron deficiency anemia is characterized by anemia along with a decreased serum iron, decreased ferritin, increased total iron binding capacity (TIBC), and decreased transferrin saturation. The decrease in serum ferritin is proportional to the decrease in total body iron stores. Hypochromic microcytic RBCs are found on peripheral smear. See Table 6-3 for a general guide to the causes of anemia based on red cell indices.

HELPFUL TIP:

The prevalence of VWD in women with menorrhagia ranges from 5% to 20%. Always make sure to take a good personal and family bleeding history.

TABLE 6-3 CAUSES OF ANEMIA BY RED CELL VOLUME

Low MCV (usually <80 fL)	Normal MCV (usually 80–100 fL)	High MCV (usually >100 fL)
Anemia of chronic disease	Acute blood loss	Alcohol effects
Copper deficiency	Anemia of chronic disease	B12 deficiency
Iron deficiency anemia	Chronic renal insufficiency	Drug effect (e.g., Hydroxyurea, AZT)
Lead poisoning	Early iron deficiency	Folate deficiency
Sideroblastic anemias	Endocrine (e.g., hypothyroidism)	Hemolytic anemia
Thalassemias	Primary bone marrow disorders	Hypothyroidism (less commonly macrocytic, usually normocytic)
		Liver disease
		Primary bone marrow disease
		Reticulocytosis (hemolytic anemia, response to blood loss)

HELPFUL TIP:

Even if it looks like iron deficiency anemia, always consider other causes of anemia such as B12 deficiency, folate deficiency, and thalassemia. Often patients will have more than one cause for their anemia. Mixed vitamin B12 and iron deficiencies may present with normocytic anemia with an elevated RDW.

You start iron supplementation therapy in this patient.

Question 6.11.2 Which of the following tests will be the first to indicate that you have instituted appropriate therapy and that the patient is responding?

- Increase in hematocrit
- Increase in reticulocyte count
- Increase in serum-free hemoglobin
- Decrease in ferritin
- Decrease in transferrin saturation

Answer 6.11.2 The correct answer is "B." The patient's reticulocyte count will increase first—before the hematocrit ("A"). This should start soon after treatment and maximize at 7 to 10 days. Pica (if present) should also resolve fairly early. "C" is incorrect. Only in exceptional circumstances (intravascular hemolysis) will there be free hemoglobin in the blood. "D" is incorrect because the ferritin is low in iron deficiency anemia and should increase with therapy. Finally, transferrin saturation ("E") should increase in patients once you start to treat their anemia, but the reticulocyte count increases first.

HELPFUL TIP:

Ferritin is not a useful test for iron deficiency in hospitalized patients or in those who are chronically ill. Ferritin is

an acute-phase reactant and thus may be elevated in these patients even when the patient has iron deficiency anemia (where the ferritin should be low). However, you can check a soluble transferrin receptor. See below for more.

HELPFUL TIP:

There may be no reticulocytosis with treatment of iron deficiency if the patient is simply iron deficient without anemia.

Question 6.11.3 How long should you continue iron supplementation once the patient's labs have normalized?

- A) Stop immediately once anemia has resolved
- B) Continue 3 to 6 months after the anemia has resolved
- C) Continue for 1 year after the anemia has resolved
- D) Indefinite iron supplementation is indicated

Answer 6.11.3 The correct answer is "B." Continue iron for 3 to 6 months once the anemia has resolved. Also address the underlying problem. In this patient, treat her heavy menstrual periods, which may respond to hormonal contraception, tranexamic acid, etc.

The patient returns in 2 months but her labs, if anything, are worse than at first presentation. The patient swears that she has been taking the iron faithfully.

Question 6.11.4 Which of the following can lead to a failure of iron therapy for iron deficiency anemia?

- A) Proton pump inhibitors (PPIs)
- B) Incorrect diagnosis
- C) Oral antacids (e.g., calcium carbonate)
- D) Atrophic gastritis, celiac disease, or *Helicobacter pylori* infection
- E) All of the above

Answer 6.11.4 The correct answer is "E." Anything that neutralizes the stomach pH will interfere with iron absorption, including PPIs, antacids, and loss of acid-producing cells (e.g., pernicious anemia). Other GI diseases (e.g., celiac disease, *H. pylori*) can also interfere with iron absorption. Tea and some green leafy vegetables can also reduce iron absorption.

HELPFUL TIP:

Vitamin C (supplements or orange juice) enhances iron absorption and should be considered if a patient is not responding to iron therapy. Meat can also increase iron absorption (which we hate to say because one of us is a vegetarian ... however, the truth hurts).

HELPFUL TIP:

A widened RDW and an elevated platelet count are typical of iron deficiency anemia. Conversely, the RDW will be normal in thalassemias.

The patient returns to your office and finally admits she has not been able to take the iron because of side effects. She has started a prenatal vitamin for the folate. Her hemoglobin is now down to 7.2 g/dL. She still feels fatigued. The patient will not agree to take any further iron orally. However, she is willing to consider other suggestions.

Question 6.11.5 What is your next step?

- A) Encourage the patient to take the iron preparation along with calcium carbonate (Tums) to reduce the GI side effects
- B) Continue her prenatal vitamin only and encourage her to eat more red meat
- C) Give iron sucrose 200 mg IV weekly for 4 weeks
- D) Transfuse 2 units of PRBCs immediately

Answer 6.11.5 The correct answer is "C." If oral iron preparations are not tolerated, IV iron preparations are available. Intramuscular preparations are best avoided due to pain at the injection site, skin discoloration, and risk for infection. The most commonly used options for IV replacement include iron dextran and iron sucrose. Iron dextran carries a risk of anaphylaxis in 0.6% to 2.3% of patients and other side effects in up to 25% of patients, including: bronchospasm, flushing, headache, fever, urticaria, nausea, vomiting, hypotension, seizures, myalgias, arthralgias, and increased thromboembolic events. Iron sucrose has a lower incidence of side effects—typically nausea, constipation, diarrhea, or a transient minty taste—and may be given to patients who have had a previous reaction to iron dextran.

There have been more recent developments of dextran-free infusions that can be provided more quickly and over a two-dose administration. Ferric carboxymaltose (Injectafer) and ferumoxytol (Feraheme) IV are other options to use for iron deficiency anemia in patients intolerant to iron or in those with CKD. Ferric carboxymaltose (Injectafer) is provided as 750 mg infusion over 15 minutes with repeat dose in 7 days. Ferumoxytol (FeraHeme) is provided as 510 mg infusion over 15 minutes with repeat dose in 3 to 8 days. Most common adverse reactions are: hypersensitivity, diarrhea, headache, nausea, dizziness, and hypotension.

"A" is incorrect because calcium will interfere with iron absorption. Additionally, she has dug in on her position of not taking oral iron, so it's time to try a different approach. "B" is incorrect because she needs more iron than can be provided through prenatal vitamins and her diet. Finally, "D" is incorrect as transfusion carries potential risks that could be avoided if she responds to IV iron replacement.

HELPFUL TIP:

Every other day iron seems to be just as effective as daily iron and may help to minimize side effects. In fact, iron absorption is higher with every other day iron (*Lancet Haematol.* 2017;4(11):e524).

**HELPFUL TIP:**

Any adult patient with microcytic anemia should be evaluated further to clarify the etiology. In adults, GI blood loss is a common cause of microcytic anemia. Colitis, malignancy, or malabsorption from inflammatory disease should be considered in the differential diagnosis. Tailor your workup to the patient's symptoms. If your patient has symptoms referable to the upper GI tract (e.g., dyspepsia), consider an upper GI endoscopy in addition to colonoscopy.

**HELPFUL TIP:**

What is that transferrin receptor anyhow? The transferrin receptor can help to differentiate between iron deficiency anemia and anemia of chronic disease. The serum transferrin receptor level is inversely correlated to iron storage levels. **When the iron is low, the soluble transferrin receptor level is high. Thus, high serum transferrin receptor levels are associated with iron deficiency, but not with anemia of chronic disease in which iron stores are adequate.** One caveat, the serum transferrin receptor level will also be elevated in states in which there is rapid cell turnover (hemolytic anemia, for example). However, it should not be checked in this situation, so you shouldn't get confused.

► **Objectives: Did you learn to ...**

- Obtain a thorough history in an anemic patient?
- Use laboratory parameters to identify the etiology of anemia?
- Initiate treatment for iron deficiency anemia?

► **CASE 6.12**

A 52-year-old woman with a history of rheumatoid arthritis is in your clinic for a 1-month follow-up after having a knee prosthesis removed secondary to a joint infection and osteomyelitis (*Staphylococcal aureus*). You obtain a CBC, revealing a WBC 8,000/mm³, Hgb 9.5 g/dL, hematocrit 28%, platelet count 450,000/mm³, and MCV 83 fL (normal). Serum iron levels are low with a normal serum transferrin receptor and increased ferritin.

Question 6.12.1 What is the most likely diagnosis?

- Iron deficiency anemia due to rheumatoid arthritis
- Anemia of chronic disease due to rheumatoid arthritis and osteomyelitis
- Hemolytic anemia induced by antibiotics
- Acute blood loss during surgery
- Myelodysplastic syndrome (MDS) associated with rheumatoid arthritis

Answer 6.12.1 The correct answer is "B." Anemia of chronic disease is a hypoproliferative anemia that occurs in the setting of chronic infection, inflammation, malignancy, heart failure, diabetes, and other serious health conditions. The anemia is usually mild and characterized by low serum iron, increased ferritin (remember that ferritin is an acute-phase reactant and these patients often have inflammation), decreased serum transferrin, normal (or low) serum soluble transferrin receptor level, and decreased transferrin saturation (see below for more on the soluble transferrin receptor). In addition, reticulocyte count is typically low, erythropoietin may be mildly elevated, and peripheral smear may show hypochromic, microcytic RBCs, or normochromic, normocytic RBCs. If differentiation between iron deficiency anemia and anemia of chronic disease is not apparent, a bone marrow biopsy can be obtained to assess iron stores.

► **Objectives: Did you learn to ...**

- Recognize a typical presentation of anemia of chronic disease/inflammation and the expected laboratory findings?

► **CASE 6.13**

A previously healthy 3-year-old female with a history of anorexia and irritability for 3 days is brought to your ED by her mother. On the day of admission, the child is difficult to arouse. You learn that her 6-year-old brother has had some difficulty reaching appropriate developmental milestones and is a "fussy eater."

Physical examination reveals a slightly pale-appearing child, who responds to tactile stimuli but not to voice. Vitals are normal and her examination is unremarkable except for her decreased level of consciousness. Laboratory studies include a WBC 8,000/mm³, Hgb 10 g/dL, platelet count 300,000/mm³, and MCV 75 fL (microcytic). Her urine dipstick is normal, except for 1 + glucose; there are no ketones in the urine. Her blood chemistries are within normal limits, with the exception of a phosphorous of 2 mg/dL (low). Her peripheral blood smear shows red cells with coarse basophilic stippling.

Question 6.13.1 What is the best working diagnosis at this time?

- Acute lead poisoning
- Anemia of chronic disease
- Early diabetic ketoacidosis (DKA)
- Severe iron deficiency anemia
- Unrecognized bacteremia secondary to pyelonephritis

Answer 6.13.1 The correct answer is "A." Lead poisoning should be considered in a child presenting with symptoms of encephalopathy and anemia with basophilic stippling on RBCs. Basophilic stippling occurs when ribosome precipitates litter the RBCs. Basophilic stippling can be seen in alcohol abuse, thalassemias, and heavy metal poisoning. This child's brother also shows some symptoms consistent with lead poisoning

with delayed developmental milestones and “picky eating” (anorexia). A child presenting in this manner should have a blood lead level checked to rule out elevated lead levels as an underlying cause. “B,” anemia of chronic disease, is unlikely because this illness is acute. “C,” DKA, is unlikely because urine ketones are 99% sensitive for DKA and her urine ketones are normal. “D” is unlikely because there should be no neurologic symptoms associated with iron deficiency anemia. “E,” pyelonephritis, is unlikely because the patient is afebrile and has a normal white count and negative urine. We could have tipped you off to the answer with a “Flint, Michigan” reference but that would have been no fun.

**HELPFUL TIP:**

Lead levels >10 mcg/dL may cause developmental delay, loss of milestones (especially language), encephalopathy, seizures, cerebral edema, and cognitive impairment. CNS effects are especially problematic in children <6 years old who have an incomplete blood–brain barrier. Lead paint in houses built before the 1970s and use of imported products such as pottery, solder, cosmetics, and crayons (and some toys made in China) still provide sources of lead ingestion. Children born in a foreign country and/or with recent foreign residence may also be at risk.

**HELPFUL TIP:**

Other symptoms of lead intoxication include: anorexia, decreased activity, irritability, insomnia, hearing loss, peripheral neuropathy, SIADH, decreased renal function, and anemia. Laboratory findings may include: anemia, signs of hemolysis, coarse basophilic stippling on RBCs, glycosuria, hypophosphatemia, positive qualitative urine coproporphyrin, and moderate increases in free erythrocyte protoporphyrin.

The patient’s lead level is 70 mcg/dL. Because of your concern about acute lead intoxication and resulting encephalopathy, you decide to admit the child and treat her with dimercaprol and calcium disodium edetate (CaNa₂EDTA).

Question 6.13.2 All of the following are true EXCEPT:

- A) Dimercaprol should not be given if the child has a peanut allergy
- B) The child’s diet should be monitored for adequate intake of calories, iron, and calcium
- C) The child’s sibling should be tested, and arrangements should be made for close follow-up for both children
- D) The dose of dimercaprol should be tripled for patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency

Answer 6.13.2 The correct answer is “D.” Dimercaprol is a lead chelator used to treat elevated lead levels. It is administered

intramuscularly, is water insoluble, and must be given in a peanut oil vehicle; hence, it should be avoided in individuals with a peanut allergy (“A”). **It may cause hemolysis in individuals with G6PD deficiency**, so these patients should be monitored closely and not receive larger doses of dimercaprol. It is important to test siblings of an affected child (“C”), because the source of lead is often in the house. Close follow-up of affected children is essential to monitor for increasing blood lead levels after treatment, which may indicate the source of lead has not been removed. The absorption of lead can be made worse by malnutrition, iron deficiency, and poor intake of calcium (“B”). Iron deficiency frequently occurs in affected patients and may worsen anemia. Other chelating agents include calcium disodium EDTA and d-penicillamine and succimer. It is recommended to use a combination of dimercaprol and EDTA for children with severe lead intoxication.

**HELPFUL TIP:**

A large percentage of lead is absorbed into bone with a half-life of greater than 25 years. In periods of physiologic stress, the inert pool of lead can be mobilized and released into the bloodstream, producing signs and symptoms of lead intoxication years after the initial exposure.

► Objectives: Did you learn to ...

- Recognize the presentation of lead poisoning and the attendant changes in blood counts and cell indices?
- Initiate treatment for lead poisoning?

► CASE 6.14

A 6-month-old male infant is brought to you for a well-baby check-up. His mother reports that the child has had difficulty with feeding, has frequent colds, and is often irritable. She has noted recurrent episodes of jaundice, especially when he is sick. His physical examination reveals a small child, faintly jaundiced. His temperature is 37.5°C, pulse 160 bpm, BP 85/50 mm Hg, and respirations 30 bpm. His abdomen is soft with palpable splenomegaly. The remainder of the examination is unremarkable. Laboratories reveal a WBC 13,000/mm³, Hgb 9 g/dL, platelet count 260,000/mm³, and MCV 60 fL (low). He is noted to have target cells on peripheral blood smear.

Question 6.14.1 Which one of the following is the most appropriate next step?

- A) Order PT/PTT
- B) Order hemoglobin electrophoresis
- C) Transfuse with 1 unit of PRBCs
- D) Test for G6PD deficiency
- E) Test for sickle cell anemia

Answer 6.14.1 The correct answer is “B.” The clinical and laboratory presentation is consistent with a hereditary

hemoglobinopathy, most likely a thalassemia. The splenomegaly, significant anemia, target cells, and the profoundly low MCV are all suggestive of thalassemia; patients with thalassemia often have recurrent episodes of jaundice reflecting hemolysis. He has no history of abnormal bleeding, so “A” would not be indicated. Also, as the child does not appear to be in distress, “C” would be an incorrect answer. G6PD-deficient patients experience episodes of hemolytic anemia. Peripheral smear review at that time may reveal bite or blister cells, rather than target cells, so “D” is not the right answer. “E” is incorrect since the peripheral smear would reveal sickle cells if the patient had sickle disease.

Beta thalassemia major is confirmed by hemoglobin electrophoresis.

Question 6.14.2 Which of the following regarding his management is NOT true?

- A) Untreated, mortality may approach 80% by 5 years of age
- B) Frequent blood transfusions may be required
- C) The condition will improve with age
- D) The child is likely to have growth retardation and delayed sexual maturation
- E) Without iron chelation therapy, there is a high incidence of mortality with this disease

Answer 6.14.2 The correct (and not true) answer is “C.” Beta thalassemia refers to the disease state in which there are mutations in both genes that code for beta globin. Without treatment, mortality from thalassemia major approaches 80% by 5 years of age. Patients with beta thalassemia will eventually develop iron overload, even without blood transfusions. The use of transfusions and concurrent chelation therapy with deferoxamine has reduced long-term complications related to the disease. Deferasirox (Exjade, Jadenu), an oral chelating agent, is available as an alternative to deferoxamine. Bone marrow transplant can be curative. Therapies to improve erythropoiesis and gene therapy are also being studied. Beta thalassemia minor (or beta trait) is much less severe and occurs when only one of the genes is defective.

HELPFUL TIP:

The FDA has approved deferiprone (Ferriprox) as an alternative chelating agent in transfusion-acquired iron overload. It is second line but can be administered orally. It can be considered when deferasirox is not effective and the patient is unable to use deferoxamine, the parenteral option.

HELPFUL TIP:

Alpha thalassemia has a more variable course. There are four alpha globin genes. If all four genes are defective, intrauterine fetal demise is the rule. When one gene is defective, there is a silent carrier state. When two genes are defective, there is a mild microcytic anemia. Here is

a memory aid: there are four alpha globin genes and “4” looks kind of like the Greek letter alpha; beta is the second letter in the Greek alphabet and beta globin has two genes.

HELPFUL TIP:

Because of the persistence of fetal hemoglobin (HbF) in the circulation up to 6 months of age, hemoglobinopathies might not be apparent until that time.

HELPFUL TIP:

Thalassemias may be erroneously diagnosed as iron deficiency anemia due to a low MCV. Consider testing for thalassemia in a patient with microcytic anemia, normal or increased iron levels, a normal RDW (less reliable), and appropriate ethnic background (e.g., Mediterranean or African descent).

HELPFUL TIP:

In other Hgb synthesis related news ... when you see that middle-aged patient with abdominal pain and psychiatric symptoms for the tenth (or twentieth or thirtieth) time, think of acute intermittent porphyria before you make the diagnosis of somatization disorder.

► **Objectives: Did you learn to ...**

- Recognize symptoms and RBC indices associated with thalassemia?

► **CASE 6.15**

A woman brings her 10-week-old female infant for evaluation. The child is colicky and irritable after feeding. She was born full term but has not been gaining weight appropriately. The patient’s sister has sickle cell trait, so you obtain an Hgb electrophoresis, which ultimately demonstrates SS genotype.

Question 6.15.1 Which of the following is INCORRECT regarding the child’s care?

- A) The patient should remain on prophylactic antibiotics until the age of 5 years due to a high risk of pneumococcal sepsis
- B) The child may develop splenomegaly and lymphadenopathy related to her disease
- C) The disease provides protection against infection with parvovirus
- D) The child may not develop pain crisis until she is older due to protection from HbF
- E) The child is likely to have a delay in puberty

Answer 6.15.1 The correct (actually “incorrect”) answer is “C.” The patient has homozygous SS sickle cell disease. This

child's mother should be counseled regarding the importance of continuing antibiotic prophylaxis until the age of 5 years ("A"), because her child is at high risk for pneumococcal sepsis. Sickle cell disease is protective against malaria, not parvovirus ("C"). In fact, parvovirus infection can be life-threatening in these patients due to the development of aplastic anemia.

During infancy, children may be noted to have reticulocytosis, hemolytic anemia, and sickling by 10 to 12 weeks. At 5 to 6 months, splenomegaly may be noted, and lymphadenopathy ("B") may be prominent between 6 months and 5 years. The earliest pain crisis often involves hands and feet (dactylitis) and occurs after the HbF decreases to adult values ("D"); this usually does not occur until after the age of 4 years. The spleen involutes by 5 to 8 years. Puberty is delayed by an average of 2.5 years ("E").

**HELPFUL TIP:**

Sickle trait, the condition in which a patient is heterozygous for Hb S, is associated with a normal life expectancy and no symptoms other than occasional hematuria and inability to concentrate urine. Pain crises are extremely rare and occur only in the settings of a low oxygen atmosphere (e.g., very high altitude) or extreme physical activity (e.g., running a marathon).

The child follows regularly with you for years, and she begins to develop more frequent pain crises in college. She is found to have an elevated C-reactive protein, increased LDH, and decreasing Hgb. You explain to her that some measures can be taken to reduce the frequency of pain crises.

Question 6.15.2 These measures include all of the following EXCEPT:

- A) Initiation of hydroxyurea therapy
- B) Avoidance of hot showers
- C) Prompt treatment of infections
- D) Adequate hydration and nutrition
- E) Avoidance of emotional stress

Answer 6.15.2 The correct (rather "incorrect") answer is "B." Two main features of sickle cell disease are shortened RBC survival and vasoocclusion due to poorly deformable RBC membranes. Pain episodes occur due to acute episodes of tissue hypoxemia and microinfarction. Crises can be precipitated by stress, fatigue, cold weather (not hot showers, which cause problems in multiple sclerosis patients), infection, dehydration, acidosis, and poor nutrition (options "C–E"). The use of hydroxyurea ("A") promotes increased levels of HbF, and HbF is associated with decreased frequency and severity of pain crises.

**HELPFUL TIP:**

Acute chest syndrome (ACS) should be suspected when a sickle cell patient presents with fever, cough, chest pain, and pulmonary infiltrates on chest x-ray. ACS may be due to infection or pulmonary infarction. Treatment involves

aggressive pain management, antibiotics for respiratory pathogens, supplemental oxygen, cautious hydration, venous thromboembolism prophylaxis, and blood transfusion if the patient is significantly anemic. Exchange transfusion may also be required in more severe cases.

**HELPFUL TIP:**

For patients with sickle cell disease, simply replacing volume is usually appropriate. However for primary and secondary stroke prevention, transfuse/exchange transfuse so that the HbS is <30%. For presurgical patients, simply getting the Hgb to 10 g/dL seems adequate.

Since you first met that little baby girl, 22 years have elapsed, and she is getting married—and you are getting old (the alternative is worse, of course). She is concerned about significant illness related to her disease. You counsel her regarding the most common causes of morbidity and mortality.

Question 6.15.3 All of the following statements are true EXCEPT:

- A) ACS and pain crises are the most common causes for hospital admission for patients with sickle cell disease
- B) Eighty percent of patients develop cholelithiasis by the age of 35 years
- C) Strokes may occur in 8% of patients by the age of 14 years, may be either symptomatic or clinically silent, and tend to be recurrent
- D) Heart failure, pulmonary fibrosis, pulmonary hypertension, and renal failure complicate fluid management, transfusions, and maintenance of adequate oxygenation
- E) Pregnancy should be avoided under any circumstance

Answer 6.15.3 The correct answer (and exception) is "E."

The average life expectancy in patients with Hb SS is 42 years for men and 48 years for women. Maternal mortality occurs in about 1% of pregnancies. All of the rest are true including cerebrovascular events causing seizures and possible cognitive difficulty early in life. Of particular note, renal failure may be the cause of death in up to 10% of cases. Avascular necrosis and osteomyelitis (classically as a result of *Salmonella* infection), chronic skin ulcers, and priapism are also common.

► **Objectives: Did you learn to ...**

- Recognize the presentation and implication of sickle cell disease?
- Initiate management of sickle cell disease?

**QUICK QUIZ: THE CURIOUS CASE OF THE MISSING VITAMIN**

A 72-year-old gentleman is brought to your office because a home health nurse noted he was becoming progressively weaker and more fatigued. He has a history of celiac disease for which

he follows a strict gluten-free diet, but he has not been eating well. He also has a history of a seizure disorder and takes phenytoin. His review of systems is positive for dyspnea on exertion and mild anorexia. He has no other symptoms.

Physical examination reveals a thin, pale-appearing man with normal vital signs. His conjunctivae are pale and his tongue is smooth, with moist mucosa and no oropharyngeal lesions. The remainder of the examination is unremarkable. A CBC reveals a WBC 4,500/mm³, Hgb 9 g/dL, hematocrit 28%, platelet count 140,000/mm³, MCV 102 fL, RDW 14, and B12 level 900 ng/L (normal).

Which of the following statements is most likely FALSE?

- A) The patient may have a high homocysteine level
- B) The patient's condition could be made better with a trial of folate replacement
- C) The patient may have a low RBC folate level
- D) The patient's condition will likely require chronic blood transfusions
- E) The patient may have a normal serum folate level

The correct (and False) answer is "D." This patient likely has folate deficiency, given a normal B12, macrocytic anemia, and risk factors for folate deficiency—old age, poor diet, avoidance of gluten (flour is normally fortified with folate), use of phenytoin, and possible malabsorption due to GI disease (celiac disease in this case, but also any other infiltrating or inflammatory process of the bowel). Dietary deficiency is uncommon in the United States due to supplementation of grain products with folate. Foods naturally high in folate include melons, bananas, leaf vegetables, asparagus, and broccoli. The recommended intake is 400 µg/day, and the body stores approximately a 4-month supply. If he has had recent adequate folate intake, the serum folate level may be normal, but the RBC folate will still be low, reflecting the deficiency (think of it as the HbA1C of folate).

To differentiate folate from B12 deficiency, check serum homocysteine and methylmalonate levels. Both will be elevated with B12 deficiency, while only homocysteine will be elevated in folate deficiency. Remember, you must exclude B12 deficiency before replacing folate because folate replacement can reverse the anemia, but will permit progression of neurologic effects of B12 deficiency, so "B" is true.

HELPFUL TIP:

Folate replacement is dosed as 1 to 5 mg daily for 1 to 4 months or until complete hematologic recovery occurs. If macrocytic anemia persists, other causes must be considered.

QUICK QUIZ: REMEMBER THAT TAPEWORM FROM MEDICAL SCHOOL? HERE IT IS AGAIN!

A 47-year-old woman presents to your office complaining of tongue soreness, fatigue, and dyspnea with exertion. She denies unusual bleeding, weight loss, fevers, and night sweats. Her past

medical history includes hypothyroidism, for which she takes levothyroxine. She does not drink alcohol or smoke. Physical examination reveals a tired-appearing woman with lemon-yellow colored skin, temperature 37°C, pulse 110 bpm, BP 120/74 mm Hg, and respirations 12 bpm. The examination is otherwise unremarkable. A CBC demonstrates a WBC count 4,000/mm³, Hgb 9 g/dL, platelet count 140,000/mm³, and an MCV of 105 fL. Her B12 level is 100 pg/mL (normal >300 pg/mL) and folate 40 ng/mL.

Which of the following historical elements is LEAST likely to contribute to her condition?

- A) History of working as a park ranger in Canada
- B) History of Zollinger–Ellison syndrome
- C) History of hypothyroidism
- D) History of new vegetarian diet started last month
- E) History of GI surgery

The correct answer is "D." Most likely, this woman has pernicious anemia caused by B12 deficiency. Pernicious anemia is caused by immune destruction of parietal cells in the stomach, resulting in decreased absorption of B12. It typically develops in people over the age of 40 and is more common in people of northern European descent or in African Americans, as well as people with type A blood. Laboratory findings include anti-parietal cell antibodies in 90% of affected patients (5% of normal individuals also have the antibody) and antibodies to intrinsic factor in 70% of patients. Individuals commonly have other autoimmune diseases such as thyroid disease, diabetes, and vitiligo. Individuals may complain of paresthesias, GI symptoms, sore tongue, or weight loss. The lemon-yellow appearance of the skin is due to anemia and mild jaundice.

Other causes of cobalamin (B12) deficiency include gastrectomy, Zollinger–Ellison syndrome (inability to alkalinize the small intestine), blind loop syndrome, bacterial overgrowth from previous surgery, and ingestion of undercooked fish infested with the tapeworm *Diphyllobothrium latum* (found in Canada, Alaska, and the Baltics—hence, the history of working as a park ranger). Although a strict vegetarian diet can cause B12 deficiency, there are sufficient stores to last 3 to 5 years (in other words, more than 1 month).

QUICK QUIZ: SAY, DID HE SWALLOW A PENNY?

A 21-year-old college student is brought to the ED by his friends because of bizarre behavior. His friends state that he has been acting "a little odd" lately, but they are unaware of any drug abuse. He does drink alcohol but is not known as a binge drinker—at least not by modern NCAA Division I drinking standards. His friends do not know his medical history but state he was taking a prescription drug for a "metabolic disorder," which he stopped several months ago. He is uncooperative, paranoid, and disoriented. You note brownish pigmentation of his corneas on physical examination. This may be the first—and last—case of Wilson disease you have ever seen.

Regarding this patient, which of the following is **INCORRECT**?

- A) The patient has likely had episodes of hemolytic anemia in the past
- B) The patient has likely discontinued penicillamine
- C) The patient likely has an elevated ceruloplasmin level on blood test
- D) The patient likely has hepatolenticular degeneration
- E) The patient is at risk for hepatic failure

The correct answer is "C." This patient likely has Wilson disease (an autosomal-recessive defect in cellular copper export), which presents with **decreased** levels of ceruloplasmin, increased liver enzymes, and signs of hemolysis (from the direct toxic effect of copper on the cell). Symptoms typically present in the teens and early 20s. Presenting symptoms may include Kayser–Fleischer rings (golden-brown pigmentation of the cornea), hemolytic anemia, or neurologic symptoms, often mimicking psychiatric illness. Treatment of the disease includes lifelong therapy with penicillamine or trientine (chelating agents) and should be considered even for asymptomatic individuals known to have the disease. By the way, pennies are primarily zinc and contain little copper.

QUICK QUIZ: "HOLE-Y BONES"

A 50-year-old man presents to your office with low-back pain of 8 weeks duration. He denies any history of trauma or overexertion. He notes the pain is constant and does not improve with positioning. Also, he has noticed some fatigue. He has no other complaints.

Physical examination reveals a well-nourished male with normal vital signs. His neurologic examination is normal. On musculoskeletal examination, he has midline point tenderness over T12. Plain films reveal a compression fracture at T12. A serum total protein level is 9 mg/dL (elevated), but the remainder of an evaluation for endocrine causes of osteoporosis is normal.

All of the following are necessary for the diagnosis of this patient EXCEPT:

- A) Bone scan
- B) Serum and urine protein electrophoresis with immunofixation
- C) Bone marrow aspirate and biopsy
- D) Quantitative immunoglobulins
- E) Skeletal survey

The correct answer is "A." A spontaneous vertebral fracture in a 50-year-old male is definitely not normal. Multiple myeloma should be considered in patients with this presentation. Multiple myeloma is a clonal disorder of plasma cells. Risk factors include African-American race, male sex, and advancing age (median age of 60–65 at presentation). Workup for the diagnosis of multiple myeloma requires a serum and urine protein electrophoresis with immunofixation ("B"). This will help to

identify a monoclonal protein. Quantitative immunoglobulins ("D") will help to assess whether this patient has an elevation of immunoglobulins in the range required for the diagnosis of multiple myeloma. A skeletal survey ("E") and bone marrow biopsy ("C") complete the diagnostic workup. A bone scan is not useful because the lytic lesions characteristic of multiple myeloma take up radioisotope only 20% of the time.

▶ CASE 6.16

On a routine insurance physical examination, a 55-year-old man was found to have a total protein of 9 g/dL (elevated). The remainder of his serum chemistries and his CBC were normal. He is active, feels well, and is not taking any medications. His physical examination is unremarkable. You order a serum and urine electrophoresis with immunofixation and quantitative immunoglobulins. He has a monoclonal spike with 1,400 g/dL of IgG kappa (elevated). His other immunoglobulins are within normal limits. A skeletal survey demonstrates no lytic lesions, and his bone marrow aspirate and biopsy demonstrate 6% plasma cells (normal is 1–4%). After the bone marrow biopsy, the hematologist sends him back to you for follow-up.

Question 6.16.1 What is your next step in the management of this patient?

- A) Monitor blood, including serum immunoglobulins, every 3 to 6 months and, if stable after 1 year, annually thereafter
- B) Monitor blood, including serum immunoglobulins, every 4 weeks indefinitely
- C) Start on chemotherapy for multiple myeloma
- D) Obtain yearly bone marrow biopsy and skeletal survey
- E) No follow-up is necessary

Answer 6.16.1 The correct answer is "A." This patient has monoclonal gammopathy of undetermined significance, or MGUS, which is found in up to 3% of asymptomatic older (over 50 years old) individuals, mostly in Caucasians. A bone marrow biopsy indicating 10% plasma cells is required to make the diagnosis of multiple myeloma; this patient only has 6%. In addition, this patient has a normal CBC and is asymptomatic (no fatigue, bone pain suggestive of lesions, etc.). Thus, this patient has MGUS. Patients with MGUS typically do well, with only 1% per year progressing to multiple myeloma.

While patients should be reassured of the typically benign nature of this condition, up to 30% will have complications (multiple myeloma, amyloidosis, and other myeloproliferative disorders). After several unchanged immunoglobulin levels and normal CBCs within the 6 months of the initial diagnosis, annual or biannual evaluation should be adequate. Any changes in the patient's condition, such as unexplained anemia, increased immunoglobulin levels, renal insufficiency, or bony pain, should prompt further evaluation. An increase in immunoglobulin does not necessarily mean the monoclonal protein is increasing, and a serum protein electrophoresis and immunofixation should be obtained. Repeat bone marrow biopsy is indicated only if the clinical picture is confusing.

► Objectives: Did you learn to ...

- Diagnose monoclonal gammopathy of undetermined significance?

► CASE 6.17

A 63-year-old woman presents to your office with complaint of fatigue. She states she felt like she spent the winter taking antibiotics because she developed “one infection after the other.” Prior to this past winter, she had been well and did not take any prescription drugs regularly. Physical examination demonstrates a slightly pale, thin woman. Her temperature is 37.5°C, pulse 90 bpm, BP 120/58 mm Hg, and respirations 12 bpm. Her oropharynx demonstrates purpuric lesions. Her abdominal examination shows no organomegaly, and the remainder of the physical examination is unremarkable.

You obtain blood tests: WBC 2,100/mm³, Hgb 8.4 g/dL, and platelet count 20,000/mm³. A bone marrow aspirate and biopsy are obtained, which demonstrate a hypercellular marrow with 4% blasts, 4% ringed sideroblasts, and megakaryocytes. You talk to the hematologist, who suspects that your patient has a myelodysplastic syndrome (MDS).

Question 6.17.1 Which of the following statements is INCORRECT?

- The small number of blasts in the bone marrow indicates a good prognosis
- The patient cannot have MDS because she has pancytopenia
- The patient may benefit from administration of erythropoietin
- The patient may develop acute myeloid leukemia
- The patient's gender may result in a better prognosis

Answer 6.17.1 The correct (rather “incorrect”) answer is “B.” Patients with MDS can be pancytopenic. MDS includes a number of clonal stem cell disorders characterized by dysplasia and ineffective hematopoiesis of one or more cell lines. The disease is typically one of older adults, with a median age of 65 to 70 years at onset; however, a better prognosis is associated with age <60 years and female gender. There is an increased risk of MDS in smokers, those exposed to benzene or alkylating agents, and with some hereditary disorders. Prognosis depends on the number of blasts, the number of lineages affected, and cytogenetic abnormalities. Median survival ranges from 10 to 66 months, and progression to acute leukemia ranges from 6% to 33% of patients, depending on the subtype of MDS.

Depending on the age and overall performance status of the individual MDS patient, treatment can range from supportive care with blood or platelet transfusions, to treatment with granulocyte colony stimulating factor (G-CSF), to chemotherapeutics such as azacytidine, or even to bone marrow transplantation.

► Objectives: Did you learn to ...

- Identify pancytopenia as a presentation of MDS?

QUICK QUIZ: IT'S JUST KIDS' STUFF

All of the following are accurate statements about neutrophil counts in children EXCEPT:

- African-American children may have a normal ANC of 1,000/mm³
- Children over the age of 6 should be expected to have a normal ANC of 1,500 to 8,000/mm³
- Neonates typically have a normal ANC of <500/mm³ at birth
- Infants typically have 20% to 30% neutrophils on WBC differential
- Five-year-old children have 50% neutrophils on WBC differential

The correct answer is “C.” In the pediatric population, neutropenia is typically described as an ANC of <1,500/mm³. Up to 30% of African-American children have an *asymptomatic* ANC of <1,000/mm³ (e.g., no increased risk of infection). At birth, neutrophils make up the majority of the WBC differential (thus, more than 500, which is why “C” is an incorrect statement), decreasing to 20% to 30% after the first few days of life. At 5 years of age, neutrophils comprise approximately 50% of the differential, and this reaches 70% by puberty.

► CASE 6.18

A 49-year-old male presents to your office complaining of joint pain, fatigue, and increased urination. There is a family history of cirrhosis of the liver, apparently not related to alcohol. He does not take any medications and does not smoke but drinks two glasses of wine each night. Physical examination reveals a thin male with tanned skin (in the dead of winter in Iowa, so he is either rich or sick, take your choice) and normal vital signs. His heart and lung examinations are unremarkable. The abdomen is soft, nontender, and nondistended, and his liver edge is palpable 2 cm below the costal margin. He has pain with range of motion in his hips, knees, and MTP joints. The remainder of the examination is unrevealing. Serum electrolytes are normal, but his glucose is 282 g/dL. His transaminases are elevated.

Question 6.18.1 Of the following, what is the most likely diagnosis?

- Alcoholic hepatitis
- Colon cancer
- Hemochromatosis
- Vitamin B12 deficiency

Answer 6.18.1 The correct answer is “C.” This patient presents with a “classic” history of hemochromatosis. Symptoms start during or after the fifth decade of life, are initially mild, and progress slowly. “Bronze diabetes” (bronze or tan skin color

due to iron deposition accompanied by hyperglycemia) is sometimes noted. Most organs can eventually be involved, but most commonly symptoms are due to liver, cardiac, joint, and testicular involvement. “A,” alcoholic hepatitis, is a consideration, but his reported use is unlikely to result in disease. You also would not expect to see some of the other symptoms (e.g., diabetes and arthritis) in relation to alcoholic hepatitis. “B,” colon cancer, is unlikely to present in this way. “D,” vitamin B12 deficiency, typically presents with anemia and neurologic symptoms.

Question 6.18.2 Which of the following laboratory values are most consistent with this patient’s presentation?

- A) Decreased iron, decreased ferritin, decreased transferrin saturation
- B) Decreased iron, decreased ferritin, increased transferrin saturation
- C) Increased iron, decreased ferritin, increased transferrin saturation
- D) Increased iron, increased ferritin, decreased transferrin saturation
- E) Increased iron, increased ferritin, increased transferrin saturation

Answer 6.18.2 The correct answer is “E.” All of these iron studies (serum iron level, ferritin and transferrin saturation) are elevated in patients with hereditary hemochromatosis. A normal person maintains approximately 3 to 4 g of iron in the body. Normal individuals absorb about 1 mg/day of iron (10% of what is ingested), which is precisely balanced with loss through sweat, sloughing of cells, and GI losses. In hereditary hemochromatosis, 2 to 4 mg of iron is absorbed daily, resulting in the accumulation of iron.

The patient’s diagnosis is confirmed, and you counsel him regarding his disease.

Question 6.18.3 All of the following statements are true EXCEPT:

- A) This is an autosomal-dominant disease
- B) Affected females typically present later in life due to increased iron losses
- C) Patients may benefit from phlebotomy even after development of symptomatic disease
- D) Patients are susceptible to unusual infections
- E) Patients are at high risk for hepatocellular carcinoma

Answer 6.18.3 The correct answer (or exception) is “A.” Hereditary hemochromatosis is an autosomal-recessive disorder. Approximately 10% of Caucasians are heterozygous, and 5/1,000 are homozygous for the gene mutation. Patients are at increased risk for infections (“D”) due to *Listeria*, *Vibrio vulnificus* (sorry, no sushi!), and *Yersinia enterocolitica*. Affected females may present later in life due to increased iron losses from menstruation, pregnancy, and lactation (“B”).

Treatment includes phlebotomy (“C”) or chelation therapy if phlebotomy is contraindicated. Patients should be monitored

closely for development of hepatoma, since therapy does not reduce the risk of hepatocellular carcinoma once cirrhosis is present (“E”). Family members should be screened for the disease so they can be started on therapy early, in order to prevent the development of cirrhosis.

HELPFUL TIP:

Hemochromatosis is a genetic disease; therefore, identifying a defect in the HFE gene makes the definitive diagnosis. Patients may have high ferritin levels for many reasons, including many causes of inflammation and liver disease. To confirm the diagnosis, test for the two genetic defects known to cause the disease: C282Y and H63D. In persons of northern European descent, heterozygosity is remarkably prevalent with about 10% of these patients carrying C282Y and 15% to 20% carrying H63D. However, the disease is autosomal recessive and will only manifest with two copies of C282Y or one copy of each (C282Y/H63D). H63D alone (and other mutations) appear less deleterious compared to C282Y.

HELPFUL TIP:

Other causes of iron overload include thalassemia, sideroblastic anemia, and frequent blood transfusions (such as with sickle cell anemia).

► Objectives: Did you learn to ...

- Describe symptoms and signs of hemochromatosis?
- Recognize complications related to iron overload?

► CASE 6.19

A 56-year-old man undergoes a laryngoscopy. In an outdated move that is generally not recommended now, his doctor used extra doses of benzocaine spray (like gallons of the stuff) to overcome a strong gag reflex. The patient tolerated the procedure well, but afterward he started to have cyanosis around the lips. You are now seeing him in the ED, and he has a bluish discoloration of his lips and fingertips and is complaining of a headache. You administer oxygen by nasal cannula with no improvement in his cyanosis. You draw venous blood for labs and find that it has an unusual chocolate color.

Question 6.19.1 All of the following statements are likely to be true about this patient EXCEPT:

- A) A measured arterial blood gas will demonstrate a normal PaO₂
- B) The pulse oximeter will show high-normal oxygen saturation
- C) The patient may require therapy with methylene blue
- D) The patient should not be treated with methylene blue if he has a history of G6PD deficiency
- E) Additional doses of benzocaine can be lethal

Answer 6.19.1 The correct answer (and exception) is “B.” This patient has methemoglobinemia, which in his case was likely a result of the benzocaine spray. Methemoglobinemia results when iron in hemoglobin is oxidized from the ferrous to the ferric state and the hemoglobin becomes incapable of binding and transporting oxygen. The blood gas oxygen may look normal (“A”) because the RBCs cannot release oxygen (and thus remain oxygenated). However, the pulse oximeter will show a low O₂ saturation. **So, there is often a gap between what you see on the blood gas and what the pulse oximeter suggests.**

In a normal patient, less than 1% of hemoglobin is found in the methemoglobin form. Depending on the percentage of methemoglobin, presentations will vary. At methemoglobin levels of 10% to 20%, patients present with cyanosis refractory to oxygen. The arterial blood gas may show a normal PaO₂ with low oxygen saturations. When methemoglobin levels are >30%, patients present with headache, dizziness, dyspnea, and tachypnea (signs of moderate hypoxemia). At >50%, patients develop stupor and obtundation (signs of severe hypoxemia), and levels >70% may be lethal.

Certain drugs such as nitroprusside, sulfonamides, some local anesthetics (in this case benzocaine “E”), and acetaminophen have been found to cause methemoglobinemia.

Treatment of methemoglobinemia is methylene blue (“C”). However, patients with G6PD deficiency should not be given methylene blue, and hyperbaric oxygen therapy should be considered instead (“D”). Remember, when patients have been exposed to cyanide, you want to **cause** methemoglobinemia. The exact mechanism by which this protects against cyanide is unknown, since patients begin to improve prior to the presence of methemoglobinemia.

HELPFUL TIP:

Children with diarrhea may develop methemoglobinemia, although it is rarely clinically significant.

HELPFUL (AND SOMEWHAT USEFUL) TIP:

Methylene blue is, a potent inhibitor of monoamine oxidase, and can cause a serotonin syndrome if used in those on SSRIs or other serotonergic drugs.

► Objectives: Did you learn to ...

- Describe findings and treatment of methemoglobinemia?

► CASE 6.20

A 16-year-old sub-Saharan African male presents to your office for progressive fatigue and dyspnea over the past few days. He also has some mild upper respiratory symptoms that are being “treated” with sulfamethoxazole—trimethoprim. (The doctor down the street is known to treat all respiratory infections with antibiotics.) On examination, you find a well-nourished male in no distress. He is afebrile but slightly tachycardic. You note mild scleral icterus and pallor of the

palmar creases, but the remainder of the examination is unremarkable. A CBC shows normal WBC count and platelets, with Hgb 10.2 g/dL. On peripheral smear, “bite cells” and rare Heinz bodies are reported. The LDH and bilirubin are elevated and the serum haptoglobin is low, but the other serum chemistries are normal.

Question 6.20.1 Which of the following is the most likely diagnosis?

- A) Hereditary spherocytosis
- B) G6PD deficiency
- C) Sickle cell disease (homozygous)
- D) Sickle cell trait (heterozygous)
- E) Iron deficiency anemia

Answer 6.20.1 The correct answer is “B.” The most likely cause of this patient’s anemia is G6PD deficiency. He appears to have a hemolytic anemia, as evidenced by the elevated LDH, bite cells, elevated bilirubin, low haptoglobin, and the acute onset of symptoms. Heinz bodies are inclusions in red cells seen on peripheral smear within the first few days of an oxidative stress in patients with G6PD deficiency. Bite cells are formed as the red cells pass through the spleen and the Heinz bodies are removed. The other diagnoses are less likely. Hereditary spherocytosis (“A”) is caused by an inherited defect in the red cell membrane, and episodes of hemolytic anemia may be brought on by environmental stress. However, patients generally have a baseline anemia, and spherocytes should be seen on peripheral smear. Sickle cell disease and trait are discussed in more detail elsewhere. “E,” iron deficiency anemia, does not generally present acutely and is not associated with findings of hemolysis.

HELPFUL TIP:

G6PD deficiency is the most common inherited RBC enzyme defect, affecting 10% of males of sub-Saharan African descent. It occurs more commonly in African and Mediterranean populations.

Hemolytic anemia in G6PD deficiency is caused by oxidative stress on red cells, most commonly as the result of infection or administration of certain drugs.

Question 6.20.2 Which of the following can precipitate a hemolytic crisis in G6PD deficiency?

- A) Sulfa antibiotics
- B) Fresh fava beans
- C) Nitrofurantoin
- D) Some antimalarial drugs
- E) All of the above

Answer 6.20.2 The correct answer is “E.” All of the above can cause a hemolytic crisis in G6PD deficiency. Multiple other drugs can be involved as well, including vitamin C, salicylates, isoniazid, and phenytoin.

**HELPFUL TIP:**

Fresh fava beans aren't worth the bother. First you have to shell them and then *peel each and every bean*. After all that work, you just end up with a hemolytic crisis if you have G6PD deficiency. Get the canned ones.

Question 6.20.3 Which of the following is the most appropriate intervention for this patient with G6PD deficiency at this point?

- A) Admit to the hospital and observe
- B) Admit to the hospital and transfuse 2 units of packed red cells
- C) Recommend supportive care and follow-up in a few days
- D) Recommend splenectomy and refer to a general surgeon

Answer 6.20.3 The correct answer is “C.” The hemolytic anemia of G6PD deficiency is self-limited and will resolve. This is because in most cases of G6PD deficiency, only about 25% of the RBCs (the older cells) are susceptible to oxidative stress. Severe episodes should be treated in the hospital setting, but most episodes can be managed as an outpatient. Patients should be educated on the drugs and stressors that may precipitate an episode of hemolytic anemia. Splenectomy may limit hemolysis in patients with more severe disease.

**HELPFUL TIP:**

If you check a G6PD level during or just after a hemolytic crisis, it will likely be normal even in those with G6PD deficiency. The cells that have low levels of G6PD have hemolyzed. The younger cells that are left (those that are tested) have normal levels of G6PD.

► **Objectives: Did you learn to ...**

- Identify clinical and laboratory manifestations of G6PD deficiency and describe its management?

**QUICK QUIZ: TOO MANY LYMPHOCYTES**

A 72-year-old man presents to your office for follow-up after a recent hospitalization for pneumonia. While he was in the hospital, he had an increased WBC with lymphocytosis. You repeat his CBC and find a WBC of $22,000/\text{mm}^3$, with 80% lymphocytes, Hgb of 14 g/dL, and a platelet count of $200,000/\text{mm}^3$. You review office records from a visit 1 year ago and find a WBC of $14,000/\text{mm}^3$ with 76% lymphocytes. You send his peripheral blood for flow cytometry, which is consistent with a diagnosis of chronic lymphocytic leukemia (CLL).

Which of the following statements about this patient is INCORRECT?

- A) This patient is at risk for the development of hemolytic anemia
- B) This patient is at risk for serious infection

- C) This patient is likely to experience a relatively benign disease course
- D) This patient should be started on chemotherapy
- E) This patient may develop “B symptoms” (fever, night sweats, weight loss)

The correct (or rather “incorrect”) answer is “D.” CLL is characterized by progressive accumulation of long-lived lymphocytes. It is more common in men and tends to be a disease of older adults (median age at diagnosis is 65 years); however, up to 20% of cases occur in patients <60 years of age. Diagnosis is made if a patient has $>5,000/\text{mm}^3$ mature-appearing lymphocytes in the blood representing a clonal line. With the use of immunophenotyping, bone marrow biopsy is not necessary for diagnosis, but may be useful for prognosis.

This patient has a low-stage CLL (the only finding is lymphocytosis) and does not require immediate treatment with chemotherapy. He should be monitored every 6 to 12 months or sooner if he develops symptoms, such as infections, fatigue, bulky lymphadenopathy, or bleeding. Patients with CLL are at risk for developing autoimmune diseases, including hemolytic anemia, autoimmune thrombocytopenia, pure red cell aplasia, and autoimmune neutropenia.

**QUICK QUIZ: TOO MANY NEUTROPHILS**

A 46-year-old woman presents to your office for a preoperative evaluation. She is planning an elective hysterectomy for uterine fibroids. She has no significant past medical history. Her review of systems is positive only for night sweats. Her physical examination is unremarkable except for a palpable spleen tip. You obtain a CBC, showing a WBC $50,000/\text{mm}^3$, Hgb 11 g/dL, and a platelet count $350,000/\text{mm}^3$. On her peripheral blood smear, she has mostly neutrophils and bands, with some metamyelocytes, myelocytes, and basophils as well.

All of the following are likely to be true EXCEPT:

- A) The patient has an underlying infection with leukemoid reaction
- B) The patient has a balanced translocation between chromosomes 9 and 22
- C) The patient will likely develop progressive leukocytosis, fevers, anemia, and thrombocytopenia if untreated
- D) This condition may be treated with oral tyrosine kinase inhibitors

The correct answer (and exception) is “A.” Although a leukemoid reaction is a possibility, it would be unusual to see a full range of maturation of myeloid cells (e.g., metamyelocytes and myelocytes) in the peripheral blood along with increased basophils and a palpable spleen. Rather, this patient likely has chronic myelogenous leukemia (CML), which is a clonal myeloproliferative disorder, characterized by the “Philadelphia chromosome” (translocation between chromosomes 9 and 22), which encodes for an abnormal tyrosine kinase protein. This protein is the target for the tyrosine kinase inhibitors, such as

imatinib (Gleevec), which have resulted in significant improvement in survival. Patients with CML typically present between the ages of 40 and 60. Up to 40% of patients are asymptomatic at presentation. Others complain of weight loss, fatigue, abdominal pain, night sweats, and fever. Five-year overall survival can be up to 85% depending on the age at diagnosis.

QUICK QUIZ: ACUTE LEUKEMIA

You have a febrile 37-year-old male with a very high WBC count, most of which are blasts. Most likely, he has an acute leukemia. A bone marrow has not yet been done, and it is unknown if this is an acute myeloid leukemia or an acute lymphoblastic leukemia.

Which of the following statements is INCORRECT?

- A) The patient's fever is likely due to the leukemic cells, and antibiotics should be started only if you identify a specific infection
- B) The patient is at risk for tumor lysis syndrome and should be started on allopurinol
- C) Aggressive inpatient chemotherapy is required for both the treatment of acute myeloid leukemia and acute lymphoblastic leukemia
- D) You should consult a hematologist/oncologist as soon as possible

The correct (or rather incorrect) answer is "A." Patients with acute leukemia and fever should be cultured, **and antibiotics should be started as soon as possible** since a fever is often the result of a concurrent infection. These patients should be kept well hydrated and given allopurinol ("B") to prevent tumor lysis syndrome, which can occur even without chemotherapy if the tumor burden is high enough. Treatment of acute leukemias requires intensive chemotherapy and should be started as soon as possible, so prompt evaluation by a hematologist/oncologist is imperative ("C" and "D").

CASE 6.21

A 65-year-old male who is on quinine for leg cramps (a non-FDA-approved indication) is brought into the ED. Last night he was complaining of a headache, fever, and numbness on the right side of his face. This morning, he was acting erratically.

His physical examination demonstrates a confused male, with a temperature of 39°C, pulse 110 bpm, BP 180/94 mm Hg, and respirations 14 bpm. He has a few petechiae on his palate. He is tachycardic and lungs are clear to auscultation bilaterally. His abdomen is soft, without organomegaly. His neurologic examination is difficult to complete due to his inability to cooperate.

Laboratory findings include WBC 6,000/mm³, Hgb 8.4 g/dL, and platelet count 50,000/mm³. Schistocytes are noted on a peripheral blood smear.

Question 6.21.1 All of the following may be expected in this patient EXCEPT:

- A) Creatinine of 3.2 mg/dL
- B) LDH of 640 IU/L
- C) Elevated haptoglobin
- D) Elevated indirect bilirubin
- E) Negative direct antiglobulin test (direct Coombs)

Answer 6.21.1 The correct answer is "C." An elevated haptoglobin would suggest the absence of active hemolysis. The presence of schistocytes suggests ongoing microangiopathic hemolysis, in this case due to thrombotic thrombocytopenic purpura (TTP). TTP is due to the lack of activity of the ADAMTS13 enzyme either via inheritance of a faulty enzyme (inherited) or via antibodies produced against the enzyme (acquired). It is classically described by a pentad of findings: microangiopathic hemolytic anemia (suggested by schistocytes on peripheral smear), thrombocytopenia, fever, renal insufficiency, and mental status changes. Not all five features need to be present for the diagnosis, but your patient seems to have the pentad. An otherwise unexplained microangiopathic hemolytic anemia in the presence of thrombocytopenia is enough to trigger treatment for TTP; fever, renal insufficiency, and mental status changes are not necessary to make the presumptive diagnosis of TTP. The negative direct antiglobulin test (direct Coombs), "E," suggests that the hemolytic anemia is not due to an autoimmune process. Note that the patient is on quinine, one of the drugs that can cause TTP. Clopidogrel (Plavix) and ticlopidine (Ticlid) can also cause TTP, although it is less common with clopidogrel.

HELPFUL TIP:

Schistocytes are the result of intravascular trauma to RBCs. Any microangiopathic hemolytic anemia can result in schistocytes as can other intravascular trauma such as that secondary to artificial heart valves, HELLP syndrome, malignant hypertension, some malignancies, transjugular intrahepatic portosystemic shunts (TIPS), eclampsia, etc.

Question 6.21.2 Which of the following laboratory findings would you expect to see in this patient with TTP?

- A) Normal PT/INR
- B) Elevated PTT
- C) Elevated fibrin degradation products
- D) Low level of fibrinogen

Answer 6.21.2 The correct answer is "A." Patients with TTP should have a normal PT/INR. This is important because TTP can be confused with DIC, in which the PT/INR should be elevated and fibrinogen should be low.

Your patient is started on plasma exchange. You note that he has not had any change in his hemoglobin or platelet count, and his renal function is worsening.

Question 6.21.3 Which of the following may mimic TTP and should be considered in a poorly responsive patient?

- A) Rocky Mountain spotted fever
- B) Disseminated aspergillosis
- C) Disseminated malignancy
- D) Malignant hypertension
- E) All of the above

Answer 6.21.3 The correct answer is “E.” When patients are poorly responsive to therapy, an alternative diagnosis should be sought. In pregnant patients, preeclampsia or HELLP syndrome can mimic TTP. Autoimmune disease (e.g., systemic lupus erythematosus and scleroderma), malignant hypertension, and disseminated malignancy may also mimic TTP. Infections that can be confused with TTP include Rocky Mountain spotted fever, disseminated aspergillosis, as well as any other disease that can cause mental status changes and a low platelet count such as Ehrlichiosis, Anaplasmosis, West Nile virus, etc.

**HELPFUL TIP:**

Therapy with plasma exchange has reduced the mortality rate for TTP from 90% to less than 25%. Other treatments may include glucocorticoids, rituximab (*Transfusion*. 2012 Dec;52(12):2525–2532), and splenectomy in refractory cases. Platelet transfusion should be avoided as it can worsen the patient’s condition.

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of TTP?
- Treat a patient with TTP?
- Develop a differential diagnosis for a patient with microangiopathic anemia?

► **CASE 6.22**

A 23-year-old G1 P0 term female goes to emergency cesarean section after she is noted to have placental abruption. She has no other significant medical history. After the delivery, you note that she is having brisk vaginal bleeding and oozing from her venipuncture sites. You obtain laboratories: WBC 9,000/mm³, Hgb 8.2 g/dL, platelet count 80,000/mm³, INR 2.4, PTT 22 seconds, and fibrinogen 80 mg/dL (normal 190–420 mg/dL). Fibrin degradation products are elevated. A CBC at admission was normal.

Question 6.22.1 Which of the following statements is INCORRECT?

- A) The patient may benefit from platelet transfusion
- B) The patient may benefit from cryoprecipitate transfusion
- C) The patient may benefit from FFP transfusion
- D) The patient may benefit from crystalloid infusion

Answer 6.22.1 The correct answer (and what not to do) is “A.” This patient is exhibiting signs of disseminated intravascular coagulation (DIC), which is characterized by the disordered

regulation of coagulation. It can be precipitated by a sepsis, malignancy, CNS trauma with release of tissue plasminogen activator, obstetrical problems (preeclampsia, retained products of conception, amniotic fluid embolism), ABO incompatibility with hemolysis, extensive burns, snake bites, etc. Thrombin also activates platelets, causing platelet aggregation and consumption. Antithrombin, previously known as antithrombin III, is consumed in this process as well. Treatment is directed at correcting the underlying cause of DIC whenever possible. *Don’t treat the numbers; patients may have a low-grade DIC and be relatively asymptomatic.* If this is the case, reversing the underlying process is enough. If the patient is bleeding, she may benefit from platelet transfusion to maintain a platelet count above 20,000/mm³, but transfusion at higher levels can worsen platelet aggregation. Transfusion of FFP will replace consumed factors. Patients with low fibrinogen levels will benefit from transfusion of cryoprecipitate. The use of heparin is generally limited to those with low grade, chronic DIC with thrombotic complications. It may also be considered acutely if there are prominent thrombotic complications.

**HELPFUL TIP:**

Laboratory findings in DIC include low platelets, prolonged PT/INR, normal or prolonged PTT, low fibrinogen, and increased fibrin degradation products. Further, D-dimer and thrombin time are also increased, antithrombin may be low, and peripheral blood smear will reveal schistocytes. An elevated D-dimer in isolation is not helpful since D-dimer is elevated in many states, including DVT/PE.

► **Objectives: Did you learn to ...**

- Distinguish DIC from TTP?

► **CASE 6.23**

A 22-year-old female college student presents to your office with complaints of an enlarged cervical lymph node and sore throat. She has felt feverish on and off for several weeks, but never measured her temperature. She is afebrile today, a rapid strep test is negative, and there is no evidence of lymphadenitis; you treat her symptomatically. You ask her to return if her symptoms do not resolve within 2 to 4 weeks.

She returns 4 weeks later. The sore throat has resolved; however, she now complains of intense pruritus and sweats at night. The cervical lymph node now measures 3 cm. The remainder of her physical examination is negative.

Question 6.23.1 What is the most appropriate next step?

- A) Direct laryngoscopy
- B) Empiric antibiotic trial
- C) Lymph node biopsy
- D) MRI of the neck
- E) Observation for another 4 weeks

Answer 6.23.1 The correct answer is “C.” The prolonged (>1 month) presence of a large (>1 cm) lymph node deserves a biopsy. MRI of the neck and laryngoscopy may be indicated depending on the biopsy results. Empiric antibiotic therapy (“B”) is inappropriate and unlikely to be helpful, as you have no source of primary infection. At this point in time, observation (“E”) will just delay the diagnosis. Note that delaying the biopsy for 1 month after initial presentation does not change outcomes even if the node is malignant.

You obtain a lymph node biopsy that is consistent with nodular sclerosing Hodgkin lymphoma.

Question 6.23.2 Which of the following statements is INCORRECT?

- A) The patient has B symptoms
- B) Further staging is necessary
- C) Chemotherapy is palliative only in this patient
- D) Treatment includes both radiation and chemotherapy

Answer 6.23.2 The correct (and untrue) answer is “C.” Chemotherapy regimens for Hodgkin lymphoma have resulted in response rates of more than 90%, with fewer long-term complications than prior regimens. Despite the fact that it is well-known, Hodgkin lymphoma is an uncommon disease, with about 8,000 cases occurring each year in the United States. It is a disease of young people, occurring typically in patients in their 20s. Patients often present with lymphadenopathy. Symptoms, known as “B symptoms,” include weight loss, fever, and drenching night sweats. The presence of “B symptoms” correlates with more advanced disease. Other symptoms may include pruritus, diffuse pain after consuming alcoholic beverages, and symptoms related to the development of a mediastinal mass. After a diagnostic lymph node biopsy, further staging includes CT scans, bone marrow biopsy, and routine laboratory tests.

HELPFUL TIP:

Non-Hodgkin lymphoma (NHL) is increasing in incidence and is more common than Hodgkin lymphoma. Risk factors for NHL include HIV infection and advancing age.

HELPFUL TIP:

The differential diagnosis of generalized lymphadenopathy is broad, and a good history is imperative. The initial evaluation should include a CBC and CXR. If these are negative and lymphadenopathy persists, consider obtaining syphilis testing and ANA and testing for TB and HIV. Also, consider testing for Epstein-Barr virus (antibody test or heterophile) as appropriate. Some medications can cause generalized lymphadenopathy secondary to serum sickness.

► **Objectives: Did you learn to ...**

- Recognize presentation of a patient with Hodgkin lymphoma?
- Describe “B symptoms”?

► **CASE 6.24**

A 34-year-old woman presents to your office with calf pain and swelling. She denies trauma to the leg. She has no other significant medical history and takes only oral contraceptives. She smokes half a pack of cigarettes daily but does not drink alcohol. Her physical examination is also unremarkable, with the exception of swelling and tenderness of the left calf. A lower extremity Doppler study demonstrates a new thrombus occluding the common femoral vein.

Question 6.24.1 Which of the following would NOT be appropriate in this patient?

- A) Start the patient on heparin or a heparinoid and warfarin to maintain an INR of 2 to 3 or start a factor Xa inhibitor (e.g., rivaroxaban) or a direct fibrin inhibitor (e.g., dabigatran)
- B) Have the patient scheduled for placement of an inferior vena cava filter
- C) Discontinue hormonal contraceptives
- D) Encourage the patient to stop smoking
- E) Obtain further history regarding her family

Answer 6.24.1 The correct (and inappropriate) answer is “B.”

This patient has an acute DVT and risk factors for developing a DVT, including smoking and hormonal contraceptive use. You should start her on heparin (or low-molecular-weight heparin) and warfarin with a goal INR of 2 to 3. Heparin should be used for **at least** 5 days and overlapped with therapeutic doses of warfarin that have reached the target INR for **at least** 48 hours. Alternatively, you can start rivaroxaban (Xarelto), apixaban (Eliquis), or dabigatran (Pradaxa). Dabigatran requires an overlap with low-molecular-weight heparin; rivaroxaban and apixaban do not. Dabigatran has a reversal agent (idarucizumab, “Praxbind”) available as do the factor Xa inhibitors (andexanet alfa, “AndexXa”). Avoid edoxaban (Savaysa) as it is less effective and more problematic when adjusting for renal disease. She should be anticoagulated for at least 3 months. Encourage her to stop smoking and to find an alternative form of birth control. “B” deserves special mention. There is no evidence that vena caval filters are of benefit in patients that can be anticoagulated except as a temporary measure for inpatients where the vena caval filter will be removed prior to discharge. There is **no** reduction in PE risk with vena caval filters in those who can be anticoagulated, and there is likely an increased risk of DVT. The role in those who cannot be anticoagulated is unclear; there is scant data.

HELPFUL TIP:

Homan sign is neither sensitive nor specific enough to allow it to be used to rule in or rule out DVT. Don't bother. However, use of a clinical prediction tool (e.g., Well's criteria) can reduce unnecessary testing.

**HELPFUL TIP:**

All of the new anticoagulants (dabigatran, rivaroxaban, and apixaban) are essentially equivalent to warfarin in terms of outcomes. There may be a bit less bleeding, but there is no overwhelming rationale to argue that the newer anticoagulants are superior to warfarin. The 2016 Chest guidelines suggest the newer anticoagulants over vitamin K antagonists with a grade 2B evidence (weak recommendation based on the data). Certainly, the new anticoagulants are more convenient. Note that dabigatran cannot be removed from blister packs or bottles in order to put it in a pillbox or pill organizer. It quickly loses potency.

**HELPFUL TIP:**

Workup of an inherited or acquired hypercoagulable state is controversial because the treatment of the patient is often not going to change whatever the outcome. The greatest risk for having another DVT is having a first DVT. When a thromboembolic event is unprovoked, it is probably prudent to screen the patient for hypercoagulable states. When there is a provoked event (e.g., surgery, prolonged immobilization, pregnancy, systemic estrogen), the role of such a workup is less well defined.

The patient returns 3 months later. She has been relatively easy to anticoagulate (somebody has to be, right?), maintaining a stable INR. She stopped smoking and knows to avoid hormonal contraception. She has learned that her mother had a DVT and her maternal aunt died of a pulmonary embolus. Now, the patient wants to know how this new information will affect her long-term care. You decide to screen her for thrombophilia.

Question 6.24.2 Which of the following sets of tests should NOT be performed while she remains on warfarin?

- A) Factor V Leiden mutation
- B) Antiphospholipid antibodies
- C) Protein C
- D) Prothrombin gene mutation

Answer 6.24.2 The correct answer is “C.” There are several types of thrombophilia for which you might initially test: factor V Leiden mutation, antithrombin (previously antithrombin III) deficiency, prothrombin gene mutation, protein C deficiency, protein S deficiency, and antiphospholipid antibody syndrome. Not all causes of thrombophilia can be tested for while on anticoagulant therapy. Factor V Leiden gene mutation, prothrombin gene mutation, and antiphospholipid antibodies are not affected by warfarin. However, warfarin can reduce protein C and S levels (giving false-positive test results) and increase antithrombin levels (giving a false-negative result). Also, proteins C

and S are depleted during the acute phase of thrombosis, so the levels should not be measured when a patient is experiencing a VTE event.

Factor V Leiden mutation is the most common cause of inherited thrombophilia, being found in 3% to 6% of non-Black blood donors. Antithrombin deficiency is less common, occurring in 1/1,000 to 1/5,000 individuals. The homozygous condition is fatal in utero. Heterozygotes have a 30% chance of developing a thromboembolic event by the age of 30 years. Protein C deficiency occurs in 1/200 to 1/300 people; however, fewer than 1/1,000 heterozygotes develop venous thromboses. Protein S deficiency is estimated to occur in 1/750 to 1/3,000 of persons and has a clinical presentation similar to protein C deficiency. The prevalence of prothrombin gene mutation varies widely and occurs most commonly in persons of southern European descent. Unlike the other thrombophilias discussed antiphospholipid antibody syndrome is an acquired disorder that is associated with arterial as well as venous thromboembolic events.

**HELPFUL TIP:**

What about checking a homocysteine level as part of a hypercoagulable evaluation? Don't bother. It is no longer recommended. As it happens, homocysteine levels correlate poorly with VTE risk (but correlate directly with obesity, which may represent a confounding factor), and treatment with folate, B12, and pyridoxine does not lower the risk of recurrent VTE.

**HELPFUL TIP:**

How long should I anticoagulate this patient? Glad that you asked. For patients on estrogen or other modifiable factor with a first DVT/PE (s/p surgery, bedrest, pregnancy, etc.), 3 months is probably adequate. For others (cancer, etc.), the recurrence rate is approximately 7% per year (*Blood*. 2002;100:3484–3488). So, if the bleeding risk is low, it is reasonable to continue anticoagulation in these patients for life (*Chest*. 2016;149(2):315–352). Current studies are identifying the role of D-dimer monitoring as a marker to assist in determination of adequate anticoagulation length and when to restart in order to prevent VTE recurrence (*Ann Intern Med*. 2015;162:27). Everyone agrees that a second unprovoked DVT mandates indefinite treatment. Finally, there is no evidence that *prophylactic* anticoagulation in those with cancer who have not had a thromboembolic event is useful.

**HELPFUL TIP:**

Should I stop oral anticoagulation for the procedures? If I do, should I bridge *warfarin* patients with heparin? There is no need to stop anticoagulation for many procedures such as dental procedures, colonoscopy, etc. But just try to get this past the dentist or gastroenterologist.

Importantly, bridging atrial fibrillation patients on warfarin with heparin increases the bleeding risk while doing nothing to prevent stroke, PE, etc. Be selective in whom you bridge. Bridge patients with a CH2ADS2-VASC score of >5 (see cardiology chapter for more on the CH2ADS2-VASC score), those with a prosthetic mitral valve or metal aortic valve, those with a history of thromboembolic events while off anticoagulation, etc. For “average” risk patients bridging with heparin adds nothing and has significant downsides (see *N Engl J Med.* 2015;373:823–833 and *Circulation.* 2015;131:488–494). *Note that it isn’t necessary to bridge patients who are on dabigatran, rivaroxaban, apixaban, etc.* They are short acting enough that just holding one dose prior to surgery is adequate; there is a minimal window for clot formation. See below for further discussion of heparin bridging in those who have had a recent thromboembolic event.

► **Objectives: Did you learn to ...**

- Obtain an appropriate history in a patient with clotting problems?
- Recognize common inherited and acquired hypercoagulable risk factors?

► **CASE 6.25**

A 19-year-old gravid female presents during her second trimester and complains of left calf swelling. With the help of Doppler studies, you diagnose her with a DVT.

Question 6.25.1 Which of the following statements is correct?

- A) DVT occurs most commonly in the right lower extremity in pregnant women
- B) DVT is common in pregnancy due to increased venous stasis and increased levels of fibrinogen, factor VIII, and vWF
- C) Anticoagulation with heparin introduces no risk to the fetus or mother
- D) DVT is most common in the third trimester

Answer 6.25.1 The correct answer is “B.” DVT, and the broader category of venous thromboembolism (VTE), occurs two to four times more often in pregnant women compared to nonpregnant controls. Increased risk is found with cesarean delivery versus vaginal delivery. The majority of DVTs occur in the **left** lower extremity of pregnant women, likely due to the compression of the left iliac vein by the right iliac artery as they cross. The increased incidence of VTE is multifactorial, including the presence of all three components of Virchow’s triad: venous stasis, endothelial injury (increased venous distension secondary to increased estrogen), and a hypercoagulable state (increased levels of fibrinogen, factor VIII, and vWF).

VTE occurs equally during all three trimesters, **but the highest risk is postpartum (2–5 times the risk during pregnancy).**

Warfarin crosses the placenta and has teratogenic effects in addition to increased risk of fetal bleeding. Heparin and danaparoid (available in Canada) do not cross the placenta but are associated with a 2% risk of maternal bleeding. Heparin also carries the risks of heparin-induced thrombocytopenia with thrombosis, osteoporosis, and bleeding at the uteroplacental junction. Dosing of unfractionated heparin is difficult during pregnancy, and low-molecular-weight heparin (e.g., enoxaparin) is probably the best choice for anticoagulation. There is increased use of enoxaparin in the immediate postpartum for DVT prophylaxis for higher risk mothers, so don’t be surprised if your patient is discharged home after her delivery with a few more days or weeks of enoxaparin. Heparin and warfarin are safe for lactating mothers.

► **Objectives: Did you learn to ...**

- Recognize the risks of VTE in the pregnant patient?

► **CASE 6.26**

A 52-year-old woman presents to the ED with shortness of breath and pleuritic chest pain. She has been on warfarin for atrial fibrillation. Despite her anticoagulation, you suspect pulmonary embolism (PE) and obtain a spiral CT scan, which shows a thrombus in the right pulmonary artery. Prior to the initiation of any therapy, her coagulation studies return and show INR of 2.8 (normal = 1) and PTT 49 seconds (prolonged).

Question 6.26.1 Which of the following is the most appropriate next step?

- A) Test the patient for antiphospholipid antibodies
- B) Place an inferior vena cava filter
- C) Repeat the INR and PTT since the patient’s sample was probably contaminated with heparin
- D) Confront the patient about her noncompliance with warfarin
- E) Throw up your hands in disgust. Aren’t they done with the hematology chapter yet?

Answer 6.26.1 The correct answer is “A.” Patients who have a new VTE while on appropriate anticoagulation therapy should be evaluated for antiphospholipid antibody syndrome. This patient has a prolonged PTT, which is also suspicious for an antiphospholipid antibody. Remember that warfarin prolongs the PT, not the PTT. She was an outpatient prior to having her blood drawn and was not taking heparin, so contamination with heparin is unlikely (although heparin definitely causes an increase in the PTT). The increased INR suggests that the patient has been compliant with her warfarin. As to “B,” see the note above about vena caval filters.

HELPFUL TIP:

Previously, retrospective studies resulted in the recommendation that patients with an antiphospholipid antibody and VTE be maintained at an INR of 3 to 4. This

recommendation has changed with newly available prospective data, and these patients should have a target INR of 2 to 3. Some patients with antiphospholipid antibody syndrome may have marked INR fluctuations that make monitoring anticoagulation difficult.

HELPFUL TIP:

Genetic testing is now available for warfarin sensitivity that can help predict which patients will need higher (or lower) doses of warfarin to maintain adequate anticoagulation. However, these tests are very expensive and contribute little to the care of most patients.

► Objectives: Did you learn to ...

- Identify a patient presenting with antiphospholipid antibodies and understand the management of such patients?

► CASE 6.27

A 50-year-old male is admitted to the hospital with a fractured tibia after a motor vehicle collision. You are asked to assist in his perioperative management. The patient is generally healthy but is taking warfarin for a DVT that he developed after a total knee arthroplasty 3 weeks ago. His INR is 1.8, and he is scheduled for open reduction/internal fixation tomorrow.

Question 6.27.1 Which of the following statements is INCORRECT?

- The patient has an approximate 50% risk of recurrent VTE without appropriate therapy
- Heparin should be started preoperatively
- Heparin should be continued postoperatively
- Resumption of warfarin alone postoperatively is adequate anticoagulation

Answer 6.27.1 The correct answer is “D.” Perioperative management of a patient with recent VTE is complicated. While there are established guidelines for VTE prophylaxis depending on the type of surgery planned, this patient already has an active thrombotic event. Discontinuing warfarin may result in a rebound hypercoagulable state, and surgery creates a prothrombotic state.

Patients who have a VTE within 1 month of surgery have a 50% risk of a second VTE if not treated aggressively with anticoagulation. These recurrent events carry a mortality rate of approximately 6%. Such patients should be placed on heparin before and after surgery if they are on warfarin. If they are on one of the newer anticoagulants, hold a dose of dabigatran, apixaban, or rivaroxaban and then restart the drug postoperatively.

Patients with a VTE within 1 to 3 months before a scheduled surgery should be considered for *postoperative* heparin/warfarin or dabigatran, apixaban, or rivaroxaban. A VTE > 3 months

before the scheduled surgery should not pose significant additional risk, and established prophylaxis guidelines should be followed. See above for a discussion of heparin bridging in atrial fibrillation and heart valves.

► Objectives: Did you learn to ...

- Describe anticoagulation approaches in perioperative care?

We will leave you with a quick primer on the direct oral anticoagulants (“DOACs”). All of these now carry indications for nonvalvular atrial fibrillation and venous thromboembolism. None are approved for use with mechanical heart valves. Transitioning between warfarin and DOACs (and vice versa) is dependent on the DOAC. Refer to FDA labeling. For VTE treatment, dabigatran (Pradaxa) and edoxaban (Savaysa) require initial therapy with a parenteral anticoagulant, such as heparin or enoxaparin.

Dabigatran (Pradaxa): A direct thrombin inhibitor. Contributes to less bleeding overall than warfarin, but prevents fewer myocardial infarctions and causes more GI bleeds. May also increase dyspepsia. The dose must be decreased in those with renal disease. May be reversed with idarucizumab (Praxbind).

Rivaroxaban (Xarelto): An oral factor Xa inhibitor (similar to enoxaparin). Does not require heparin at initiation. There are multiple drug interactions (though fewer than with warfarin). Not indicated in those with severe renal disease and those with moderate liver disease.

Apixaban (Eliquis): An oral direct factor Xa inhibitor. Does not require heparin at initiation. Not recommended for patients with moderate hepatic impairment. Dose must be decreased in renal impairment. May cause hypercoagulable state when stopped, increasing the risk of stroke if stopped without adequate continuous anticoagulation.

Other oral direct factor Xa inhibitors: *Betrixaban (Bevyxxa)*, *Edoxaban (Lixiana, Savaysa)*

Annexa (Andexanet alfa, Portola Pharmaceuticals): A new recombinant modified factor Xa to work as an antidote for patients receiving Xa inhibitors.

Clinical Pearls

- A platelet count of >20,000/mL is adequate for hemostasis.
- Do not perform an exhaustive hypercoagulability workup in patients with VTE who have a major risk factor (e.g., systemic estrogen, surgery, trauma, prolonged immobility).
- Do not use plasma or a prothrombin complex concentrate to reverse anticoagulation unless there is significant bleeding (e.g., intracranial bleed).
- Do not use venocaval filters to prevent a second PE in a patient with a prior history of DVT. They do not work.
- If a patient is on warfarin and the INR is 10 or less and the patient is asymptomatic, do not treat with vitamin K; simply hold the warfarin. If the INR is >10, give 1 to 5 mg of PO vitamin K.

- It is not necessary to anticoagulate patients with a first DVT that can be explained by a reversible cause (e.g., estrogen, surgery, and immobilization) for more than 3 months.
- The PTT is the most useful single test when screening for coagulopathy.
- Transfuse stable patients to a hemoglobin of 7 to 8 mg/dL. A higher target can worsen outcomes.
- Transfusing platelets will not work in ITP. The platelets will just get destroyed.
- With iron deficiency anemia, the reticulocyte count should go up within 10 days when appropriately treated with iron. If this doesn't happen, reconsider your diagnosis.

Gastroenterology

7

Jason Kruse and Mark A. Graber

► CASE 7.1

A 43-year-old woman complains of a burning pain in the retrosternal area. Her symptoms started about 2 years ago and initially responded to self-medication with antacids or histamine-2 receptor antagonists (H_2 blockers). However, within the last 4 months, she has had nearly daily problems. She frequently wakes up in the middle of the night with retrosternal, burning pain radiating to her neck. She also frequently notices an acidic taste in her mouth. While antacids help somewhat, they only provide transient relief. She has otherwise been healthy. She currently takes up to 150 mg of ranitidine twice daily plus the antacids. She denies tobacco or alcohol use. Her physical examination is normal.

Question 7.1.1 Which of the following is NOT considered a “red flag” when it comes to patients with acid reflux/dyspepsia?

- A) Weight loss
- B) Trouble swallowing liquids
- C) Trouble swallowing solids
- D) A craving for doughnuts

Answer 7.1.1 The correct answer is “D.” OK, we will give you this one. One of the most critical parts of patient assessment is to make sure there are no “red flag” symptoms that may indicate more than simple gastroesophageal reflux disease (GERD). “Red flag” symptoms include: dysphagia, weight loss, anemia, aspiration, early satiety or vomiting, and cough. Dysphagia for solids progressing to dysphagia for liquids is especially problematic. A craving for doughnuts is benign (although eating them is not) and may be seen among the book editors, police, college students, and others.

Question 7.1.2 Which of the following statements is true?

- A) All patients with GERD need endoscopy
- B) Routine endoscopy in patients with GERD markedly reduces the risk of esophageal cancer

- C) The diagnostic sensitivity and specificity of typical symptoms of GERD is $>90\%$
- D) Patients over the age of 45 with new onset symptoms are considered to be at high risk
- E) C and D

Answer 7.1.2 The correct answer is “E.” Because of the high sensitivity and specificity of symptoms ($>90\%$), most patients do not need endoscopy or any other procedure or test to make the diagnosis of GERD. Patients with refractory GERD or those with new symptoms over the age of 45 years (50 by some sources) warrant endoscopy. “B” is incorrect. Screening for the presence of Barrett esophagus in patients with GERD is low yield. Targeted, not routine, endoscopy may be beneficial.

HELPFUL TIP:

The link between *Helicobacter pylori* and GERD is poorly defined. There is no good evidence to support eradication of *H. pylori* for the treatment of GERD. The thinking in dyspepsia has evolved (more on this later).

The patient denies any “red flags.” Based on the history, you assume that this patient has GERD.

Question 7.1.3 You recommend:

- A) Barium swallow study
- B) Esophageal manometry
- C) Esophagogastroduodenoscopy (EGD)
- D) Ambulatory pH study of the esophagus
- E) Trial of omeprazole and life style modifications

Answer 7.1.3 The correct answer is “E.” As noted above, the sensitivity and specificity of classical symptoms allows for the diagnosis of GERD without additional studies. Testing is actually less sensitive than symptoms for GERD with the sensitivity of tests varying between 50% and 70%. Many patients have a false-negative EGD. H_2 blockers can be used as the first-line

treatment in patients with GERD, but this patient has already failed ranitidine. Starting a proton pump inhibitor (PPI) like omeprazole is the next step and is preferred as the first-line therapy in patients with severe symptoms. Lifestyle modifications should be made including weight loss (if overweight); avoidance of carbonated beverages, caffeine, excessive alcohol, and large or late evening meals; avoidance of anticholinergics, calcium channel blockers, NSAIDs, and sedative drugs; smoking cessation; and elevation of the head of the bed using 6-in blocks.

HELPFUL TIP:

Most patients with GERD will have negative endoscopic findings (termed nonerosive reflux disease [NERD]—really, we didn't make this one up). Symptoms do not correlate well with the presence or degree of esophageal inflammation or erosion.

Your patient is willing to try the PPI you prescribe, but she also wants to know about surgery that a friend had.

Question 7.1.4 Regarding surgery for GERD, you can tell her:

- A) Bloating and inability to belch do not occur with antireflux surgery
- B) Antireflux surgery should be thought of as the first-line because it is vastly superior to medical therapy
- C) Years after antireflux surgery, many patients will require medication for GERD symptoms
- D) Laparoscopic fundoplication will ruin her fabulous bikini body by leaving a large midline scar

Answer 7.1.4 The correct answer is “C.” Surgery may be an option in select patients with reflux disease. The usual indications for antireflux surgery include failure of medical therapy to control symptoms and failure of medical therapy to prevent complications (e.g., stricture and pneumonia). The most commonly performed surgery is fundoplication, in which the lower esophageal sphincter is “wrapped” to enhance its competency. While fundoplication will alleviate symptoms in 80% to 95% of patients, there is progressive loss of effectiveness over time (only 40% are without medication after 10 years). Adverse effects of surgery include persistent dysphagia (requiring additional interventions in 3–7%), gas, bloating, and inability to belch. “D” is incorrect because a laparoscopic procedure should result in just a few small scars.

After making lifestyle changes and a trial of your favorite PPI (that her insurance will cover after you play “Guess What’s on Our Formulary”), the patient feels markedly better. She is so pleased with your care, she refers her brother to you. He just turned 52 and has been struggling with heartburn for many years. He smokes 1 ppd and has a BMI of 35 kg/m². He was hoping for a prescription of PPI and a quick exit. You inform him that he has multiple risk factors and needs screening for Barrett esophagus. You refer him for EGD. The

esophageal biopsy is consistent with the visual report, which shows Barrett esophagus.

Question 7.1.5 All of the following are true regarding Barrett esophagus EXCEPT:

- A) Males are more likely to have Barrett esophagus than females
- B) Barrett esophagus is due to a change in the esophageal mucosa from columnar to squamous
- C) Barrett esophagus occurs in 10% to 15% of patients with erosive esophagitis
- D) Barrett esophagus increases the risk of adenocarcinoma by up to 30-fold
- E) Patients with Barrett esophagus should undergo periodic screening EGD

Answer 7.1.5 The correct answer is “B.” Barrett esophagus is diagnosed histologically when esophageal mucosal metaplasia has occurred and the usual squamous epithelial cells have changed to columnar epithelium. Targeted screening for Barrett’s in males with >1 additional risk factors is recommended. Risk factors for Barrett include long-standing reflux (>5 years of weekly symptoms), male gender (6:1 male:female preponderance), advancing age (>50 years old), central adiposity, tobacco use, and white race. Barrett esophagus occurs in 10% to 15% of patients with erosive esophagitis, and it dramatically increases the risk of esophageal adenocarcinoma by up to 30-fold (*N Engl J Med.* 2011;365:1375). However, the absolute risk of adenocarcinoma is still small, about 0.2% to 0.5% annually. Surveillance for Barrett depends on the level of dysplasia found on initial examination, and guidelines exist that dictate the frequency with which repeat EGD should be performed.

Question 7.1.6 The patient returns to you alarmed by his new diagnosis of Barrett esophagus. He quit smoking and is working to lose weight. He admits to a glass of wine nightly with dinner. His symptoms are well controlled on daily PPI. He will follow up as directed for surveillance endoscopy. Which of the following regarding management of this patient’s Barrett’s esophagus is true?

- A) The patient should increase to twice daily PPI to prevent progression
- B) The patient should be on aspirin or NSAID prophylaxis to prevent progression to cancer
- C) The patient should consider antireflux surgery to prevent further damage
- D) The patient should quit drinking alcohol, his nightly glass of wine is accelerating his progression to malignancy
- E) None of the above are true

Answer 7.1.6 The correct answer is “E.” In patients with good symptom control there is no additional benefit to twice daily PPI and patient should remain on his daily dose. Current ACG guidelines recommend against aspirin or NSAID as an antineoplastic strategy. While antireflux surgery should be considered in patients with poor control on optimized medical therapy, it is not recommended for management of Barrett’s in a patient with good symptom control. Alcohol consumption is not associated

with progression of Barrett's (though there is an association of hard liquor with squamous cell cancer of the esophagus). The patient's wine may in fact be protective.

HELPFUL TIP:

Prokinetic agents, like metoclopramide (Reglan), can be useful in the treatment of GERD. In addition to promoting stomach emptying, metoclopramide increases gastroesophageal sphincter tone. Remember that metoclopramide can cause extrapyramidal side effects with chronic use.

HELPFUL TIP:

Complications of chronic GERD include erosive esophagitis, peptic stricture, and adenocarcinoma of the esophagus. However, the absence of heartburn symptoms does not rule out reflux-related complications since approximately one-fourth of patients with peptic stricture (a stricture of the esophagus, which results from the healing of ulcerative esophagitis) and one-third of those with adenocarcinoma of the esophagus had no heartburn prior to diagnosis. Barrett esophagus can regress with the adequate treatment of GERD.

► Objectives: Did you learn to ...

- Describe the diagnosis and management of GERD?
- Use H₂ blockers and PPIs in the management of GERD?
- Recognize complications of GERD and risk factors for Barrett esophagus?

► CASE 7.2

A 53-year-old woman comes to your office complaining of chest pain and problems swallowing. She says food seems to hang up in the retrosternal area. This started several years ago, has gradually worsened, and now occurs at least twice per week. Generally, only solid foods cause problems. She has become very careful, only taking small bites and chewing them well before swallowing. Should she experience problems, she has found that drinking additional liquids alleviates her symptoms within minutes. She does not regurgitate food and has not lost weight.

Question 7.2.1 What is the symptom this patient is complaining of?

- A) Dysphagia
- B) Globus sensation
- C) Odynophagia
- D) Aerophagia
- E) Phagophobia

Answer 7.2.1 The correct answer is "A." Dysphagia, from the Greek *dys* (meaning "with difficulty" . . . as opposed to "Dis,"

which is a city in Dante's Hell in addition to being a neologism) and *phagia* (meaning "to eat"), refers to the sensation that food is being hindered in its passage from the mouth to the stomach. Odynophagia refers to pain upon swallowing, aerophagia to swallowing of air, and globus sensation to a perception of a lump or fullness in the throat that is temporarily relieved by swallowing. Phagophobia is just what you think it is: fear of eating or swallowing.

HELPFUL TIP:

Aerophagia is a common and underdiagnosed cause of abdominal symptoms. Generally, patients will complain of belching associated with abdominal bloating, especially after meals. It is not uncommon for patients to mention that they have to loosen their belt after meals. Aerophagia is exacerbated by gum chewing (which causes frequent swallowing of air), eating quickly, drinking carbonated beverages, and smoking. Aerophagia can be mitigated by eating more slowly, avoiding carbonated beverages, etc.

Question 7.2.2 Given the above patient's description of symptoms and the location of her discomfort (food sticking in the retrosternal esophagus), what type of dysphagia is she most likely to suffer from?

- A) Oropharyngeal dysphagia
- B) Esophageal dysphagia
- C) Functional dysphagia
- D) Aberrant dysphagia

Answer 7.2.2 The correct answer is "B." Dysphagia can be differentiated by where the symptoms seem to occur. Oropharyngeal dysphagia, also known as "transfer dysphagia," arises from difficulty in the upper esophagus and pharynx. Patients complain of food getting stuck immediately upon swallowing, and when asked to point to the location, patients frequently identify the cervical region. Patients with oropharyngeal dysphagia often have more problems with liquids than solids and may complain that liquid comes out of their nose when they try to swallow. The best initial test for oropharyngeal dysphagia is a modified barium swallow (video fluoroscopic swallow exam) with a liquid phase and a solid phase. Esophageal dysphagia is usually described as beginning several seconds after swallowing, and patients frequently point to the suprasternal notch or retrosternally when trying to localize the area causing symptoms. Patients in whom no cause can be found after detailed investigation are often categorized as having functional dysphagia. There is no such thing as aberrant dysphagia.

A complete review of systems and physical examination is unrevealing. She is not taking pills that can cause erosive esophagitis such as doxycycline or bisphosphonates, she is not HIV positive making candidal and HSV esophagitis unlikely, and she again notes progressive dysphagia, initially to solids and now to liquids.

FIGURE 7-1. Telangiectasias in a patient with Raynaud's.

Question 7.2.3 Which of the following is the single best test to arrive at a diagnosis in this patient?

- A) Barium swallow
- B) Esophageal manometry
- C) Esophagogastroduodenoscopy (EGD)
- D) Ambulatory pH study of the esophagus
- E) Diagnostic trial of a high-dose PPI

Answer 7.2.3 The correct answer is “C.” Visualization of the esophagus is critical in patients with esophageal dysphagia. Our patient presents with esophageal dysphagia for solids, which is most consistent with a structural problem, such as a stricture, web, or neoplasm. Endoscopy is the best diagnostic study to evaluate the esophageal mucosa as it allows one to obtain biopsies and perform endoscopic interventions such as dilations, if indicated. Barium swallows are second best and have fallen out of favor when endoscopy is available. That said, barium swallow is inexpensive, noninvasive, and does not require sedation. Barium swallow can help map the esophagus and assess for lesions posing a high risk of perforation (*Cleve Clin J Med.* 2009;76(2):105–111). Should the endoscopy come back negative, esophageal manometry (“B”) may be useful as it will help determine if a motility disorder is the cause of symptoms. While a “diagnostic” trial with a PPI (“E”) is an appropriate strategy in patients with typical GERD, the presence of an alarm symptom, such as dysphagia, requires further testing. “D,” an ambulatory pH study, does not help in defining the etiology of the dysphagia.

HELPFUL TIP:

Many patients have breakthrough pain at night even when on a PPI. The reason for this is that PPIs only act on cells that have been activated (such as by a meal). PPIs should be taken 30 minutes before eating. Try adding an H₂ blocker at nighttime for patients having breakthrough pain.

HELPFUL TIP:

Rebound acid hypersecretion can lead to symptom recurrence if potent antisecretory agents, such as PPIs, are stopped abruptly. Many experts recommend stepping down to H₂ blockers prior to cessation. However, even H₂ blockers can also cause a lesser degree of rebound acid hypersecretion. So, consider tapering these drugs as well.

The patient returns from her endoscopy. According to the report, she had severe esophagitis with confluent erosions in the distal esophagus. During your physical examination, you find the skin changes shown in Figure 7-1. When you ask about these, the patient reports a history of bluish fingertip discoloration with cold temperatures. She also complains that her fingers feel “tight” at times.

Question 7.2.4 With this new information, which of the following diagnoses are you considering?

- A) CREST syndrome
- B) Esophageal adenocarcinoma
- C) Metastatic colonic adenocarcinoma
- D) Sicca syndrome
- E) Peptic ulcer disease (PUD)

Answer 7.2.4 The correct answer is “A.” Note the telangiectasia on the finger pads in Figure 7-1. CREST is an acronym for a syndrome that includes Calcinosis cutis, Raynaud phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasias. Up to 60% of patients with CREST have erosive esophagitis. Dysphagia is common and is due to esophageal stricture and/or dysmotility.

Question 7.2.5 Given her endoscopic findings and the fact that she likely has CREST syndrome, what treatment do you suggest?

- A) H₂ blocker
- B) PPI
- C) High-dose corticosteroids
- D) *H. pylori* eradication
- E) Laparoscopic fundoplication

Answer 7.2.5 The correct answer is “B.” Severe reflux and dysphagia are hallmarks of CREST syndrome. The esophagus has poor motility with impaired function of the lower esophageal sphincter allowing reflux while poor motility reduces esophageal clearance. Chronic and potent acid suppressive medications, such as PPIs, are indicated. Fundoplication is **relatively contraindicated**, as the poor contractile function of the esophagus may not generate enough force to overcome the barrier created by fundoplication. *H. pylori* treatment has no role in the management of this illness. Steroids could certainly worsen the gastrointestinal (GI) symptoms by irritating the gastric mucosa. Other causes of esophageal dysphagia are listed in Table 7-1.

HELPFUL (AND IMPORTANT) TIP:

It would not surprise us to see this one on the board examination. An increasingly recognized cause of dysphagia is **eosinophilic esophagitis**. The classic adult patient presents with dysphagia, “GERD symptoms” and upper abdominal pain unresponsive to PPIs, and possibly food impaction. Children often present with feeding problems (age 2), recurrent vomiting (age 8), and chronic abdominal pain (age 12), or food impaction (teenage years). Association with childhood asthma is strong and dietary elimination therapy may be helpful in children. This entity is found especially in those who are atopic and requires both symptoms and an esophageal biopsy result showing an increased number of eosinophils. Treatment in adults (and often children) involves swallowing inhaled corticosteroids (e.g., fluticasone or budesonide), and, in severe cases, systemic steroids. Systemic eosinophilia is rare; montelukast has a checkered record when it comes to treating eosinophilic esophagitis and appears less effective than steroids.

HELPFUL TIP:

Dysphagia that progresses from solids and then to liquids is a classic symptom of esophageal cancer and cannot be ignored.

► **Objectives: Did you learn to ...**

- Differentiate dysphagia from other GI symptoms?
- Take an adequate history to evaluate the etiology of dysphagia?

TABLE 7-1 CAUSES OF ESOPHAGEAL DYSPHAGIA

Mechanical Lesions	
Intrinsic	Extrinsic
Benign tumors	Aberrant subclavian artery
Caustic esophagitis/stricture	Cervical osteophytes
Radiation esophagitis/stricture	Enlarged aorta
Peptic esophagitis/stricture	Enlarged left atrium
Eosinophilic esophagitis	Mediastinal mass
Diverticula	Postspinal surgery
Malignancy	
Post-GI surgery	
Rings and webs	
Foreign bodies	
Motility Disorders	
Achalasia	
Chagas disease (<i>Trypanosoma cruzi</i>)	
Diffuse esophageal spasm	
Hypertensive lower esophageal sphincter	
Nonspecific esophageal motility disorder	
Nutcracker esophagus	
Scleroderma	

- Describe different types of dysphagia and identify various causes of dysphagia?
- Recognize that CREST syndrome as a cause of dysphagia?

QUICK QUIZ: REGURGITATION

You see a 61-year-old woman in your office complaining of halitosis, heartburn, and regurgitation of undigested food 4 hours after eating. She also feels that the food is sticking in her throat.

What is the most likely cause of her symptoms?

- A) Schatzki ring
- B) Zenker diverticulum
- C) Achalasia
- D) Foreign body
- E) Esophageal web

The correct answer is “B.” Late regurgitation of undigested food is pathognomonic for Zenker diverticulum. A Zenker diverticulum is an acquired out-pouching of esophageal mucosa, which typically becomes symptomatic in middle age or later in life. The diagnosis is confirmed by lateral view of a barium swallow or by visual confirmation with EGD. The other diagnoses listed can cause dysphagia and regurgitation but are less likely. “A,” Schatzki ring, is a lower esophageal mucosal ring that can “catch” food and cause dysphagia. “C,” achalasia, results from a loss of innervation of the lower esophagus with impaired esophageal motility and generally occurs in young and middle-aged adults. Patients with achalasia typically have dysphagia with solids and liquids. “D,” foreign body, should be diagnosable by history. Elderly adults, children, and patients

with psychiatric disease are most at risk for foreign body in the esophagus. “E,” esophageal web, is caused by a thin layer of mucosa across the esophageal lumen and presents much like a Schatzki ring.

► CASE 7.3

A 48-year-old woman presents with 3 years of intermittent GI complaints after eating. She describes epigastric pain and bloating after food intake. Pain is described as pressure, mild-to-moderate in intensity, and nonradiating. Her weight is stable. She denies heartburn, dysphagia, vomiting, diarrhea, constipation, or blood in her stools. She only takes a multivitamin and she has not tried any specific remedies. The physical examination is normal. CMP and CBC are benign.

Question 7.3.1 What is the most likely diagnosis given the information above?

- A) Pyrosis
- B) Peptic ulcer disease (PUD)
- C) Functional dyspepsia
- D) Stomach cancer

Answer 7.3.1 The correct answer is “C” functional dyspepsia. “A,” pyrosis, is just another name for heartburn. “B,” PUD, is relatively unlikely, given the lack of risk factors and mild nature of illness. “D” is unlikely for similar reasons.

There have been significant shifts in evaluation and management of dyspepsia. ACG/CAG 2017 guidelines define dyspepsia as “predominant epigastric pain lasting at least one month.” Associated symptoms often include epigastric fullness, vomiting, and heartburn. Conventional wisdom has been upended with the most recent evidence-based guidance, so let’s review...

Question 7.3.2 What is the most appropriate next step in this 48-year-old female patient?

- A) Obtain *H. pylori* serum antibodies
- B) Obtain an abdominal ultrasound examination of liver, biliary tree, and pancreas
- C) Obtain a detailed dietary history
- D) Obtain an upper GI x-ray series
- E) Refer for gastroscopy

Answer 7.3.2 The correct answer is “C.” A good history and physical is always a good starting point! While food intolerance does not cause functional dyspepsia, the symptoms of the two types of disorders overlap to some degree. Considering the prevalence of selective carbohydrate malabsorption syndromes, high intake of lactose- and fructose-containing foods and beverages may contribute to GI symptoms in a significant number of patients. Therefore, the history should always contain a detailed assessment of dietary habits and symptoms in relation to food intake.

You obtain a detailed dietary history, suggesting a potential contribution of fructose intolerance and excessive carbonated beverage intake (it’s those five Giant Gulp soft drinks a day). After appropriate dietary modification, her symptoms of postprandial pain and bloating are unchanged.

Question 7.3.3 Now what is the most appropriate next step in this patient?

- A) Obtain *H. pylori* stool antigen
- B) Obtain an abdominal ultrasound examination of liver, biliary tree, and pancreas
- C) Run a trial of PPI
- D) Obtain an upper GI x-ray series
- E) Refer for gastroscopy

Answer 7.3.3 The correct answer is “A.” Patients under the age of 60 with dyspepsia should have noninvasive testing for *H. pylori*, with plans to treat if positive. Preferred noninvasive testing includes stool antigen and 13C urea breath test. Treat for *H. pylori* if positive. If symptoms persist despite treatment, or if *H. pylori* testing is negative, it’s appropriate to proceed to PPI trial. If symptoms persist with PPI, addition of a tricyclic antidepressant or prokinetic agent is reasonable. When all else fails, consider psychotherapy to help your patient cope with ongoing symptoms. Without focal symptoms or lab abnormalities, there is no indication for ultrasound at this point. Endoscopy is not indicated for dyspepsia in patients <60 years old unless they are high risk (e.g., family history, growing up in South East Asia or South America). Note that even an isolated alarm feature (including weight loss, anemia, vomiting) in the **absence** of refractory or new onset GERD > age 45–50 years of age is no longer considered reason for endoscopy!

HELPFUL TIP:

The shift away from endoscopy is uncomfortable for this author and flies in the face of traditional practice. In the end, remember these are guidelines and not standards of care. A move away from unnecessary invasive testing is good for patient safety and cost management. Patients with progressive symptoms, progressive weight loss, risk factors for malignancy, and **all patients greater than age 60 with dyspepsia warrant EGD.**

Question 7.3.4 Which of the following is true of the natural history of functional dyspepsia?

- A) Most patients will not have symptom-free periods, instead having constant dyspepsia
- B) Most patients improve with placebo treatment
- C) Most patients will go on to develop ulcers
- D) Spontaneous resolution of symptoms is rare

Answer 7.3.4 The correct answer is “B.” Up to 60% of patients in placebo-controlled trials respond to placebo, making it difficult to prove the efficacy of medications. As the above number suggests, spontaneous resolution of symptoms is common,

while many patients will have a chronic, intermittent course characterized by symptom-free periods. Most patients will not develop serious pathology.

HELPFUL TIP:

For functional dyspepsia, general management principles call for reassurance by the physician and the avoidance of repeated diagnostic testing. Patients should make appropriate life style modifications (avoid tobacco, caffeine products, and alcohol) and limit or avoid aggravating medications (NSAIDs). Patients should chew their foods slowly and eat more frequent, smaller meals. Finally, if there is underlying psychiatric morbidity, relaxation training, or treatment of specific diseases can be helpful.

Back to our 48-year-old. *H. pylori* testing is negative. You continue to avoid invasive testing and start the patient on a PPI with modest benefit. One week later, your nurse receives a call from your patient about abdominal cramping and diarrhea. She has not noticed blood in her stool.

Question 7.3.5 What is the best next step?

- A) She is having withdrawal from the five Giant Gulp sodas. Add back the fructose and the 2,000 kcal
- B) Check fasting gastrin level
- C) Add antibiotic therapy for bacterial overgrowth
- D) Discontinue the PPI
- E) Add an antidiarrheal

Answer 7.3.5 The correct answer is “D.” Diarrhea, including from *Clostridium difficile*, is a common adverse effect of PPIs that occurs in at least 5% to 7% of patients. Discontinuation of the PPI generally leads to a rapid resolution in the majority of cases (although maybe not in *C. difficile*-related diarrhea). While reduced stomach acidity from PPIs or H_2 blockers may result in bacterial colonization of the proximal GI tract, the early onset and severity of symptoms described argue against bacterial overgrowth as the etiology of this patient’s symptoms (“C”). While PPIs can elevate gastrin levels, the hypergastrinemia seen is not comparable to levels seen in Zollinger–Ellison syndrome, which can also cause diarrhea. Stool studies and empiric therapy with antidiarrheals may be considered if discontinuing the PPI does not improve symptoms.

HELPFUL TIP:

For dyspepsia, prokinetic agents may be helpful, and in the United States this means metoclopramide or erythromycin. Cisapride (Propulsid) has been removed from the market secondary to cardiac arrhythmias (QT prolongation with torsades de pointes). Metoclopramide (Reglan), of course, is associated with tardive dyskinesia and extrapyramidal reactions. Erythromycin causes GI side effects and QT prolongation.

HELPFUL TIP:

PPIs are not benign drugs and have been associated with (1) increased risk of osteoporosis and hip fracture in the elderly, (2) increased risk of pneumonia, (3) increased risk of *C. difficile* colitis, (4) interference with vitamin and mineral absorption (B vitamins, iron, calcium), and (5) diarrhea as noted previously. Initially, data suggested that PPIs were associated with dementia. This association has not held up (*J Am Geriatr Soc.* 2018 Feb;66(2): 247–253, etc.) and the association with pneumonia has been questioned (*BMJ.* 2016 Nov 15;355:i5813). Nonetheless, stop PPIs after the treatment is completed (if you can . . . GERD is a chronic disease and stopping a PPI is associated with rebound acid secretion) and aim for the lowest effective dose.

► Objectives: Did you learn to ...

- Diagnose and manage nonulcer dyspepsia?
- Appreciate the natural history of nonulcer dyspepsia?
- Recognize important side effects of PPIs?

► CASE 7.4

A 56-year-old woman comes to the emergency department after a sudden episode of hematemesis. Yesterday, she had two bowel movements that were dark, sticky, and foul-smelling. She woke up nauseated and has since twice vomited a small amount of bright red blood. She also feels dizzy. Because of knee pain related to skydiving 1 week ago, she started taking five tablets of naproxen (1,100 mg) twice daily. She takes no other medicines and denies any significant past medical history.

On physical examination, you find a pale, uncomfortable, but alert patient. She is tachycardic (pulse of 115 bpm) and has a blood pressure drop from 116/72 mm Hg supine to 93/65 mm Hg standing. Her abdomen is flat with hyperactive bowel sounds. You note epigastric tenderness but no rebound or guarding. There is melena on rectal examination.

Question 7.4.1 Which of the following steps will be LEAST helpful at this point in time?

- A) Admission to the hospital
- B) Immediate treatment with an intravenous (IV) H_2 blocker
- C) Referral for emergent endoscopy
- D) IV access and fluid resuscitation
- E) Laboratory tests including hemoglobin, coagulation studies, and blood type and cross-match

Answer 7.4.1 The correct answer is “B.” The patient has symptoms and clinical findings of a hemodynamically significant upper GI tract bleed. Although she is “walking and talking” just fine, fluid administration and hospital admission with close monitoring in an intensive care environment are indicated. A baseline hemoglobin and hematocrit should be obtained. However, a normal hemoglobin concentration does not

exclude a significant acute bleed, as hemodilution (in the absence of IV fluids) requires several hours. Two large-bore IVs should be placed. Given the presentation, a blood transfusion may become necessary in the future; therefore, blood should be sent for type and cross-match. Early endoscopy (ideally within 24 hours) should be performed to identify the cause of her bleeding, and endoscopic therapy should be undertaken if appropriate. Treatment with H₂ blockers does not affect the rate of bleeding; however, IV PPI therapy **does** decrease the risk of rebleeding in high-risk patients by increasing gastric pH to enhance coagulation. **PPI therapy and endoscopy are standard of care for upper GI bleeding.**

**HELPFUL TIP:**

Orthostatic vital signs are not that useful in determining a patient's volume status. Many hypovolemic patients are **not** orthostatic and many patients who are euvoletic **have** orthostatic changes (e.g., patients on antihypertensives and the elderly). So, use orthostatic vital signs to confirm your clinical suspicion, but do not use them as an absolute guide to the patient's volume status (*JAMA*. 1999;281:1022–1029).

**HELPFUL TIP:**

Nasogastric aspirate may be heme (e.g., Gastrocult®) negative in up to 72% of upper GI bleeds. A positive test is confirmatory, but a negative test is fairly meaningless. NG tubes are not routinely recommended.

Question 7.4.2 What is the risk of suffering a clinically significant GI event on NSAIDs?

- A) Up to 4% per year
- B) Up to 10% per year
- C) Up to 25% per year
- D) Up to 50% per year
- E) Nearly 99% per year

Answer 7.4.2 The correct answer is “A.” The risk of a clinically significant NSAID-related GI event, including GI bleeding, perforation, or obstruction, is about 1% to 4% per year.

The patient undergoes endoscopy, which shows a small duodenal ulcer in the bulb with a visible vessel in the ulcer base. Biopsies show chemical gastropathy and no evidence of *H. pylori*. After endoscopic treatment, the patient recovers nicely. Then, 3 months later, she returns to your office for a follow-up evaluation. She is asymptomatic and continues taking a PPI. Her physical examination is normal. Laboratory tests show normal hemoglobin.

Question 7.4.3 What is the best next step?

- A) Repeat endoscopy to document healing and rule out malignancy
- B) Perform upper GI x-ray series to document healing

- C) Switch to a H₂ blocker
- D) Discontinue acid-suppressive medication
- E) Obtain serum *H. pylori* antibody test

Answer 7.4.3 The correct answer is “D.” While nonhealing ulcers may be due to a neoplasm, the vast majority of **duodenal** ulcers are benign. Therefore, neither endoscopic nor radiologic documentation of healing is necessary. See Table 7-2 for more on risk factors for malignancy in gastric ulcers. “C” is incorrect. Patients with uncomplicated and small (<1 cm) duodenal or gastric ulcers who have received adequate treatment of *H. pylori* or NSAID-induced ulcer do not need long-term therapy directed at ulcer healing as long as they are asymptomatic following therapy. Antisecretory drugs can be discontinued after 4 to 6 weeks in these patients. “E” is incorrect. Serology for *H. pylori* will not be helpful in this patient. First, histology is as sensitive as other tests for *H. pylori* infection and the patient's biopsies were negative for *H. pylori*. Second, **serologic testing does not tell us if the patient is currently infected**, as many patients maintain antibody positivity even a year after treatment.

**HELPFUL TIP:**

Sensitivity of serologic testing for *H. pylori* is 90% to 100%. But this does not indicate current infection and may reflect prior infection. Breath testing is 88% to 95% sensitive with most false negatives the result of the use of antibiotics and antacids, including H₂ blockers and PPIs. Thus, make sure that the patient has been off antibiotics for at least a month prior to testing and has not taken acid suppressors for 2 weeks prior to testing. This also holds true for CLO testing. Stool antigen testing (94% sensitive, 92% specific) is also available to help with the noninvasive documentation of *H. pylori* infection or eradication. False-negative stool antigen assays may be due to recent (within 2 weeks) use of antibiotics or antacids.

Question 7.4.4 If your patient had come back *H. pylori* positive, which of the following combinations IS NOT indicated in the treatment of *H. pylori*?

- A) Omeprazole, clarithromycin, metronidazole
- B) Cephalexin, omeprazole, amoxicillin

TABLE 7-2 RISK FACTORS FOR MALIGNANCY IN GASTRIC ULCERS

- Occurrence in ethnic groups raised in endemic areas (Asians, Latinos, etc.)
- *Helicobacter pylori* infection
- Absence of recent NSAID use
- Absence of concomitant duodenal ulcer or a prior history of duodenal ulcer (duodenal ulcers require higher acid secretion, which is incompatible with the pancreatitis typical of most gastric cancers)
- Giant ulcers (>2–3 cm)
- Absence of a protracted ulcer history—in general, the longer the ulcer history, the lower the risk that a gastric ulcer is cancer. Gastric ulcers require acid and gastric cancer usually develops in the setting of atrophic pancreatitis

- C) Metronidazole, amoxicillin, omeprazole
- D) Bismuth subsalicylate, metronidazole, tetracycline, lansoprazole
- E) Omeprazole, clarithromycin, amoxicillin

Answer 7.4.4 The correct answer (and the regimen you would not want to use) is “B.” All of the other regimens can be used to treat *H. pylori* infection. Of note are regimens “A” and “D.” There is resistance to metronidazole, so it should only be used when the patient is penicillin allergic or taking quadruple therapy. Triple therapy with PPI should be used where clarithromycin resistance is low. Quadruple therapy should be used in patients with recent or repeated exposure to clarithromycin or metronidazole or areas with high clarithromycin resistance (>15%).

Question 7.4.5 Which of the following IS NOT useful for testing for *H. pylori* eradication after treatment?

- A) Serum IgG antibody titers
- B) CLO test
- C) Breath urea test
- D) Radioactive CO₂ blood test
- E) Stool antigen test

Answer 7.4.5 The correct answer is “A.” Remember the helpful tip mentioned previously? Only 57% of patients are antibody negative to *H. pylori* a year after successful treatment. Thus, antibody titers cannot document eradication. All of the other tests mentioned are functional tests for the presence of *H. pylori*. The CLO test is done on biopsy specimens and documents the presence of urea splitting. The same is true for the breath urea test and the radioactive CO₂ blood test. In both of these tests, urea is ingested. If *H. pylori* is present, radioactive CO₂ is generated that can be measured in the blood or breath. Confirmation of eradication should be considered for all patients receiving *H. pylori* treatment 1 month after treatment and at least 1 to 2 weeks off of PPI, but definitely should be performed in the following: (1) patients with persistent symptoms of dyspepsia despite *H. pylori* treatment; (2) patients with *H. pylori* associated ulcer; (3) patients with gastric mucosa-associated lymphoid tissue-type lymphoma; (4) patients who had resection for early gastric cancer (*N Engl J Med.* 2010;362:1597–1604).

HELPFUL TIP:

NSAID-induced ulcers can occur in the stomach, duodenum, and occasionally in the small bowel and colon. However, NSAIDs are more frequently found to be the cause of gastric ulcers (up to 30%) than the cause of duodenal ulcers (up to 20%). Remember that NSAIDS (except for aspirin) can precipitate acute coronary syndrome.

► Objectives: Did you learn to ...

- Appreciate the role of NSAID use in peptic ulcer disease (PUD)?
- Manage an acute GI bleed?

- Identify patients at high risk for gastric malignancy?
- Diagnose and treat *H. pylori*?

QUICK QUIZ: PILL PROBLEMS

Which of these medications would be the LEAST likely cause of esophagitis if caught in the esophagus?

- A) Potassium chloride
- B) Ferrous sulfate
- C) Alendronate
- D) Loratadine
- E) Tetracycline

The correct answer is “D.” Many medications can cause “pill esophagitis,” including potassium chloride, ferrous sulfate, alendronate, tetracycline antibiotics, and ascorbic acid. Aspirin and other NSAIDs can also cause esophagitis. Smaller pills are less likely to cause problems. In addition to not being irritating, loratadine is tiny.

QUICK QUIZ: THE CASE OF THE HOLY STOMACH

One of your patients presents complaining of diarrhea and epigastric pain unresponsive to H₂ blockers or PPIs. He denies smoking tobacco, taking NSAIDs, or drinking alcohol. Endoscopy reveals several ulcers. Biopsy for *H. pylori* is negative and there is no malignancy.

Which of the following would be the most appropriate laboratory test to obtain in order to discover an etiology for the *multiple* ulcers (and diarrhea)?

- A) Vasoactive intestinal peptide (VIP)
- B) Gastrin
- C) Glucagon
- D) Somatostatin

The correct answer is “B.” Some sort of screening test for gastrinoma is warranted in a patient who has recurrent or refractory ulcers and who is *H. pylori* negative and does not use NSAIDs. Zollinger–Ellison syndrome is the name given to the state in which there is acid hypersecretion secondary to increased gastrin production, usually from a gastrin-producing tumor (gastrinoma). Up to 1% of patients with PUD have a gastrinoma. Serum gastrin levels should be obtained with the patient fasting and off PPIs, as PPIs will increase gastrin levels. If the serum gastrin is elevated (>10 times upper normal limit), further investigations will need to be performed. Other reasons to consider obtaining a serum gastrin level include ulcers in unusual locations (distal duodenal and jejunum), family history of ulcers, and ulcers associated with severe esophagitis. “A” is incorrect. VIP actually works to suppress acid secretion. VIPomas do occur, but VIPomas are associated with watery diarrhea and hypokalemia—not ulcers. “C,” glucagon, will not be of much help here. Glucagon over secretion results in hyperglycemia and

anemia. “D,” somatostatin, is a hormone that inhibits the secretion of gastrin and thus would be protective vis-à-vis ulcers. Somatostatin secreting tumors are very rare.

QUICK QUIZ: GI BLEEDING

Isolated bright red hematemesis (e.g., no tachycardia and no fever), which occurs after several bouts of vomiting or dry heaves, is referred to as:

- A) Boerhaave syndrome
- B) Mallory–Weiss tear
- C) Cameron lesion
- D) None of the above

The correct answer is “B.” A Mallory–Weiss tear occurs after repeated trauma to the lower esophageal and gastric mucosa from forceful retching. This can be differentiated from a Boerhaave tear by the (generally) self-limited nature of the bleeding and the absence of other symptoms. Boerhaave syndrome (“A”) is a perforation of the esophagus resulting from a sudden increase in intraesophageal pressure, caused by vomiting, retching, less frequently by coughing, childbirth, or weight lifting. It occurs higher in the esophagus and is associated with mediastinitis, fever, shock, and death if intervention is not forthcoming. Cameron lesions (“C”) are small ulcers in patients with a hiatal hernia, are usually an incidental finding, and are likely caused by rubbing of the stomach against the diaphragm as the hernia slides. They can bleed, but the history given above is classic for a Mallory–Weiss tear.

QUICK QUIZ: ABDOMINAL PAIN

A 35-year-old female presents to your clinic complaining of onset of severe mid-epigastric pain, weight loss, and vomiting following meals. Between meals she is asymptomatic. This has been going on for the past 2 years ever since she purposefully lost 25 lb to attain a healthy weight for her height. Unfortunately, she has continued to lose weight because of the postprandial pain and vomiting. On her examination you notice a mid-epigastric bruit.

The most likely diagnosis is:

- A) Aortic aneurysm
- B) Atherosclerotic disease of the celiac trunk
- C) Superior mesenteric artery (SMA) syndrome
- D) Chronic pancreatitis
- E) None of the above

The correct answer is “C.” This is a typical history and physical examination for SMA syndrome. SMA syndrome is more likely to occur in a patient who has lost significant weight, resulting in thinning of the mesenteric fat pad. Here’s the pathophysiology: the SMA runs above the duodenum and becomes stretched and partially occluded in response to meals (as the stomach and duodenum expand), leading to mesenteric ischemia and

food aversion; the fat pad is protective. SMA syndrome can be diagnosed using Doppler ultrasound to demonstrate increased velocity of blood in the SMA or by a CT-angiogram. “A” and “B” are unlikely in a young patient, and “D” should not be associated with a bruit. Celiac artery syndrome may have a similar presentation to SMA syndrome but, obviously, involves the celiac trunk.

CASE 7.5

A 54-year-old man comes to your office for his annual physical. He is taking naproxen for a recent ankle injury. Based on your recommendation last year, he started taking one aspirin (81 mg) daily. He does not take any other medications. He exercises regularly, does not smoke, and drinks one glass of wine every day. Your examination is completely normal, except that a test for occult fecal blood is positive.

Question 7.5.1 What is the next best step?

- A) Upper endoscopy
- B) CBC
- C) Colonoscopy
- D) A and B
- E) B and C

Answer 7.5.1 The correct answer is “E.” This patient has heme positive stools and needs a colonoscopy. See below for details of colon cancer screening. Since the patient currently has no symptoms referable to upper GI pathology, evaluation of the upper GI tract should only be considered if the colonoscopy is negative.

HELPFUL TIP:

Iron supplements may cause stool to darken but they DO NOT cause false-positive guaiac tests. Guaiac tests rely on the presence of hemoglobin in the stool, not iron. Don’t blame a positive guaiac on an iron supplement.

Question 7.5.2 Regarding colon cancer, what is the most likely type of cancer you will find?

- A) Squamous cell carcinoma
- B) Adenocarcinoma
- C) Clear cell carcinoma
- D) Lymphoma

Answer 7.5.2 The correct answer is “B.” Adenocarcinoma represents the overwhelming majority of colon cancers. Other histologic types of colon cancer include adenosquamous, poorly differentiated cancers with neuroendocrine aspects, small cell carcinomas (of neuroendocrine origin), and others.

Your patient asks the perennial question that theologians are usually better qualified to answer: “Why me?” In this case, however, we can provide some insight.

Question 7.5.3 Which of the following is NOT considered a risk factor for colon cancer?

- A) Familial polyposis
- B) Alcohol use
- C) Obesity
- D) Inflammatory bowel disease
- E) Chronic constipation

Answer 7.5.3 The correct answer is “E.” Chronic constipation is not a risk factor for colon cancer. Aside from those listed above, risk factors include: acromegaly, diabetes mellitus, African-American race, immunosuppression, and tobacco use, among others. African Americans have the highest risk for colon cancer of any ethnic group, as well as a higher mortality (20% higher compared to white Americans). Screening for colon cancer in African Americans should begin at age 45 (see the following).

Review of his records shows that he underwent a colonoscopy 3 years ago. Three small adenomatous polyps were found. He also had scattered diverticula in the sigmoid.

Question 7.5.4 Based on this new information, which strategy do you now recommend?

- A) Colonoscopy now
- B) Colonoscopy in 5 years
- C) Yearly tests for fecal occult blood
- D) Yearly tests for fecal occult blood and colonoscopy in 7 years
- E) Colonoscopy in 7 years

Answer 7.5.4 The correct answer is “A.” Adenomatous polyps are considered precancerous. Recommended follow-up of an adenomatous polyp is by colonoscopy every 3 to 5 years. So, he did not truly have a “negative” colonoscopy 3 years ago. Plus, we are not doing the colonoscopy in this case for screening purposes; it is diagnostic. We may find another source of his bleeding. If his previous colonoscopy was completely normal (no adenomatous polyps), you could argue for stopping the aspirin and NSAIDs and following up with serial fecal occult blood tests (FOBTs). In this alternative scenario, persistently positive tests for occult blood would lead to colonoscopy as well.

HELPFUL TIP:

Adenomatous colon polyps, either pedunculated or sessile, are associated with transformation to cancer. Hyperplastic polyps are considered benign.

HELPFUL TIP:

US Preventive Services Task Force recommends routine screening for colorectal cancer, starting at the age of 50 to 75 years for average-risk patients (earlier in high-risk patients—positive family history, known adenomatous polyps, etc.). Any of the following modalities is

acceptable. The USPSTF does not favor one screening method above others:

- 1) **Annual FOBT alone** (fecal immunochemical test [FIT] or high sensitivity guaiac [e.g., SENSEA] ... other guaiac tests are less sensitive). **Fecal immunochemical test (FIT)** detects human hemoglobin by immunologic means and is more sensitive and specific than guaiac. It also circumvents many of the weaknesses of the old guaiac test (e.g., false positive with rare meat), but will still give a false positive secondary to bleeding from NSAIDs
- 2) **FOBT every 3 years with sigmoidoscopy every 5 years**
- 3) **Colonoscopy every 10 years (without annual FOBT)**
- 4) **FIT + DNA** is more sensitive but less specific than FIT alone
- 5) **Other options** include fecal DNA testing (Cologuard), computed tomography colonography

In general, the FIT and guaiac-based FOBT have lower sensitivity for proximal neoplasm. Also, FIT does not detect serrated polyps that are the progenitors of 20% to 30% of malignancies. Between the ages of 75 and 85 years, *routine screening* is not recommended but select patients should be counseled on screening. After the age of 85, no screening should be done.

HELPFUL TIP:

US Multi-Society Task Force on Colon Cancer (includes the American College of Gastroenterology, the American Gastroenterological Association, and The American Society for Gastrointestinal Endoscopy) published recommendations in 2017 to start screening African Americans of average risk at age 45. First-tier options include annual fecal immunochemical testing or colonoscopy every 10 years. Second-tier screening options include CT colonography every 5 years, FIT testing every 3 years, or flexible sigmoidoscopy every 10 years. Third-tier option was capsule colonoscopy every 5 years. Guaiac-based FOBT was dropped from their screening recommendations.

You refer the patient for a colonoscopy. The report from the endoscopist shows one small tubular adenomatous polyp in the sigmoid colon that was completely removed. The patient wants to know when he needs another colonoscopy.

Question 7.5.5 Your answer is:

- A) In 3 months
- B) In 1 year
- C) In 5 years
- D) In 10 years
- E) Any of the above is an equally valid recommendation

Answer 7.5.5 The correct answer is “C.” The current surveillance guidelines recommend the following intervals for screening:

1. No polyps or only rectal hyperplastic polyps, repeat in 10 years.
2. One to two tubular adenomas less than 1 cm in size with only low-grade dysplasia should have repeat colonoscopy in 5 years.
3. Three to ten tubular adenomas, or villous features or high-grade dysplasia should have surveillance in 3 years.
4. Patients with >10 adenomas should be screened more frequently, and familial colon cancer syndromes should be considered.
5. If a large sessile polyp is removed in piecemeal fashion, then a repeat examination in 3 months is appropriate to assure complete removal.
6. If the prep is not good, repeat colonoscopy at earliest convenience is indicated.

Whoops, the pathologist calls back and it turns out your patient has a colon cancer. He is justifiably worried about the possibility of colon cancer in his offspring. Unfortunately, none of his kids exercise (which reduces colon cancer risk) and they are avowed carnivores, eschewing fruit, vegetables, and anything with fiber (which may reduce colon cancer risk, although the data is conflicting).

Question 7.5.6 Which of the following has been shown to reduce cancer risk and takes so little effort that even your patient’s slothful offspring may partake?

- A) Metformin
- B) Aspirin
- C) Antioxidants
- D) Vitamin B6 but no other antioxidants
- E) B and C

Answer 7.5.6 The correct answer is “B.” Aspirin does have a slight protective effect on colon cancer (USPSTF found 40% relative risk reduction in incident colon cancer with aspirin use) but not heart disease. Unfortunately, the rest of the answers are incorrect and none have been found to reduce the risk of colon cancer.

Question 7.5.7 Patients presenting with hereditary non-polyposis colorectal cancer (HNPCC), or “Lynch syndrome,” are more likely than patients with sporadic colon cancer to have which of the following findings?

- A) Left-sided colon cancers
- B) Late age onset of colon cancer
- C) Multiple colon cancers diagnosed simultaneously
- D) An unusual desire to visit Lynchburg, Tennessee, and a dedication to all things Jack Daniels

Answer 7.5.7 The correct answer is “C.” Patients with HNPCC (Lynch syndrome) are at increased risk of developing colon cancer. About 5% of colon cancers occur in patients with Lynch syndrome. Transformation from an adenoma to cancer is faster in patients with Lynch syndrome. In addition, many of the neoplasms are located in the right colon, so “A” is incorrect.

Compared to sporadic colon cancer patients, those with Lynch syndrome are younger at the time of diagnosis, more frequently present with multiple colon tumors, and are more likely to have extracolonic tumors—especially endometrial cancer. This is a genetic disorder, and the occurrence of colorectal and/or endometrial cancer in three relatives before the age of 50 should suggest HNPCC. The current recommendation is to perform surveillance colonoscopies at least every 3 years in these patients.

It is time to stage your patient’s cancer. The Duke’s classification system is no longer used for colon cancer and has been replaced with the more standardized TMN system.

Question 7.5.8 Which of the following is the most common first site of metastasis of colon cancer?

- A) Lungs
- B) Liver
- C) Bone
- D) Brain

Answer 7.5.8 The correct answer is “B.” The liver is the most common first site of colon cancer metastases, which arrive via the portal system. Colon cancer can also metastasize to the lungs, bone, lymph nodes, and brain (uncommon). Intraperitoneal spread may also occur.

Your patient wonders if blood tests can predict his death (and the direction of the stock market ... and if the Cubs will ever again win the world series).

Question 7.5.9 While tumor markers for colon cancer are not used in staging disease, the presence of which of these markers suggests a poor prognosis if it remains elevated after surgical resection of the tumor?

- A) Carcinoembryonic antigen (CEA)
- B) β -hCG
- C) CA-125
- D) Vasoactive intestinal peptide (VIP)
- E) α -Fetoprotein (AFP)

Answer 7.5.9 The correct answer is “A.” The presence of CEA after resection of a colon cancer is a poor prognostic factor. This should be obvious: there is still tumor present. β -hCG is elevated in some testicular cancers. CA-125 is a marker for ovarian cancer (although it is also expressed by colon cancer cells and is *not* to be used as a screening test for ovarian cancer). VIP is either the patient who everyone swarms over and nobody can please or vasoactive intestinal peptide, which is found with some pancreatic adenocarcinomas and carcinoid tumors. AFP is elevated in germ-cell tumors, such as testicular and ovarian cancer, and liver cancer.

HELPFUL TIP:

Flushing? Diarrhea? Elevated heart rate? While 5-HIAA sounds like an acronym for some new government initiative, it is a marker of carcinoid tumor activity.

John undergoes surgery and ends up with a total colectomy and ileostomy.

Question 7.5.10 Which of the following is NOT true of ileostomy care?

- A) Fluid output tends to be relatively high with an ileostomy requiring increased fluid intake to prevent dehydration
- B) Since the diameter of the ileostomy is limited, avoiding large amounts of nondigestible fiber helps to prevent bezoar formation
- C) Extended-release drugs are usually well absorbed
- D) Proteolytic enzymes are present in the effluent and may lead to skin breakdown

Answer 7.5.10 The correct answer is “C.” Extended-release medications should be used with caution. Many extended-release medications are absorbed through the entire length of the bowel. Have your patient notify you if they are finding undigested pills in their ostomy bag. All of the rest are correct.

HELPFUL TIP:

Loperamide can be used to reduce output in short bowel syndrome (including in those with an ostomy) as long as bacterial overgrowth is not an issue.

Your patient does well and has a happy and long life, although his children remain slugs and he supports them well into their forties.

► **Objectives: Did you learn to ...**

- Describe the limitations of FOBT?
- Choose the appropriate tests and screening and surveillance intervals for colorectal neoplasia?
- Learn how family and personal history of colorectal neoplasia affects screening and surveillance strategy?

► **CASE 7.6**

A 28-year-old graduate student comes to your office complaining of diarrhea. About 6 months ago, she noted a sudden onset of loose stools. While she initially attributed these symptoms to “stomach flu,” her problem has persisted. She currently has about four to six loose bowel movements per day with nighttime defecations. She has not seen blood in her stool. In addition, she complains of cramps located in the left and occasionally right lower abdomen. The cramps are made worse with food intake and often are associated with a need to defecate. She has lost about 8 kg unintentionally within the last 3 to 4 months. She denies any travel or antibiotic use. On physical examination, you notice some tenderness in the right lower quadrant. You see a painless anal fissure in the anterior commissure, and by the appearance, you judge that the fissure is probably chronic in nature.

Question 7.6.1 What do you recommend as the next step in the evaluation and management of this patient?

- A) Trial of loperamide on a scheduled basis
- B) Referral to a holistic clinic for a coffee colonic cleansing regimen (using fair trade, shade grown organic coffee only, of course)
- C) Titers for atypical antineutrophil cytoplasmic antibodies (ANCA)
- D) Colonoscopy
- E) Botulinum toxin injection into the area of the anal fissure

Answer 7.6.1 The correct answer is “D.” The patient’s history and physical findings with a painless, anteriorly located anal fissure and diarrhea are consistent with Crohn disease. The best next step in her evaluation is colonoscopy with inspection of the terminal ileum. You may want to do some stool testing before colonoscopy. Testing for *Giardia*, *C. difficile* toxin, and other pathogens is appropriate. CRP can be helpful to track response to therapy if elevated but is normal in 40% of patients with active flare so cannot be used to “rule out” Crohn disease. But of the choices presented, colonoscopy is the best option. “A” is inappropriate since this is longstanding with weight loss; symptomatic control is fine, but we need to figure out what is going on with this patient. “B” is incorrect, coffee is better PO. “C,” serologic testing, is a reasonable choice but not ANCA, and here’s why: Crohn disease is associated with antibodies against saccharomyces (ASCA), while ulcerative colitis (UC) patients are more often positive for ANCA. However, the sensitivity of these tests is only about 60%. Moreover, there is about a 20% overlap (e.g., ANCA positive in Crohn disease), raising further questions about the overall usefulness of these tests. ASCA can also be positive in celiac disease. “E” is also incorrect. Fissures are one of the anal manifestations of Crohn disease and should be approached by treating the underlying disease rather than using surgical techniques, botulinum injection, etc. Botulinum injections, nitroglycerin ointment, and nifedipine have all been used for anal fissures with success, but we need to diagnose this patient and address the underlying disease. Botulinum injections also get rid of those embarrassing anal wrinkles.

HELPFUL TIP:

Fecal calprotectin levels are helpful in distinguishing irritable bowel syndrome (IBS) from inflammatory bowel disease (IBD) in adults. Calprotectin is produced by granulocytes, and its presence in the stool indicates active inflammation and suggests IBD. Sensitivity 93% and specificity 96% (*BMJ*. 2010;341:c3369). Despite being markers of white cells, neither fecal leukocytes nor fecal lactoferrin are helpful.

HELPFUL TIP:

In Crohn disease, about 25% of patients have disease confined to the colon. Another 40% have disease in the ileum and cecum, and 30% have disease confined to the small bowel. The remainder have more diffuse disease and/or disease in the proximal GI tract.

Question 7.6.2 Which of the following is true regarding the pathophysiology and natural history of Crohn disease?

- A) Crohn disease is a genetic disorder, transmitted in an autosomal-dominant fashion
- B) Crohn disease is a relapsing/remitting disease, and 30% of patients will improve spontaneously
- C) Patients with Crohn disease rarely progress to disease requiring surgery
- D) Maintenance therapy with glucocorticoids will reduce the rate of recurrence of Crohn disease
- E) GI fistulae and abscesses are rare complications of Crohn disease

Answer 7.6.2 The correct answer is “B.” Crohn disease and UC are both relapsing/remitting diseases. Up to 30% of initial exacerbations of Crohn disease will remit without any intervention. While there is a genetic component to inflammatory bowel disease (up to a 100-fold increase in risk among first-degree relatives with IBD), no single, autosomal-dominant gene has been identified. “C” is incorrect because half or more of patients with Crohn disease will ultimately require some sort of surgery. “D” is incorrect. Unfortunately, chronic glucocorticoid administration does not lower the rate of relapse. There are many complications of IBD (see next question), and GI abscesses and fistulae occur with a relatively high frequency (20–40%) in Crohn disease.

**HELPFUL TIP:**

Although considered a disease of young adults, there is a bimodal distribution of IBD with a second peak in older adults in their seventies.

Question 7.6.3 Extraintestinal features of IBD include all of the following EXCEPT:

- A) Alopecia
- B) Arthritis
- C) Sclerosing cholangitis
- D) Uveitis
- E) Cholelithiasis

Answer 7.6.3 The correct answer is “A.” Alopecia is not an extraintestinal manifestation of IBD. Arthritis (“B”) related to IBD (enteropathic arthritis) is fairly common and usually migratory in nature, involving the large joints. Spondyloarthropathy may also be seen. Sclerosing cholangitis (“C”) and autoimmune hepatitis can occur and may be fatal. Eye disease may include uveitis (“D”) and episcleritis. Importantly, the main treatment of extraintestinal manifestations is to treat the IBD. IBD spondyloarthropathy and pyoderma gangrenosum are important exceptions, as these do not always improve with the treatment of the underlying IBD.

**HELPFUL TIP:**

Toxic megacolon is a potentially deadly complication of IBD that should be suspected in a patient with IBD who presents with fever, abdominal pain, and shock. Even in

nontoxic patients a transverse colon diameter >5.5 cm or sigmoid colon diameter >10 cm should prompt evaluation for obstruction or impending disaster.

Returning to your patient, you next see her in the emergency department, where she presents with fever, abdominal pain, and bloody diarrhea. She is tachycardic and slightly hypotensive but alert and oriented. You suspect a relapse of her Crohn disease.

Question 7.6.4 All of the following are important aspects of her management at this time EXCEPT:

- A) Surgical consultation
- B) IV access and fluid administration
- C) Glucocorticoids
- D) NSAIDs
- E) Metronidazole and ciprofloxacin

Answer 7.6.4 The correct answer is “D.” What’s in a name? NSAIDs are contraindicated and in spite of being “anti-inflammatory” can actually exacerbate IBD. Acetaminophen or narcotics can be used for pain control if necessary. The patient should be stabilized, and this includes IV access and fluid resuscitation. An exacerbation (or relapse) of IBD can be treated with glucocorticoids in the acute setting. Metronidazole and ciprofloxacin are no longer used to induce remission of Crohn disease and occupy a niche role in preventing recurrence after bowel resection. However, antibiotics are often used in unstable patients. In this patient, who may have an abscess or obstruction, antibiotics and further evaluation (e.g., labs and abdominal CT) and surgical consultation are necessary. Finally, thalidomide has been used for Crohn disease but is not standard of care.

Question 7.6.5 Which of the following is indicated in the long-term treatment of Crohn disease?

- A) Azathioprine
- B) Methotrexate
- C) 5-ASA moieties
- D) Loperamide
- E) All of the above

Answer 7.6.5 The correct answer is “E.” All the options are indicated for the treatment of IBD. Systemic steroids (e.g., prednisone) are useful acutely to induce remission but should be tapered and stopped as soon as possible. Use of steroids for greater than 4 months is discouraged.

Methotrexate and thiopurines (azathioprine, 6-mercaptopurine) are mainstays of oral therapy. Advanced therapy options continue to grow and include TNF inhibitors (e.g., infliximab [Remicade], Etanercept [Enbrel], Adalimumab [Humira]), interleukin 12 and 23 inhibitors (e.g., ustekinumab [Stelara]), alpha-4 integrin binders (e.g., natalizumab [Tysabri] and vedolizumab [Entyvio]), and Janus kinase inhibitors. Mesalamine is a mainstay of ulcerative colitis treatment, but is not used to treat active Crohn disease. Antidiarrheal drugs such as loperamide are useful to control symptoms. However, be sure to avoid

antidiarrheal drugs in patients who may have impending toxic megacolon. Probiotics and lactose avoidance may also be useful (although there is less evidence for these).

HELPFUL TIP:

Test for thiopurine methyltransferase (TPMT) enzyme prior to starting thiopurines. Around 10% of the population is deficient and are at higher risk of toxicity with these medications.

After discussions with your patient about ongoing therapy at discharge, you find that cost is a major consideration for her. Therefore, you consider discharging her on sulfasalazine.

Question 7.6.6 Which of the following is an absolute contraindication to the use of sulfasalazine?

- A) Sulfa allergy
- B) Aspirin allergy
- C) Anemia
- D) A and B
- E) B and C

Answer 7.6.6 The correct answer is “D.” Sulfasalazine contains both sulfa and salicylate moieties and thus is contraindicated in patients with sulfa or aspirin allergy.

Question 7.6.7 Which of the following is LEAST likely to be a complication of anti-tumor necrosis factor (TNF)-alpha antibody therapy (e.g., infliximab [Remicade®]) for IBD?

- A) Sepsis
- B) Headache
- C) Abdominal pain
- D) Diarrhea
- E) Anemia

Answer 7.6.7 The correct answer is “E.” Anemia will generally improve with the treatment of IBD. Anemia in IBD is often due to a combination of iron deficiency and anemia of chronic disease, but IBD can cause an autoimmune hemolytic anemia as well. All of the rest are common complications of infliximab. Infection deserves special mention. Patients on anti-TNF drugs are more prone to sepsis. In fact, ongoing infection is an absolute contraindication to the use of anti-TNF drugs. Take any complaints attributable to infection (e.g., fever) very seriously in patients on anti-TNF drugs (not that you don’t take them seriously in all patients ... just more seriously in these). Tuberculosis and active hepatitis B are contraindications to the use of anti-TNF drugs and patients need to be screened for these before prescribing these drugs.

Question 7.6.8 All of the following characteristics differentiate ulcerative colitis (UC) from Crohn disease EXCEPT:

- A) The risk of colon cancer is greater in UC than in Crohn disease
- B) Histologically, UC appears as transmural disease, whereas Crohn disease involves only the mucosal and submucosal layers

- C) UC almost always involves the rectum, whereas Crohn disease may or may not
- D) In UC, the diseased segments are continuous, while “skip” areas of healthy bowel are seen in Crohn disease

Answer 7.6.8 The correct answer (and exception) is “B.” Histologically, UC involves only the mucosa and submucosal tissue, while Crohn disease is transmural. All of the other statements are true. UC involves the rectum in 95% of cases and advances proximally.

HELPFUL TIP:

Patients with long-standing UC with frequent relapses are candidates for colectomy.

HELPFUL TIP:

IBD increases the risk of colon cancer, so more frequent and earlier colonoscopies are recommended. Recommendations vary, but most expert guidelines recommend colonoscopy every 1 to 2 years in patients with UC after 8 years with disease. Screening parameters in those with Crohn disease are less well established.

HELPFUL TIP:

Sclerosing cholangitis is an inflammatory process that causes strictures of the intrahepatic and/or extrahepatic ducts. Biochemically, there is evidence of cholestasis manifested by an elevated alkaline phosphatase. This progresses to fibrosis, cirrhosis, and hepatic failure with a median survival of 10 years without a transplant. The rate of cholangiocarcinoma is also elevated in these patients. The diagnosis of sclerosing cholangitis is made by cholangiography, which demonstrates strictures and dilatation (beaded appearance) of intrahepatic and/or extrahepatic ducts. The majority of cases are related to inflammatory bowel disease, particularly UC.

► **Objectives: Did you learn to ...**

- Diagnose IBD?
- Differentiate Crohn disease from UC?
- Manage a patient with IBD?
- Recognize extraintestinal manifestations and complications of IBD?

► **CASE 7.7**

A 52-year-old woman complains of abdominal pain, bloating, and constipation. Her symptoms started about 5 years ago and became more bothersome within the last 6 months. She describes a dull pain in the left lower abdomen occurring 2 to 3 days a week. This pain is alleviated by passing gas or having a bowel movement, which she does with excessive

straining. The pain is generally related to eating, and she has had intermittent diarrhea and constipation, with constipation predominating. Two years ago, she underwent a screening colonoscopy, which was completely normal. Her review of systems is notable for a weight gain of about 5 lb within the last 3 years. She is taking only a multivitamin daily. Her physical examination is normal.

Question 7.7.1 Which is the best next step?

- A) Defecogram
- B) Barium enema
- C) Anorectal manometry
- D) TSH level
- E) Colonoscopy

Answer 7.7.1 The correct answer is “D.” The patient’s presentation with pain and constipation meets criteria for constipation-predominant IBS. Of note, irritable bowel is not an uncommon complication of GI infections including *E. coli*, *Campylobacter*, viral infections, and *Giardia* (*Gut*. 2010;59:605). There is also a relationship between anxiety and the presence of irritable bowel. This patient underwent colonoscopy for screening 2 years prior to presentation, so further evaluation for colon cancer (“B” and “E”) can be delayed unless there is another indication. Secondary causes of constipation, such as hypothyroidism, medication side effects, or hypercalcemia, should be ruled out. Therefore, a TSH level should be obtained prior to deciding on additional diagnostic or therapeutic steps. At this point in time, anorectal manometry (“C”) and defecogram (“A”) are

unnecessarily invasive procedures, and neither will help you to determine if this patient has IBS. New Rome IV criteria provide an algorithm (see Figure 7-2).

The patient is euthyroid. Hypercalcemia and other electrolyte abnormalities have been ruled out. Since she does not use medications other than the multivitamin, you decide to initiate the treatment of IBS. Based on available evidence, you suggest using fiber supplements such as psyllium.

Question 7.7.2 What do you tell your patient to expect?

- A) Complete resolution of her symptoms
- B) Increase in stool frequency and stool volume with less need for straining
- C) Not much. Fiber supplementation doesn’t work very well for IBS
- D) Decrease in abdominal pain and bloating
- E) Enlightenment and absolute bliss

Answer 7.7.2 The correct (and unfortunate) answer is “C.” Although it has been one of the mainstays of irritable bowel therapy, the efficacy of fiber for IBS has always been in question. A meta-analysis (*Am J Gastroenterol*. 2014;109(9):1367–1374) suggests an NNT of 7 with psyllium to benefit one patient. Perhaps surprisingly, there are only 14 randomized trials of only 906 patients. While bowel habits can be successfully changed with bulking agents for constipation or loperamide for diarrhea-predominant IBS, pain is generally not affected by

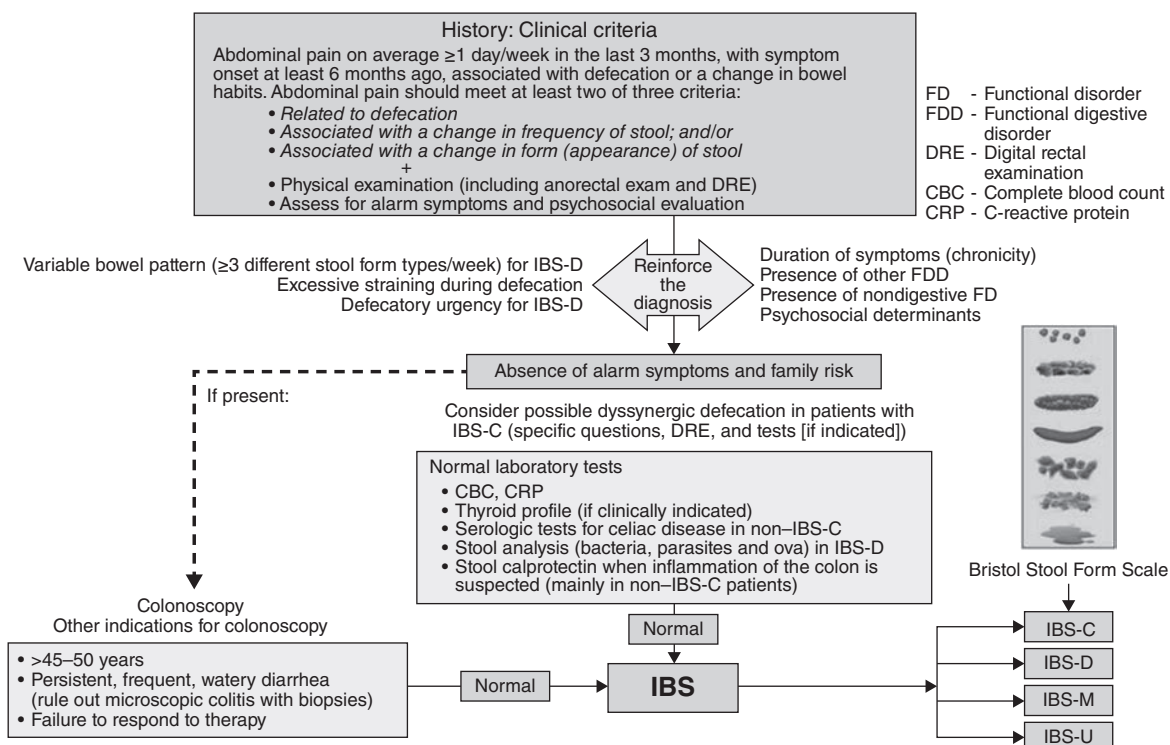

FIGURE 7-2. Rome IV algorithm for IBS. (Used with permission from Drossman DA, et al. *Rome IV: Functional Gastrointestinal Disorders for Primary Care and Non-GI Clinicians*. Raleigh, NC: The Rome Foundation; 2016.) Copyright © 2016 Rome Foundation, Inc. All rights reserved.

these measures. In fact, increased fiber intake may transiently worsen some symptoms due to fermentation and generation of gas, potentially resulting in flatulence or bloating. “E” requires special mention. Bliss and enlightenment can only occur with proper colon purging procedures provided at a very expensive resort!

Question 7.7.3 Which of the following has the best record in treating IBS?

- A) Eliminating FODMAPs from the diet
- B) Probiotics
- C) Rifaximin
- D) St. John’s wort
- E) Eliminating the use of GOOGLEMAPS

Answer 7.7.3 The correct answer is “A.” First, you need to know what FODMAPs are. FODMAP stands for “Fermentable, Oligo-, Di-, Monosaccharides, And Polyols” (say that five times fast). These are poorly absorbed carbohydrates that can cause fermentation and gas in the colon. Some FODMAPs include fructose, lactose, fructans (from wheat ... think this is why everyone believes they have gluten intolerance?), and others. Eliminating FODMAPs from the diet seems to have the best NNT of any of the irritable bowel treatments. Of the others, probiotics (“B”) have an NNT of 7 to 11 (*Am J Gastroenterol.* 2014;109:1547), rifaximin (“C”) (at \$1,200/month) has an NNT of 11 and a marginal benefit at best (*N Engl J Med.* 2011;364:22–32), and St. John’s wort (“D”) actually increases the symptoms of IBS and should be avoided. Use of GOOGLEMAPS (“E”) has not been shown to have any effect on IBS symptoms that we know of. Remember that a strong patient–physician relationship is key to treatment. Acknowledge the patient’s disease experience without ordering unnecessary testing or providing unnecessary medications.

HELPFUL TIP:

About 4% of children diagnosed with IBS who are referred to an academic GI clinic have celiac disease. The number will be less in the general patient population (*JAMA Pediatr.* 2014;168(6):514–515).

HELPFUL TIP:

IBS has a relatively good prognosis. Up to 60% of patients improve with placebo treatment in trials, making it hard to show benefit with any treatment. There is no increase in mortality with IBS, and symptoms usually improve over time.

HELPFUL TIP:

TCA, SSRIs, may be beneficial in IBS. Psychologic management including CBT can be helpful in managing symptoms.

► **Objectives: Did you learn to ...**

- Diagnose and manage IBS?
- Describe the role of FODMAPs in irritable bowel?
- Realize that both you and your patient will be frustrated with the treatments for IBS?

► **CASE 7.8**

A 32-year-old male complains about fatigue and episodic abdominal pain. His pain is located in the periumbilical region and the left lower quadrant. It is cramp-like in nature and is associated with flatulence and diarrhea. Passing gas alleviates his symptoms. He notes that milk and other dairy products worsen his symptoms. His weight has remained stable. His prior medical history, family and social history, and physical examination are unremarkable. Laboratory tests reveal hemoglobin of 11.5 g/dL and a normal glucose and TSH.

Question 7.8.1 What is the most appropriate next step in your evaluation?

- A) Lactose breath test
- B) Dietary trial of strict lactose avoidance
- C) Enteroclysis
- D) Colonoscopy
- E) Tissue transglutaminase antibody titer

Answer 7.8.1 The correct answer is “B.” The patient’s symptoms are consistent with lactose intolerance. He may have malabsorption secondary to lactose intolerance, which may be partially responsible for his anemia. If his symptoms resolve with a trial of a lactose-free diet, you have your diagnosis. Follow-up should include re-checking his CBC and perhaps other studies, such as stool for occult blood. If these symptoms are new, he could have a secondary form of lactase deficiency (e.g., Crohn disease or bacterial overgrowth) or a coincidental problem with the absorption of this carbohydrate. Colon cancer is not common at this age, but endoscopy should also be considered if anemia does not resolve.

The patient tries a lactose-free diet, but this is of no benefit and his abdominal cramping and diarrhea continue. At this point, you are considering additional diagnoses.

Question 7.8.2 Which of the following is LEAST likely in this patient?

- A) Bacterial overgrowth syndrome
- B) Gluten-sensitive enteropathy
- C) *Giardia lamblia*
- D) *C. difficile*
- E) Whipple disease

Answer 7.8.2 The correct answer is “E.” It is unlikely that this patient has Whipple disease, which is a result of an infection with *Tropheryma whippelii*. Whipple disease is associated with

nondeforming arthritis, weight loss, fever, diarrhea, etc. All of the others are possibilities in this patient. “A,” bacterial overgrowth syndrome, presents with bloating, diarrhea, dyspepsia, and possible malabsorption and weight loss. It can occur as a result of bowel dysmotility, bowel redundancy or diverticula, chronic pancreatitis, etc. “B,” gluten-sensitive enteropathy (nontropical or celiac sprue), presents with symptoms similar to those in our patient including malabsorption. “C,” *Giardia* infection, can be chronic and presents with gas, diarrhea, and occasionally constipation. Finally, *C. difficile* infection (pseudomembranous colitis) can also be chronic in nature with chronic diarrhea and blood loss.

**HELPFUL TIP:**

Giardia is a common pathogen that may be contracted in the day care setting. Symptoms may consist of diarrhea, malaise, and nausea. The treatment of choice is metronidazole.

You continue to work up this patient's diarrhea with stool cultures, stool for *C. difficile* toxin, direct immunofluorescence analysis for *Giardia* and *Cryptosporidium*, and three stools for ova and parasites. All of the studies are negative. You now turn your attention to possible bacterial overgrowth syndrome.

Question 7.8.3 The best test(s) for bacterial overgrowth syndrome is (are):

- A) Quantitative stool culture
- B) Stool leukocytes
- C) 72-hour fecal fat
- D) [14-C] d-xylose breath test
- E) B and D

Answer 7.8.3 The correct answer is “D.” The d-xylose breath test takes advantage of the fact that the bacteria responsible for bacterial overgrowth syndrome (Gram-negative aerobes) catabolize d-xylose. The breath test measures radioactive CO₂ that is formed as a result of bacterial breakdown of radioactive d-xylose (you too, like Godzilla, can have radioactive breath). The glucose breath test, in which glucose is administered to the patient and breath hydrogen is measured, is also helpful and commonly used. However, it is less sensitive and specific than the d-xylose test and has a 30% to 40% false-negative rate. Workup of bacterial overgrowth syndrome should also include an upper GI endoscopy and possible small bowel biopsy. GI hypomotility, small bowel dilatation, or small bowel diverticula support the diagnosis of bacterial overgrowth syndrome. Of the others, “B,” stool leukocytes are pretty useless in general and do not have a good correlation with infectious causes of diarrhea (high false-positive and false-negative rates). “C,” fecal fat collection, is useful in documenting fat malabsorption syndromes, including those secondary to severe pancreatic insufficiency (e.g., cystic fibrosis with >90% pancreatic dysfunction) and short bowel syndrome.

**HELPFUL TIP:**

Another option to diagnose bacterial overgrowth is empiric treatment for 7 to 10 days with medications to cover aerobes and anaerobes (cephalexin plus metronidazole, TMP/SMX plus metronidazole, amoxicillin/clavulanate). Rifaximin can be used but is expensive. Definitive treatment may require surgical intervention to shorten the bowel, resect diverticula, etc.

This patient's d-xylose test is negative, and you consider the possibility of gluten-sensitive enteropathy (celiac disease).

Question 7.8.4 Of the following, the BEST test for the diagnosis of gluten-sensitive enteropathy is:

- A) Antiendomysial antibodies
- B) Tissue transglutaminase antibodies
- C) Antigliadin antibodies
- D) Radiolabeled wheat flour absorption test
- E) All of the above are equally accurate for detecting celiac disease

Answer 7.8.4 The correct answer is “B.” Tissue transglutaminase antibodies are sensitive and specific for severe gluten-sensitive enteropathy, but may be falsely negative in mild-to-moderate cases. Antiendomysial IgA antibodies are less sensitive than tissue transglutaminase antibodies for gluten-sensitive enteropathy, but very specific for gluten-sensitive enteropathy. Antigliadin antibodies are less sensitive and specific and have fallen out of favor. The definitive test (“gold standard”) is a small bowel biopsy and should be considered if your clinical suspicion is high and the patient has negative antibodies. Patients with positive antibodies should also have an endoscopy; the diagnosis should be confirmed by endoscopy and biopsy before committing the patient to a gluten-free diet for life.

**HELPFUL TIP:**

Up to 1:200 Caucasians living in the United States may be affected with gluten-sensitive enteropathy (while 1:20 grocery store aisles appear to be devoted to gluten-free products).

**HELPFUL TIP:**

Remember FODMAPs from earlier? Studies of patients who believe that they have gluten-sensitive enteropathy show that eliminating FODMAPs will improve the symptoms of many of these patients (*Gastroenterology*. 2013;145(2):320-8.e1-3). The culprit here is not the whole wheat bread but the seven Big-Gulp-Fructose-Laden pops the patient drinks each day. To be fair, wheat has FODMAPs, so wheat, but not gluten sensitivity, may make symptoms worse in these patients. **Differentiating gluten-sensitive enteropathy from FODMAP-induced symptoms is important. Keep reading...**

Eureka! The results of his tissue transglutaminase test are positive. You educate him about gluten-sensitive enteropathy (celiac disease) and have an endoscopy performed. A small bowel biopsy demonstrates blunted villi with a significant increase in intraepithelial lymphocytes, consistent with gluten-sensitive enteropathy. With a gluten-free diet, the patient experiences a significant increase in his energy level. Two years later he comes for a routine visit. He has gradually reintroduced some wheat products into his diet and tolerates these very well.

Question 7.8.5 What do you recommend?

- A) Resume gluten-free diet
- B) Continue dietary challenge and repeat examination in 6 months
- C) Repeat small bowel biopsy
- D) Check tissue transglutaminase antibody titer
- E) Completely liberalize diet and return to a typical American diet

Answer 7.8.5 The correct answer is “A.” While there is no good data on the benefit of a long-term gluten-free diet in patients who can tolerate small amounts of gluten, several factors argue for continuing a gluten-free diet. The first is that many patients will have subclinical nutrient deficiencies if they reintroduce gluten. For this reason, patients with gluten-sensitive enteropathy should be screened for osteoporosis and take a multivitamin. This is especially true in pediatric patients where deficiencies may lead to stunted growth. The second is that there is some data that patients who reintroduce gluten may have increased mortality from GI lymphoma despite the fact that they are tolerating the gluten well (*Ann Intern Med.* 2013;159(3):169–175).

Question 7.8.6 All of the following are gluten-free grains EXCEPT:

- A) Oats
- B) Corn
- C) Sticky (glutinous) rice
- D) Rice
- E) Rye

Answer 7.8.6 The correct answer is “E.” Rye contains gluten (as does barley). Despite its name, glutinous rice contains no gluten. The rest are gluten-free. Other gluten-free grains/starches include: buckwheat, flax, quinoa, teff, millet, amaranth, and tapioca. Oats have a gliadin peptide that can activate celiac disease in *some* patients. Generally, oats are fine in small quantities as long as they are not contaminated with wheat in the processing.

HELPFUL TIP:

With a gluten-free diet, antibodies (tissue transglutaminase, antigliadin, antiendomysial) often return to normal levels.

HELPFUL TIP:

Patients with gluten-sensitive enteropathy must be compulsive about their diet. Rice, corn, and soybean-based flours are safe to consume.

► Objectives: Did you learn to ...

- Evaluate a patient with chronic diarrhea?
- Recognize clinical manifestations of gluten-sensitive enteropathy?
- Manage a patient with gluten-sensitive enteropathy?

► CASE 7.9

A 22-year-old previously healthy male reports a 3-day history of explosive and watery diarrhea. He is having up to six bowel movements per day. He recalls eating at a new Mexican restaurant 5 days ago. His head sinks a little low as he recalls drinking a “fish bowl-sized” margarita ... or at least he thinks he remembers drinking it. He denies fever, blood in his stool, or recent travel. Multiple people ate the same food but he is the only one who is sick. His vital signs are normal (including supine and standing blood pressures), and the remainder of the physical examination is remarkable only for mild, diffuse abdominal tenderness.

Question 7.9.1 What is the most likely diagnosis?

- A) Celiac sprue
- B) Viral gastroenteritis
- C) Lactose intolerance
- D) Small bowel bacterial overgrowth
- E) *C. difficile* colitis

Answer 7.9.1 The correct answer is “B.” This is always a dilemma. It can be difficult to differentiate acute gastroenteritis from food poisoning. What makes gastroenteritis more likely is that there is no clustering of cases among people who ate the same food. With only 3 days of symptoms, it would be premature to diagnose “A,” “C,” or “D.” Without recent antibiotic exposure, “E” would be unlikely in an otherwise healthy male. See Table 7-3 for a differential diagnosis for diarrhea.

Question 7.9.2 What is the MOST appropriate next step in the care of this patient at this point?

- A) Order a CBC
- B) Order electrolytes
- C) Order stool examination for ova and parasites
- D) Recommend oral hydration and antidiarrheals as needed
- E) Order an abdominal film

Answer 7.9.2 The correct answer is “D.” No workup is needed for a mild case of acute diarrhea, since such cases are usually self-limited. Generally, the history and physical examination should provide the diagnosis and indicate need for further workup. Further workup and treatment are indicated if the patient has severe or bloody diarrhea, dehydration, systemic toxicity, or severe pain.

TABLE 7-3 DIFFERENTIAL DIAGNOSIS FOR DIARRHEA**Acute Diarrhea**

- Bacteria (e.g., *Campylobacter*, *Salmonella*, and *Clostridium*)
- Viruses (e.g., Norwalk and rotavirus)
- Parasites (e.g., *Giardia*)
- Protozoa (especially in HIV-infected patients)
- Medications
- Anything that causes chronic diarrhea

Chronic Diarrhea

- Inflammatory (e.g., IBD and radiation enteritis)
- Osmotic (e.g., gluten-sensitive enteropathy and lactase deficiency)
- Secretory (e.g., Zollinger–Ellison syndrome and villous adenoma)
- Disordered motility (e.g., irritable bowel syndrome and overflow from fecal impaction)

**HELPFUL TIP:**

Patients with severe, bloody diarrhea, and fever ($T > 101^{\circ}\text{F}$, > 6 stools per day) should be treated with a single dose or 3-day course of a fluoroquinolone while awaiting stool culture results. **Bloody diarrhea in an afebrile patient should suggest *Escherichia coli* 0157:H7.** These patients should **NOT** get antibiotics because of an increased risk of hemolytic–uremic syndrome. As always, there is an “except.” Patients who have been traveling to areas with resistant organisms should be treated with azithromycin 1,000 mg once or 500 mg daily for 3 days. This includes most of Asia.

You treat the patient with oral rehydration and prochlorperazine for nausea and he does well. He returns to see you a few weeks later after a trip to Mexico. He liked that fish bowl-sized margarita so much that he decided to go for an original. He has diarrhea that began a couple of days after his arrival in Cancun and has now been present for 5 days. He has had frequent, watery diarrhea with nausea but no vomiting. He has noticed no blood in the stool. He was very careful to avoid salads and water, but did have some ice in a soft drink and his margarita was “on the rocks.”

Question 7.9.3 The most likely organism causing illness in this patient is:

- A) *Salmonella*
- B) *Shigella*
- C) Enterotoxigenic *E. coli*
- D) Enterohemorrhagic *E. coli*
- E) *Campylobacter*

Answer 7.9.3 The correct answer is “C.” Enterotoxigenic *E. coli* is the most common cause of traveler diarrhea in patients traveling to Mexico. Enterohemorrhagic *E. coli* is less likely and should be associated with bloody diarrhea. The others are much less likely to be causes of travelers’ diarrhea.

**HELPFUL TIP:**

Many physicians would not treat a patient with *Shigella* unless that patient is clinically ill (e.g., fever). Treatment with antibiotics is **relatively** contraindicated in *Salmonella* because it prolongs the carrier state. However, use judgment in the patient who is particularly ill.

**HELPFUL TIP:**

A variety of PCR panels are now available to help identify the pathogen causing GI distress. These panels are superior to traditional evaluation in both sensitivity and timeliness (results in hours). These tests are useful in determining treatment (or nontreatment for viral infections), but are unnecessary in mild disease as they will not change management. Note these tests are so sensitive they can detect nonpathogenic levels of potential pathogens, yielding a false-positive result.

Question 7.9.4 Which of the following is/are appropriate for the treatment of this patient’s travelers’ diarrhea (remember, he has no vomiting)?

- A) Oral rehydration
- B) Antidiarrheals
- C) Eat any food (e.g., no need for a bland diet with slow advancement)
- D) All of the above
- E) None of the above

Answer 7.9.4 The correct answer is “D.” This patient has non-bloody diarrhea and no systemic signs, so it should be safe to treat him with antidiarrheal agents (e.g., loperamide) and avoid antibiotics. Oral rehydration is the rule unless a patient is too nauseated or has some other reason that he cannot take adequate fluids by mouth. *Patients (including children) should eat anything they can tolerate.* The concept of “gut rest” is a misnomer and actually leads to increased bowel permeability and more persistent diarrhea. **Lactose deserves special mention.** The American Academy of Pediatrics has changed its recommendation about lactose in diarrhea, recommending caregivers withhold lactose **only** in children less than 3 months of age. This seems to be the group in which transient lactase deficiency occurs.

► **Objectives: Did you learn to ...**

- Evaluate a patient with acute diarrhea?
- Treat acute diarrhea?
- Recognize different bacterial causes of diarrhea?

► **CASE 7.10**

A 49-year-old man comes to your office, requesting testing for hepatitis C. He recently attended his 25-year college reunion where an old friend he had “partied” with during experimentation with injectable drugs related that he has cirrhosis due

to hepatitis C. The patient is otherwise healthy and denies any symptoms except for occasional fatigue after a long day at work. Physical examination of the patient is unremarkable. There are no stigmata of chronic liver disease.

Question 7.10.1 Which of the following is the most appropriate course of action?

- A) Check a quantitative Hepatitis C virus (HCV) PCR (“viral load”)
- B) Order a recombinant immunoblot assay (RIBA)
- C) Order HCV antibody test (enzyme immunoassay)
- D) Order a qualitative HCV PCR
- E) Order ALT and AST

Answer 7.10.1 The correct answer is “C.” The sensitivity and specificity of the present-day HCV antibody test are excellent; thus, this is the best initial test to perform to diagnose HCV infection. Rarely, patients with immunologic impairment, such as HIV infection, have HCV viremia without detectable antibody, but this would not be a concern in this otherwise healthy patient. Quantitative HCV PCR is not a reliable means for diagnosing HCV infection because currently used methods are insensitive at low levels of viremia; thus, infection cannot be ruled out if the level of HCV viremia is below the lower limit of detection of the test. RIBA is an old test that is no longer used. **Qualitative** HCV PCR is the most sensitive test for the presence of HCV RNA, with a limit of detection that is lower than that of quantitative PCR. It is useful to establish the presence of viremia, but is more expensive than antibody testing and thus not a first-line test. Many patients with chronic HCV infection (including patients with cirrhosis) have normal liver enzymes and can still have progressive disease; therefore, in a high-risk patient, ALT and AST are not appropriate for screening for HCV.

HELPFUL TIP:

Hepatitis C antibody can remain positive lifelong even in patients who have cleared their infection. Unlike HAV and HBV antibodies, HCV antibodies are not protective. Just because a patient cleared HCV once does not mean they cannot be reinfected. If these patients have ongoing high-risk behaviors, consider periodic evaluation with qualitative PCR to assess for reinfection.

The patient returns several weeks later to discuss his test results. His HCV antibody test is positive. A liver panel obtained that day shows an ALT of 48 IU/L (reference range, 0–20) and an AST of 39 IU/L (0–31). His albumin and total bilirubin are within normal limits. Subsequent HCV PCR confirms active disease. He is extremely anxious about his liver.

Question 7.10.2 To most accurately assess the degree of liver disease, your next step is to:

- A) Obtain a liver–spleen scan to assess for evidence of cirrhosis
- B) Order a right upper quadrant ultrasound with Doppler to assess for evidence of cirrhosis

- C) Order elastography for evidence of cirrhosis
- D) Obtain an abdominal CT to assess for evidence of cirrhosis
- E) Reassure the patient that his mild liver test abnormalities rule out cirrhosis

Answer 7.10.2 The correct answer is “C.” Having established that the patient has hepatitis C with elevated liver enzymes, the next step is to determine the severity of his liver disease. Although his liver function tests are reassuring, this does not exclude the possibility of advanced fibrosis or even well-compensated cirrhosis. While biopsy has been the definitive test for liver fibrosis in the past (and you would not be wrong to order a biopsy if it were an option in this question), ultrasound elastography, a noninvasive technique of determining liver fibrosis, is being used more and more. The idea is that a fibrotic liver is a stiff liver, and that stiffness can be determined by imaging modalities, including ultrasound. The sensitivity of elastography for detecting cirrhosis ranges from 70% to 87% and specificity of 84% to 91% (with better accuracy at higher stages of cirrhosis). The “F” score, discussed below, should allow you to make decisions about your hepatitis C patients. You would not be incorrect to order ultrasound imaging as well, but it would not be the best modality for determining degree of cirrhosis.

HELPFUL TIP:

Fibrosis is scored from F0 to F4, with F0 representing no fibrosis and F4 representing cirrhosis. In addition to elastography, another noninvasive method of determining the degree of fibrosis is the AST/platelet ratio index, abbreviated APRI. This is calculated as follows:

$$APRI = [(patient\ AST / upper\ normal\ of\ lab\ AST) / platelet\ count] \times 100.$$
 Platelet count should be given as $\times 10^9/L$ (e.g., if the count is 100,000/ μL , use 100).

Significant fibrosis (F2–F4) is present if the APRI is 0.7 or greater (77% sensitivity, specificity 72%), although some sources use 0.5 as the lower limit for “significant fibrosis.” An APRI of 1 or greater represents cirrhosis. Finally, the FibroSure, Fibrotest, and ActiTest are proprietary methods of determining liver fibrosis—all of which have separate scoring systems for fibrosis. Note that a biopsy is not necessary for making a decision about who to treat: more on this below.

After a few phone calls, you find that elastography is not available anywhere nearby. The patient agrees to a liver biopsy to diagnose cirrhosis and you make the referral. He is still very concerned about his situation and asks what you think the chances are that he already has cirrhosis.

Question 7.10.3 Regarding the development of progressive liver disease in hepatitis C, all of the following are true EXCEPT:

- A) Approximately 20% of patients with chronic HCV infection will develop serious liver disease
- B) Heavy alcohol use is a risk factor for development of serious liver disease

- C) Acquisition of HCV infection after the age of 40 is associated with increased risk of developing serious liver disease
- D) HCV genotype affects the probability of developing end-stage liver disease
- E) Males are more likely than females to develop serious liver disease

Answer 7.10.3 The correct answer is “D.” While only a minority of persons infected with HCV develop serious liver disease (about 20%), the likelihood of progression is difficult to predict in an individual patient. Of the rest of those infected, 80% will not clear the virus and have a chronic infection that *does not* progress to end-stage liver disease. Nonetheless, male gender, heavy alcohol use, and acquisition of HCV infection after the age of 40 are associated with increased risk of progressive liver disease, while genotype is not. In addition, Japanese ancestry, smoking (both cigarettes and marijuana), and acquiring hepatitis C from a blood transfusion have been associated with an increased risk of progression. The genotype of the hepatitis C certainly makes a difference when it comes to treatment but not with progression to cirrhosis.

HELPFUL TIP:

Screen for hepatitis C at least once in all U.S. adults aged 18–79 years (per USPSTF draft recommendation published for public comment in 2019). Other populations deserving of screening include those with HIV, dialysis patients, and incarcerated patients.

The patient is concerned that he may transmit the virus to his wife or children. They are tested and are found to be negative for HCV antibody. He is relieved but asks for advice to prevent infecting them.

Question 7.10.4 You advise all of the following EXCEPT:

- A) No change in sexual practices is recommended for couples in a long-term monogamous relationship in which one partner is HCV+ and the other HCV–
- B) The use of condoms is recommended for couples in a long-term monogamous relationship in which one partner is HCV+ and the other HCV–
- C) Hepatitis C is not spread by hugging, sneezing, or sharing a drinking glass
- D) Household members of persons infected with HCV should not share items that might be contaminated with small amounts of blood, such as razors or nail clippers
- E) Parenteral exposure to infected blood is a major route of transmission of HCV

Answer 7.10.4 The correct answer is “B.” HCV is spread by parenteral contact with infected blood. In contrast to hepatitis B, sexual transmission of HCV is inefficient and appears to be a minor route of spread. In addition, the efficacy of latex condoms in preventing disease is not known. The NIH and the US Public Health Service do not recommend condom use for patients in a stable, long-term, and monogamous relationship. That said,

using condoms will likely reduce an already low risk even further (0.1% per year without condoms).

The patient’s liver biopsy shows mild-to-moderate inflammatory activity and portal and periportal fibrosis (stage 2). He is relieved to find out that he does not have cirrhosis, but remains very concerned about his hepatitis and wants to do everything possible to “get rid of” hepatitis C. He asks about the treatment of his HCV.

Question 7.10.5 At what stage of fibrosis should treatment be considered?

- A) F2 or higher
- B) F3 or higher
- C) F4, no need to treat until cirrhosis sets in
- D) Any stage

Answer 7.10.5 The correct answer is “D.” Current recommendation is to treat everybody. Unless the patient has a short life expectancy, they should be treated regardless of fibrosis score. F-score still matters, as duration of therapy is determined in part by severity of disease but there is not a minimal level of disease to qualify for treatment. The current regimens of antivirals are effective and well tolerated. Unfortunately, the cost of these new drugs—at least, in the United States—remains immorally high, in some cases over \$100,000 for a complete 12-week treatment depending on the drug. Public and private insurers have been forced into outright rationing. If the United States treated all of the approximately 3 million HCV-infected persons with the new drugs, it would cost our country about \$300 billion. Because of the pharmaceutical companies setting prices differently in different markets, at least one of these new HCV drugs costs about 1% of the US price in Egypt. So ... one option is to send your HCV patients to Egypt for the treatment and put them up in a nice hotel—it would be significantly cheaper.

Question 7.10.6 You tell him which of the following?

- A) Combination therapy with interferon and ribavirin results in sustained virologic responses (SVR) in 40% to 70% of patients treated
- B) Combination therapy with interferon and ribavirin can cause numerous side effects including pancytopenia, flu-like symptoms, worsening of autoimmune conditions, depression, and hemolytic anemia
- C) The HCV genotype is a strong predictor of response to the treatment
- D) Newer treatment regimens including ledipasvir/sofosbuvir are much more effective than the traditional combination of interferon/ribavirin
- E) All of the above

Answer 7.10.6 The correct answer is “E.” Combination therapy with interferon and ribavirin is the traditional treatment of HCV and it is clearly not as effective at achieving an SVR as the newer drugs. In fact, it is no longer part of the recommended treatment algorithm. Similarly, the protease inhibitors (telaprevir and boceprevir) have also come and gone. Current

treatments are based on genotype, fibrosis score, whether or not a cirrhotic patient is compensated or decompensated, and prior treatment status. Higher baseline viral levels also tend to predict poorer response to the treatment. There are currently safe, effective oral regimens for all 6 genotypes. While there is a higher rate of success in the treatment of naïve patients, the new regimens are useful even in patients with prior treatment failure.

Question 7.10.7 Overall, the new oral “direct acting antiviral” drugs for hepatitis C have a cure rate of approximately:

- A) 50%
- B) 70%
- C) 80%
- D) 90%

Answer: 7.10.7 The correct answer is “D.” The direct acting antivirals have a cure rate of over 90% (and some up to 99%). Some of these drugs include: Harvoni, Viekira, and Technivie. Epclusa (sofosbuvir and velpatasvir) is effective in all genotypes. However, knowing and targeting the genotype is crucial. Patients should be tested 12 weeks after treatment is completed. About 1% will relapse between 12 and 24 weeks post-treatment, so some practitioners recheck viral levels at 24 weeks.

HELPFUL (AND CRUCIAL) TIP:

HCV treatment is rapidly changing. In order to keep pace, the Infectious Disease Society of America (IDSA) and American Association for the Study of Liver Disease (AASLD) maintain current guidelines at www.hcvguidelines.org.

► **Objectives: Did you learn to ...**

- Evaluate a patient at risk for hepatitis C?
- Understand the natural history of the disease process in hepatitis C?
- Describe the transmission of hepatitis C?
- Discuss the treatment issues for a patient with hepatitis C?

► **CASE 7.11**

A 24-year-old female graduate student from China comes to your office complaining of fatigue for the past month. She has also had a poor appetite and has lost about 3 lb over this period. She reports that she was told that she had “hepatitis” when she was about 10 years old, but does not recall what type. She is otherwise healthy and takes no medications. She has no history or percutaneous exposures or blood transfusion. Her grandfather died of liver cancer.

Physical examination reveals a thin, tired-appearing woman. The liver edge is palpable 2 cm below the right costal margin and is slightly tender. There is no ascites, splenomegaly, or cutaneous stigmata of chronic liver disease.

Laboratory studies are remarkable for anemia (hemoglobin 9.1 g/dL). Liver tests reveal elevated aminotransferases (ALT 289 IU/L, AST 158 IU/L), albumin 3.2 g/dL, and total bilirubin 1.5 mg/dL (normal 0.2–1.0 mg/dL).

Question 7.11.1 Diagnostic possibilities at this point include:

- A) Hepatitis A
- B) Hepatitis B
- C) Hepatitis C
- D) Autoimmune hepatitis
- E) All of the above

Answer 7.11.1 The correct answer is “E.” Constitutional symptoms such as fatigue and anorexia can be seen with any form of acute or chronic liver disease; thus, they are not helpful in establishing a specific diagnosis. The first priority is to rule out infectious hepatitis including hepatitis A, B, and acute hepatitis C. Autoimmune hepatitis deserves consideration, particularly in female patients. While HCV infection is a worldwide problem, HBV infection is endemic in Asia and Africa, and the possibility of chronic hepatitis B also warrants special attention in this patient.

Question 7.11.2 Appropriate laboratory studies at this point include which of the following?

- A) Quantitative HCV PCR
- B) Hepatitis B surface antigen (HBsAg)
- C) Antihepatitis A antibodies (IgG and IgM)
- D) B and C
- E) All of the above

Answer 7.11.2 The correct answer is “D.” As discussed previously, the quantitative HCV PCR is not a useful test for diagnosing HCV infection. HCV antibody testing would be a better choice. Both HBsAg and anti-HAV are useful tests in this patient. HBsAg identifies active infection (but does not distinguish between acute and chronic). HBsAb IgM indicates acute infection but usually gives way to HBsAb IgG within 6 months of infection. Anti-HAV antibodies will rule out acute hepatitis A infection. A positive total anti-HAV (positive IgG) with a negative IgM would indicate past infection, while a positive IgM would suggest acute HAV infection. In this scenario, you might also consider testing for Epstein–Barr virus (mononucleosis), CMV virus, and other viral infections. Interpreting the HBV antigens (Ag) and antibodies (Ab) can be confusing, and Table 7-4 may help.

The patient’s results show a positive HBsAg, indicating ongoing hepatitis B infection. She is immune to hepatitis A and is hepatitis C negative.

After being out of contact for 4 months, she returns for a follow-up visit. She tells you that she took an herbal medicine her mother sent from China and has been feeling much better recently. Her HBsAg remains positive, but her liver enzymes, albumin, and total bilirubin are now completely normal.

Question 7.11.3 Appropriate actions at this time include:

- A) Treatment with interferon-alpha 5 million units daily for 16 weeks
- B) Order hepatitis Be antigen, anti-HBe, and HBV DNA level

TABLE 7-4 HEPATITIS B VIRAL SEROLOGIES FOR DIFFERENT PHASES OF INFECTION

Antigen/Antibody	Acute	Chronic	Recovered	Vaccinated/Immune
HBsAg	+	+	—	—
HBeAg	+	+	—	—
Anti-HBsAb	—	—	+	+
Anti-HBcAb	+ (IgM)	+ (IgG)	+ (IgG)	—
Anti-HBeAb	—	+/-	+	—
HBV DNA	+	+/-	+/-	—

Ab, antibody; Ag, antigen; HBc, core antigen or antibody; HBe, "e" antigen or antibody; HBs, surface antigen or antibody.

- C) Begin periodic screening for hepatocellular carcinoma (HCC) with ultrasound and alpha-fetoprotein (AFP)
 D) A and C
 E) B and C

Answer 7.11.3 The correct answer is "E." The HBe antigen reflects viral replication. Loss of HBeAg indicates decreased viral replication and less of a risk of progression to cirrhosis. Loss of HBeAg may occur spontaneously; it is also the therapeutic endpoint of the antiviral treatments of HBV infection (interferon, lamivudine, entecavir). If she is negative for HBeAg and is anti-HBe antibody positive (anti-HBe +) or has low or undetectable levels of HBV DNA, she has a low level of viral replication and will not benefit further from the antiviral treatment.

Her liver panel should be monitored periodically as should AFP and liver ultrasound. Ultrasound is recommended every 6 months with or without AFP. An AFP alone should not be done because of the poor sensitivity and specificity. Even asymptomatic HBV carriers with minimal liver disease are at risk for HCC. Screening for HCC in those who are carriers of hepatitis B is indicated in: Asians (men >40 years old, women >50 years old); those with a family history of HCC; cirrhotic patients; and those of African ancestry >20 years of age. Our patient had positive family history of HCC, so monitoring for HCC is indicated.

The patient returns to discuss the results of her tests. Laboratory results show that she is positive for HBsAg and is anti-HBeAb positive. Her HBV DNA is undetectable using an unamplified assay, making her a carrier without evidence of viral replication (no chronic, active, hepatitis B). AFP is within limits and abdominal ultrasound is unremarkable. She continues to feel well. She also tells you that she will be getting married in 2 months. She asks you what can be done to prevent her fiancé and future children from becoming infected with HBV.

Question 7.11.4 All of the following are accurate responses to her question EXCEPT:

- A) No special precautions need to be taken because she has undetectable HBV and is therefore not infectious

- B) If her fiancé has not been immunized against HBV, he should be tested and vaccinated if not immune
 C) If her fiancé is not immune to HBV, they should use barrier contraceptives (e.g., condoms) until he has completed his HBV vaccination series
 D) She should cover any open cuts or scratches with a bandage and clean up any blood spills with bleach
 E) Administration of hepatitis B immune globulin (HBIG) and HBV vaccination begun immediately after birth is 95% effective in preventing perinatal transmission of HBV

Answer 7.11.4 The correct answer is "A." Although patients with higher levels of HBV DNA are more infectious than those with lower levels of viral DNA, the risk of transmission in the latter case is not zero. In the case of this patient, having "undetectable" HBV DNA simply indicates a level of HBV DNA that falls below the limit of detection of an unamplified assay (on the order of 10^5 copies/mL). Also, the positive HbsAg means she is still a carrier. Thus, precautions should be taken to prevent sexual or household transmission to her fiancé (use of condoms, immunization if required, etc.) and to her future children (HBIG and HBV vaccination).

VERY HELPFUL (IF LONG) TIP

ALT and AST can be elevated secondary to:

- **Viral agents:** Hepatitis (A, B, C, D, E), CMV, Epstein-Barr virus, and other viruses.
- **Drugs and chemicals:** Acetaminophen overdose, the "glitazones," HMG-CoA reductase inhibitors, INH, griseofulvin, anticonvulsants, NSAIDs, chemicals (carbon tetrachloride, etc.), alcohol, and many other agents.
- **Primary liver diseases:** Primary sclerosing cholangitis, primary biliary cirrhosis (positive antimitochondrial antibody [AMA]).
- **Metabolic diseases:** Wilson disease (decreased ceruloplasmin), hemochromatosis, alpha-1 antitrypsin deficiency, and cystic fibrosis.
- **Mechanical difficulties:** Ductal obstruction secondary to common duct stone or carcinoma (especially pancreatic, hepatoma, metastatic), Budd-Chiari syndrome (thrombosis of the hepatic vein).

- **Cholestasis** from central venous nutrition (CVN), pregnancy, or ceftriaxone therapy.
- **Infiltrative processes:** Fatty liver (especially those with diabetes, hypothyroidism, obesity; determine by U/S), amyloid, granulomatous hepatitis, liver abscess (including amebic or echinococcal; diagnosis by U/S or CT; may have eosinophilia), AIDS-related lymphoma, or other neoplasm.
- **Other:** Congestive heart failure, celiac sprue, muscle diseases (e.g., polymyositis).

Alkaline phosphatase may be elevated secondary to:

- Pregnancy, after a fatty meal in persons with type O or B blood.
- **Liver:** Cholestasis, partial obstruction of the biliary ducts, primary sclerosing cholangitis, adult bile ductopenia, primary biliary cirrhosis, sarcoidosis, and other granulomatous disease.
- **Bone diseases** such as Paget disease and metastatic disease.

For elevated liver tests, workup should include (in approximate order, which may vary depending on patient presentation):

- Rule out toxin exposure (alcohol, drugs).
- Hepatitis A, B, and C serology.
- Serum ferritin, iron, TIBC, transferrin saturation (hemochromatosis).
- Ultrasound or CT imaging (ultrasound first).
- ANA and antismooth muscle antibody (autoimmune hepatitis but only 28–40% sensitive).
- Serum alpha-1 antitrypsin.
- Serum protein electrophoresis (elevated levels in autoimmune hepatitis, 80% sensitive).
- Antiendomysial antibodies or tissue transglutaminase (gluten-sensitive sprue).
- Serum ceruloplasmin (Wilson disease).

(What a long strange tip it's been!)

► **Objectives: Did you learn to ...**

- Generate a differential diagnosis for patients with abnormal liver enzymes?
- Identify patients at risk for hepatitis B?
- Use the various hepatitis B antigens and antibodies to determine a patient's infection status?
- Describe the route of transmission of hepatitis B?
- Workup elevated liver tests in a stepwise fashion?

► **CASE 7.12**

A 73-year-old man comes to your office, complaining of abdominal and ankle swelling, decreased energy, and poor appetite for the past 2 months. He dates the onset of his symptoms to a “reaction” to penicillin given for dental work. He says that before taking the penicillin, he was in excellent health and walked 3 miles per day. Now he is too weak and tired to even care for his own yard.

His past medical history is remarkable for coronary artery bypass surgery done 6 years ago. He also recalls having “yellow jaundice” (as opposed to the purple kind?) when he was stationed in Vietnam decades ago. He has no significant family history. He “drank a bit” on the weekends when he was in the service but has drunk very little alcohol in the past 50 years. He also quit smoking about 50 years ago. His medications are aspirin 81 mg daily and ibuprofen 600 mg as needed for knee pain due to degenerative joint disease.

Question 7.12.1 Diagnostic considerations suggested by the history should include which of the following?

- A) Adverse drug reaction to penicillin
- B) Malignancy
- C) Cirrhosis
- D) Heart failure
- E) All of the above

Answer 7.12.1 The correct answer is “E.” The patient's history of abdominal and lower extremity swelling suggests fluid overload. Penicillin is known to cause interstitial nephritis and secondary nephrotic syndrome, which can lead to fluid retention. Sources of fluid overload besides the kidneys should be considered in this patient, including liver and heart disease. Malignancy, especially with liver involvement, can cause ascites. He is on an NSAID, which can cause fluid retention, although rarely to this degree.

Physical examination reveals a fragile-appearing elderly man with temporal wasting. There is no JVD. The lungs are clear to auscultation. The heart sounds are regular, with no murmurs or gallops. The abdomen is protuberant with bulging flanks. Shifting dullness is present. There is 2+ ankle edema bilaterally and scattered telangiectasias on skin examination. He has no asterixis.

Question 7.12.2 Which of the following findings would you expect on laboratory examination?

- A) Elevated hemoglobin and HCT (17.5 g/dL and 55%)
- B) Decreased platelet count of 80,000/mm³
- C) Elevated serum albumin
- D) BUN/Cr ratio <20
- E) All of the above

Answer 7.12.2 The correct answer is “B.” This patient likely has portal hypertension given his ascites and stigmata of liver disease (spider angiomas/telangiectasias). Blood flow is shifted toward the spleen because of the increased portal pressure (the blood, like the rest of us, takes the path of least resistance). Shunting of blood through the spleen results in thrombocytopenia through increased platelet destruction. Spider telangiectasias and palmar erythema develop due to excess circulating estrogens. Along with this, gynecomastia and testicular atrophy can be an issue in men. “A” is wrong since liver patients often have anemia. “C” is incorrect because liver patients frequently have a low albumin. And, “D,” a BUN/Cr ratio <20 is associated with intrinsic kidney disease (see Chapter 5).

Diagnostic paracentesis is performed and approximately 50 mL of clear light yellow fluid are obtained.

Question 7.12.3 Appropriate laboratory studies on the ascitic fluid include which of the following?

- A) pH
- B) Albumin
- C) Lactate
- D) Triglycerides
- E) All of the above

Answer 7.12.3 The correct answer is “B.” The ascitic fluid albumin is needed to calculate the serum-ascites albumin gradient (SAAG), which is helpful in distinguishing between ascites resulting from portal hypertension and ascites due to other causes. Lactate (“C”) and pH (“A”) have been proposed as markers for spontaneous bacterial peritonitis (SBP) but have proven unreliable. Measurement of triglycerides (“D”) is useful to confirm chylous ascites; however, in the absence of grossly milky-appearing fluid, there is no need to perform this test.

HELPFUL TIP:

In addition to albumin, all ascitic fluid should be sent for total protein, cell count, and cultures. A cell count showing ≥ 250 polymorphonuclear leukocytes/mm³ is presumptive evidence of SBP and mandates treatment for such. Gram stain is nearly useless since ascitic fluid bacterial counts are typically so low that bacteria are rarely seen on Gram stain. Serum albumin and total protein should be obtained within an hour before or after the tap.

Your patient’s laboratory tests reveal an ascitic fluid total protein of 2.2 g/dL with an ascitic fluid albumin of 1.9 g/dL. A liver panel reveals normal aminotransferases, normal bilirubin, serum albumin 3.3 g/dL, and alkaline phosphatase 147 IU/L. Electrolytes, BUN, and creatinine are within normal limits.

Question 7.12.4 Which of the following is the most accurate interpretation of these results?

- A) The SAAG is 1.7, which is consistent with portal hypertension as its cause
- B) The SAAG is 1.7, which rules out portal hypertension as its cause
- C) The SAAG is 1.4, which is consistent with portal hypertension as its cause
- D) The SAAG is 1.4, which rules out portal hypertension as its cause
- E) The SAAG confuses me, so I don’t want to do it

Answer 7.12.4 The correct answer is “C.” The SAAG can tell us whether the fluid is a transudate or exudate. The SAAG is simply the difference between the serum albumin and the ascitic fluid albumin, or $3.3 - 1.9 = 1.4$, in this case. A SAAG of ≥ 1.1

indicates portal hypertension with 97% accuracy. Remember this by remembering that a high SAAG means high pressure in the portal system.

HELPFUL TIP:

Ascites from any cause of portal hypertension will have a high SAAG. Aside from cirrhosis, portal hypertension also may result from schistosomiasis, sarcoidosis, portal vein thrombosis (Budd–Chiari syndrome), congenital hepatic fibrosis, heart failure, myxedema, etc. **Causes of a low SAAG include:** serositis from connective tissue disorders, nephrotic syndrome, pancreatic-related ascites, and peritoneal carcinomatosis, among others.

HELPFUL TIP:

SAAG > 1.1 and ascites total protein > 2.5 suggests a cardiac process with congestive hepatopathy (e.g., heart failure or constrictive pericarditis). This should prompt further evaluation if cause of the ascites is not already known.

Question 7.12.5 In addition to a complete evaluation to determine the cause of his portal hypertension, which of the following is/are appropriate action(s) at this time?

- A) Refer the patient to a nutritionist for instruction on a low-sodium diet
- B) Discontinue ibuprofen and prescribe a COX-2-selective inhibitor for arthritis
- C) Prescribe spironolactone 100 mg daily and furosemide 40 mg daily
- D) A and C
- E) A, B, and C

Answer 7.12.5 The correct answer is “D.” The initial approach to the management of ascites due to portal hypertension is sodium restriction and diuretics. The goal is a 2-g sodium diet (which is very difficult to follow—just look at a can of soup!). The majority of patients will **not** have an adequate response to sodium restriction alone, so it is reasonable to begin diuretics at the outset. Typically, diuretics are *started* at furosemide 40 mg and spironolactone 100 mg (or $\frac{1}{2}$ this in patients < 50 kg). They are escalated by 40 mg and 100 mg increments to max of furosemide 160 mg daily and spironolactone 400 mg daily. The ratio is dictated largely by potassium levels. **Remember the focus is on sodium balance, and if the patient is nonadherent to their diet, max dose diuretics will remain ineffective.** NSAIDs should be avoided, due to sodium retention and GI bleeding. COX-2-selective inhibitors have no advantage over nonselective NSAIDs in this regard. Other approaches to the patient’s knee pain should be considered, including intra-articular injections, acetaminophen (up to 2 g daily is likely safe in cirrhosis), and narcotics, provided encephalopathy is not a problem.

**HELPFUL TIP (AND PET PEEVE):**

Don't use NSAIDs in liver disease. The patient may already have a coagulopathy and a low platelet count. They may have varices prone to bleeding. NSAIDs can also cause GI bleeding and are **NOT** a safe alternative to acetaminophen.

**HELPFUL TIP:**

In the author's experience it is not uncommon for cardiologists and hepatologists to express concern about each other's spironolactone regimen. Hypertension and heart failure doses range from 25 to 100 mg. Be sure you know **WHY** your patient is on the medication they are on so you can communicate effectively with your consultants.

The patient does relatively well and abstains from alcohol. He is now taking spironolactone and furosemide and following a low-salt diet. He seems to be following your instructions well but returns to the clinic because of increasing dyspnea, abdominal distention, and pain. He admits to eating his way through the state fair including the Giant Pork Tenderloin and just about anything fried on a stick (he insists he removed the pickles). On examination, he has no peritoneal signs but obviously has massive ascites. You are considering a large-volume paracentesis in your office.

Question 7.12.6 Which of the following statements best reflects the current thinking on large-volume paracentesis?

- A) A patient who has over 4 L of fluid removed should receive IV albumin
- B) There is no consistent data with regard to the use of albumin in large-volume paracentesis
- C) Under no circumstance should more than 5 L of ascites be removed at one time
- D) Given this patient's dyspnea, large-volume paracentesis is contraindicated
- E) If more than 10 L of ascites fluid is removed, an equal volume of normal saline should be replaced intravenously

Answer 7.12.6 The correct answer is "B." It is unclear what patient factors indicate albumin replacement. "A" is incorrect. Unless the patient has had prior issues with renal insufficiency or hypotension with paracentesis, there is no need for albumin in patients who have less than 5 L of fluid removed. However, for patients who have more than 5 L of fluid removed, the standard of care is replacement with albumin although the data are limited. "C" is incorrect. Large-volume paracentesis can be done with even the removal of >10 L. "D" is incorrect. In fact, respiratory compromise is one reason to do a large-volume paracentesis. Removal of fluid will help with diaphragmatic excursion and may help with the resolution of pleural effusions. "E" is wrong as albumin replacement is

recommended instead of normal saline. Giving normal saline will further induce fluid shifting and increase sodium load. And, it just sounds wrong, don't you agree? That's a lot of fluid shifting.

**HELPFUL TIP:**

A meta-analysis of albumin replacement following paracentesis suggests that 6 to 8 g of albumin be given per liter of ascites removed in those patients having more than 5 L of ascitic fluid removed (*Hepatology*. 2012;55:1172–1181). Be sure to use the 25% concentrated version; more dilute versions result in a higher sodium load and the rapid re-accumulation of ascites.

A few months later, your patient comes to the emergency department "feeling sick." He complains of diffuse abdominal pain and swelling, stating that his abdomen feels "tense." On examination, you find a pale, uncomfortable male with a temperature of 38.3°C. His other vital signs are normal. His abdomen is tense, distended, and diffusely tender with hypoactive bowel sounds. You perform a paracentesis that shows 400 polymorphonuclear leukocytes/mm³.

Question 7.12.7 What is the most appropriate next step in the evaluation and treatment of this patient?

- A) Discharge to home with increased doses of spironolactone and furosemide
- B) Discharge to home with amoxicillin and the same doses of diuretics
- C) Perform a large-volume paracentesis for symptomatic relief and discharge to home
- D) Admit to the hospital and start IV ceftriaxone
- E) Admit to the hospital and place a peritoneal tube for drainage

Answer 7.12.7 The correct answer is "D." This patient meets criteria for spontaneous bacterial peritonitis (SBP), which is diagnosed when the peritoneal fluid contains ≥ 250 polymorphonuclear leukocytes/mm³ and clinical findings suggest infection. This patient could become unstable quickly, so discharge from the emergency department is not recommended. Increasing doses of diuretics and/or large-volume paracentesis may be required, but these interventions should only be considered in the setting of hospital admission once the patient is stabilized. Beta-blockers, which may be used for portal hypertension, should be stopped; mortality is increased in SBP with continued use. Broad-spectrum antibiotics are the standard of care for SBP, and IV third-generation cephalosporins (e.g., ceftriaxone, cefotaxime) are typically the first-line agents in hospitalized patients. Levofloxacin is a good second-line agent, *but should not be used in those on levofloxacin prophylaxis as resistance is likely*. Amoxicillin ("B") is not sufficient.

In addition, albumin in the dose of 1.5 g/kg on day 1 followed by 1 g/kg on day 3 reduces the chance of renal failure, which occurs in 30% to 40% of patients with SBP. Albumin also

improves mortality and should be given to all patients with SBP. Also, send the ascitic fluid for culture. Blood cultures, CBC, serum chemistries, and PT/PTT should be obtained as well. Consider imaging the abdomen with ultrasound or CT. Further tests should be ordered as indicated.

**HELPFUL TIP:**

The most common organisms in SBP include *Streptococcus pneumoniae*, *E. coli*, and *Klebsiella*.

**HELPFUL TIP:**

Fluoroquinolones and TMP/SMX have been used prophylactically to decrease the frequency of SBP episodes. Prophylaxis is indicated in anyone with cirrhosis and either (1) an episode of SBP **or** (2) an ascitic fluid protein of <1.0 **or** (3) an active GI bleed. *For active GI bleeding in those with ascites, ceftriaxone or norfloxacin for 7 days has been shown to reduce SBP and mortality.* Consider SBP prophylaxis in those with an ascites protein of <1.5 g/dL, if the Cr >1.2 mg/dL or Na is <130 mg/dL, or the BUN >25 mg/dL or the bilirubin is >3 mg/dL.

► **Objectives: Did you learn to ...**

- Generate a differential diagnosis for ascites?
- Analyze ascitic fluid to determine potential causes of ascites?
- Initiate appropriate treatment for a patient with ascites?
- Diagnose and manage SBP?

► **CASE 7.13**

A 42-year-old male with known hepatitis C who is also a heavy drinker presents to your office because of increasing confusion. He hasn't noticed much of anything (hey, most of his life has been like this ...), but his family states that he is somewhat confused and on occasion difficult to wake up. He has a known history of end-stage liver disease. He recently decided to start a running regimen and has been "carb loading" on boxed mac and cheese.

Question 7.13.1 Which of the following is NOT a common cause of hepatic encephalopathy?

- A) GI bleeding
- B) Constipation
- C) High-carbohydrate diet
- D) Sepsis
- E) Alteration in gut flora

Answer 7.13.1 The correct answer is "C." High-carbohydrate diets are not associated with hepatic encephalopathy, but a high-protein diet is. Similarly, a GI bleed ("A") delivers a large protein load to the GI tract. **Thus, any patient with hepatic encephalopathy should be evaluated for a GI bleed.** Other causes of acute hepatic encephalopathy include constipation,

sedative use (e.g., benzodiazepines), and hypokalemic metabolic alkalosis.

**HELPFUL TIP:**

An elevated ammonia level is associated with hepatic encephalopathy, although there is not a direct linear correlation between serum ammonia level and mental status.

**HELPFUL TIP:**

While it's true a high protein diet *does* result in increased ammonia production in the gut, **DO NOT put your patient on a low protein diet.** Protein malnutrition is a predictor of mortality in patients with cirrhosis. The current recommendation is actually for a robust 1 to 1.5 gram per kg of dry weight (nonedematous, nonascitic state). Don't trade a short-term decrease in encephalopathy for a higher mortality rate.

You decide to admit the patient to the hospital for treatment of his hepatic encephalopathy.

Question 7.13.2 Which of the following IS NOT part of the standard treatment of hepatic encephalopathy?

- A) Oral lactulose
- B) Polyethylene glycol (e.g., GoLyteLy and Mira-Lax)
- C) Oral antibiotics
- D) Fluid and electrolyte management

Answer 7.13.2 The correct answer is "B." Polyethylene glycol does have some evidence for efficacy (*JAMA Intern Med.* 2014;174(11):1727–1733), but it is not currently the standard for treatment of hepatic encephalopathy and requires more study. There are concerns about excess volume depletion and electrolyte shifts. While polyethylene glycol and lactulose both increase bowel movements, the action of the drugs in the bowel differs. The mechanism of action of lactulose is dependent on bacterial metabolism of lactulose into lactic and acetic acids. This reduces the pH of the colon leading to precipitation of nonabsorbable ammonia in the colon, which reduces serum ammonia levels. **Enemas (soap suds, etc.), on the other hand, may help acutely** by removing colonic contents. "C" is of particular note. Oral antibiotics like rifaximin, metronidazole, or neomycin can be used when patients do not respond to lactulose or when lactulose is contraindicated (e.g., severe diarrhea). Rifaximin (though expensive) has become the standard in treating hepatic encephalopathy acutely and for chronic management. Neomycin is inexpensive (but also likely ineffective) and is only approved for episodic use. Metronidazole comes with risk of peripheral and central neurotoxicity.

The patient recovers his mental status on a regimen of lactulose and oral rifaximin.

Question 7.13.3 Which of the following problems do you need to worry about in this patient?

- A) Prolonged bleeding time
- B) Elevated PT/INR
- C) Thrombocytopenia
- D) A and B
- E) All of the above

Answer 7.13.3 The correct answer is “E.” Patients with end-stage liver disease tend to have a lack of vitamin K-dependent clotting factors (and thus elevated PT/INR and prolonged bleeding times) and have thrombocytopenia due to shunting of blood from the liver to the splanchnic bed because of elevated portal pressures. However, a platelet count of 50,000 is generally considered adequate for clotting. In addition, it is likely that there is platelet dysfunction in cirrhosis, although the clinical significance is not clear.

HELPFUL TIP:

The INR is not a great measure of coagulation in liver disease. Even when the INR is elevated, the patient may be hypercoagulable due to low levels of Protein C and Protein S, both synthesized in the liver. Thromboelastography (TEG), a measure of clot formation, or a fibrinogen level (which should be >120mg/dl) are better markers for whether the patient needs anticoagulation for an appropriate indication or is “autoanticoagulated” (data are limited). Unfractionated heparin can be used for DVT/PE, portal vein thrombosis in those with stable cirrhosis. This can be followed by a DOAC, LMWH or warfarin. Cirrhosis without varices does not increase bleeding risk. (Get the article free online: Gastroenterology July 2019 Volume 157, Issue 1, Pages 34–43.e1)

Several months after the index hospitalization, the patient returns with severe ascites and recurrent encephalopathy. Patient and family are adamant he is sober and adherent to diet and medication regimens.

Question 7.13.4 What evaluation needs to be done at this time?

- A) Diagnostic paracentesis
- B) Vascular ultrasound of the liver
- C) ETOH level
- D) All of the above

Answer 7.13.4 The correct answer is “D.” While nonadherence is a major concern, it is important to rule out SBP and evaluate for portal vein thrombosis (PVT). Patients with cirrhosis are at elevated risk for bleeding AND clotting. PVT is surprisingly common in those with cirrhosis (11% over 5 years). It can present as acute decompensation of chronic liver failure. Anticoagulation for *acute* PVT (fever, chills, abdominal pain, tender liver, acute decompensation) is indicated.

The benefit of anticoagulation in long-standing PVT, such as that found incidentally on ultrasound, is not defined. However,

in the non-cirrhotic patient portal thrombosis should prompt an evaluation for a hypercoagulable state (e.g., cancer). Long-term treatment with non-warfarin anticoagulants can be undertaken but increases bleeding episodes and has an uncertain benefit. There is a high risk of re-thrombosis when anticoagulation is stopped (39% in 6 weeks [*Clin Gastroenterol Hepatol.* 2012;10(7):776–783]).

After a few bowel movements the patient admits he has been skipping his lactulose (“Doc, even my dog won’t touch the stuff!”). During hospitalization, he underwent EGD which revealed him to have large esophageal varices. He is ready for discharge.

Question 7.13.5 Which of the options is/are indicated for this patient at the time of discharge, assuming he is hemodynamically stable?

- A) Nadolol
- B) Propranolol
- C) Carvedilol
- D) A or B
- E) Any of A, B, or C

Answer 7.13.5 The correct answer is “E.” All of the above are indicated in the further treatment of this patient. It should go without saying (but we’ll say it) that only one beta-blocker should be prescribed, not three. Nonselective beta-blockers (“A” and “B”) will reduce portal pressures, decreasing the risk of variceal bleeding. Recently, low-dose carvedilol, 3.125 to 6.25 mg PO BID, has been shown to be effective. Other selective beta-blockers should NOT be used in patients with varices.

Primary prophylaxis is indicated for medium or large varices or small varices with red wale sign (evidence of a recent bleed) on EGD or Child Pugh Class C. In patients *without* prior variceal bleed, primary prevention with one of the above beta-blockers is noninferior to *recurrent banding*. Patients who start beta-blockers do not need a follow-up EGD unless they have a bleed. Note that beta-blockers may need to be stopped or reduced if patient has renal insufficiency, systolic pressures <90 mm Hg, or other side effects like fatigue. Also note that nitrates for reducing portal pressures are out. They do reduce portal pressures but do not reduce bleeds.

HELPFUL TIP:

Prednisolone (40 mg/day) for 28 days then tapered over 2 to 4 weeks may have some benefit in severe alcoholic hepatitis. This is controversial as steroids can increase risk of sepsis and most of alcoholic hepatitis patients die of sepsis. In order to determine which patients with alcoholic hepatitis are candidates for corticosteroids, calculate the **discriminant function (DF)**. Simply measure prothrombin time and total bilirubin and plug the numbers into an online calculator (Qxmd.com). If the DF ≥ 32 , the patient may benefit from corticosteroid therapy.

Unfortunately, between hospital admissions, the patient continues to drink. You next admit him when he presents vomiting blood. There is clear concern for a variceal bleed in spite of adherence to his beta-blocker regimen. Two large-bore IVs are placed and aggressive volume resuscitation is initiated.

Question 7.13.6 Which of the following medications should be started in this patient?

- A) Octreotide
- B) IV Proton pump inhibitor
- C) Ceftriaxone
- D) A and B
- E) All of the above

Answer 7.13.6 The correct answer is “E,” all of the above. Octreotide is a somatostatin analog and will decrease the amount of blood going to the intestinal (splanchnic) circulation. This means less blood to go to the portal vein and up the collaterals to the bleeding vessels. A PPI should be started to cover for possible ulcer disease in this briskly bleeding patient. Start ceftriaxone for SBP prophylaxis (which will also reduce rebleeding).

HELPFUL TIP:

The goal hemoglobin in patients with acute variceal bleed is 7 to 9 g/dL. Higher transfusion targets result in higher rates of rebleeding.

The patient survives the initial bleed and appears to be recovering. Guidelines suggest placing a transjugular intrahepatic portosystemic shunt (TIPS) within 72 hours to help reduce portal pressures, prevent the re-accumulation of ascites, and hopefully prevent further bleeding (*Hepatology*. 2017;65(1):31–35).

Question 7.13.7 Which of the following statements best reflects the status of TIPS?

- A) TIPS unequivocally worsens survival from end-stage liver disease
- B) TIPS is associated with an increased risk of hepatic encephalopathy
- C) Once placed, TIPS remains effective for at least 3 years
- D) TIPS is only indicated for waiters, bar tenders, baristas, and cab drivers

Answer 7.13.7 The correct answer is “B.” TIPS is effective in controlling variceal bleeding and may help ascites by reducing portal pressures. It is clearly indicated in this patient, but is not an entirely benign procedure. TIPS is clearly associated with an increased risk of hepatic encephalopathy; the effect on mortality in patients after a bleed when compared to a beta-blocker is still not well-studied. “A” is incorrect. In fact, there may be some survival advantage to TIPS in those who are at high risk but have never had a variceal bleed (not standard of care but you may see it done [*Hepatology* 2019;69(1):282–293]). “C” is incorrect

because TIPS shunts tend to clot and may need to be evaluated for patency by Doppler if ascites re-accumulates or other symptoms occur. Newer devices, however, tend to clot off less often.

HELPFUL TIP:

Over-diuresis can lead to hepatorenal syndrome, which is characterized by oliguric renal failure. Sepsis, GI bleeding, etc., can also lead to hepatorenal syndrome. The mechanism has more to do with altered circulation to the kidneys from hepatic disease than with the diuresis itself.

► **Objectives: Did you learn to ...**

- Recognize causes of hepatic encephalopathy and identify patients at risk?
- Manage a patient with hepatic encephalopathy?
- Discuss risks and benefits of TIPS and large-volume paracentesis?

QUICK QUIZ: AUTOIMMUNE LIVER DISEASE

Which of the following is a marker for primary biliary cirrhosis?

- A) Antimitochondrial antibodies (AMA)
- B) Antismooth muscle antibodies
- C) Alpha-1 antitrypsin
- D) Polyclonal antibodies on serum protein electrophoresis

The correct answer is “A.” Antimitochondrial antibodies are found in primary biliary cirrhosis (95% sensitive and 98% specific). “B,” antismooth muscle antibodies, are found in autoimmune hepatitis. “C,” reduced levels of alpha-1 antitrypsin, are found in hepatitis from alpha-1 antitrypsin deficiency (surprise!). “D,” polyclonal antibodies, are found in autoimmune hepatitis.

Autoimmune liver disease encompasses multiple etiologies including primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune hepatitis. Immune infiltrates feature prominently on biopsy in drug-induced liver injury. Other causes of liver disease, including NASH and alcohol abuse, can be associated with positive ANA and antismooth muscle antibodies leading to diagnostic uncertainty. In these cases, biopsy is reasonable.

CASE 7.14

A 31-year-old man comes to your office for evaluation of “abnormal liver tests.” He had labs for disability insurance and the following was noted: elevated total bilirubin (2.1 mg/dL) with normal direct bilirubin. AST, ALT, GGT, albumin, and alkaline phosphatase are normal. A CBC obtained at that time was unremarkable.

The patient feels generally well. When you ask about jaundice, he recalls that once when he was sick with the “flu” while in college, his roommate told him that he “looked a little

yellow.” He went to the student health service a few days later when he felt better and was told there was nothing to be concerned about. He drinks 6 to 8 beers/week and takes ibuprofen once or twice a month for knee pain.

Physical examination is unremarkable. A repeat liver panel shows a total bilirubin of 2.4 mg/dL with normal conjugated (direct) bilirubin, an elevated unconjugated (indirect) bilirubin, and normal AST, ALT, and alkaline phosphatase. CBC and reticulocyte count are also normal. A blood smear, LDH, and haptoglobin are normal.

Question 7.14.1 The most likely diagnosis is:

- A) Crigler–Najjar syndrome type I
- B) Choledocholithiasis
- C) Gilbert syndrome
- D) Hemolytic anemia
- E) Occult acetaminophen abuse

Answer 7.14.1 The correct answer is “C.” Gilbert syndrome is the most common inherited disorder of bilirubin metabolism, affecting up to 5% of Caucasians. It is characterized by isolated mild unconjugated (indirect) hyperbilirubinemia, with serum bilirubin levels usually less than 3 mg/dL. However, bilirubin levels in patients affected with Gilbert syndrome can increase with fasting or during febrile illnesses, though rarely exceeding 6 mg/dL. Crigler–Najjar syndrome type I is a rare disorder leading to severe unconjugated neonatal jaundice and neurologic impairment due to kernicterus. Both choledocholithiasis and acetaminophen hepatotoxicity would be unlikely to cause an isolated increase in unconjugated bilirubin; the LFTs should be elevated with these. The normal blood smear, reticulocyte count, normal LDH, and normal haptoglobin make significant hemolysis unlikely. Thus, this presentation is most consistent with Gilbert syndrome.

Several months later, the patient’s older sister comes to see you. She had gone to a local health fair where screening liver tests were found to be abnormal. She recalled her brother mentioning something about a familial problem causing liver test abnormalities and wonders if she has the same thing.

She is 39 years old with good general health, although she wishes she could lose weight. She says she has been 30 to 40 lb overweight for at least 10 years and is now at her heaviest weight ever. She is a nonsmoker, who takes no medications and drinks no alcohol. She denies any risk factors for viral hepatitis.

Physical examination reveals an obese woman. Blood pressure is 138/88 mm Hg; BMI is 35 kg/m². There is no scleral icterus or other cutaneous stigmata of chronic liver disease. The abdomen is protuberant with the liver edge palpable about 3 to 4 cm below the right costal margin and is slightly tender to palpation. There is no splenomegaly and no evident ascites.

Her liver panel from the health fair 3 months ago shows the following: ALT 87 IU/L (normal range, 0–20), AST 53 IU/L (0–31), alkaline phosphatase 110 IU/L (30–115), total

protein 7.8 g/dL (6.0–8.0), albumin 4.2 g/dL (3.3–5.0), total bilirubin 0.9 mg/dL (0.2–1.0), and conjugated (direct) bilirubin 0.1 mg/dL (<0.2).

Question 7.14.2 Appropriate steps at this time include all of the following EXCEPT:

- A) Repeat the liver panel
- B) Counsel the patient that her labs suggest Gilbert syndrome
- C) Counsel the patient regarding weight loss
- D) Recommend a serologic evaluation to assess for chronic viral and autoimmune hepatitis if the liver test abnormalities persist
- E) Right upper quadrant ultrasound

Answer 7.14.2 The correct answer is “B.” As discussed above, Gilbert syndrome is defined by *isolated* unconjugated hyperbilirubinemia. This patient’s pattern of liver test abnormalities with aminotransferase elevations clearly indicates a different type of problem. If these abnormalities persist, an evaluation for causes of chronic aminotransferase elevations is warranted (see differential earlier in this chapter of elevated liver enzymes). Chronic viral hepatitis and autoimmune hepatitis would be among the diagnostic considerations. Given the apparent hepatomegaly and tenderness on physical examination, an imaging study of the liver is also indicated.

The repeat liver panel is remarkable for ALT 129 IU/L and AST 76 IU/L. The other tests are normal. HBsAg and HCV antibody are negative. Antinuclear and antismooth muscle antibodies are <1:40 (normal). The ultrasound examination shows an enlarged liver with increased echogenicity, suggestive of diffuse fatty infiltration.

Question 7.14.3 Regarding nonalcoholic fatty liver disease (NAFLD), or nonalcoholic steatohepatitis (NASH), all of the following are true EXCEPT:

- A) It is frequently associated with one or more features of the metabolic or insulin resistance syndrome
- B) It is more common in women than men
- C) The histologic features can closely mimic those of alcoholic hepatitis
- D) It may cause cirrhosis in a minority of patients

Answer 7.14.3 The correct answer is “B.” NAFLD prevalence is two times higher in men than in women and is among the most common causes of elevated liver enzymes. NAFLD refers to a spectrum of histologic findings that range from simple steatosis to an aggressive injury pattern. NAFLD often occurs in association with obesity, dyslipidemia, and/or glucose intolerance, hypothyroidism, and occurs more commonly in men than women. While most patients with NAFLD will not develop progressive liver disease, a minority are at risk to develop cirrhosis. However, due to its high prevalence in our population (thank you, fast food nation!), NAFLD/NASH is now the most common cause of cirrhosis and second only to hepatitis C for liver transplant.

**HELPFUL TIP:**

Vitamin E 800 IU BID has been shown to be helpful in *nondiabetics* with biopsy proven NASH (*N Engl J Med.* 2010;362:1675). However, Vitamin E is not benign and may contribute to excess mortality overall. Given the association between NAFLD and metabolic syndrome, many patients warrant statin therapy. Transaminitis from NASH is **not** a contraindication to statin use, though statins should be avoided in decompensated cirrhosis. Pioglitazone has been shown to reverse NASH histology in diabetics with biopsy-proven NASH.

**HELPFUL TIP:**

In France, they force-feed geese to produce fatty liver (Foie Gras). In the United States, we do it to ourselves...

Question 7.14.4 In this patient with NAFLD, all of the following are appropriate actions EXCEPT:

- A) Obtain a fasting lipid panel
- B) Obtain fasting serum glucose
- C) Recommend weight loss to get her BMI to the normal range
- D) Start ursodeoxycholic acid

Answer 7.14.4 The correct answer is “D.” Weight loss, including from gastric surgery, can improve NAFLD. However, too rapid weight loss may be counterproductive in the setting of NAFLD, as mobilization of peripheral fat stores may worsen hepatic steatosis. Also, addressing underlying metabolic illnesses (e.g., diabetes and hypothyroidism) would be important elements in the treatment. Treating hyperlipidemia and diabetes can also improve NAFLD. Ursodeoxycholic acid has been shown to be ineffective in NAFLD as has metformin. Evidence for statin use to treat NASH is mixed, but many patients with NASH warrant statin therapy (see the following).

Question 7.14.5 Which of the following are acceptable options for assessing fibrosis score in NAFLD?

- A) NAFLD fibrosis score (NFS)
- B) Elastography
- C) Liver biopsy
- D) FIB-4
- E) All of the above

Answer 7.14.5 The correct answer is “E.” While liver biopsy is the gold standard, it is generally not required. The role of liver biopsy is primarily in patients with possible alternative diagnosis (very elevated iron studies, positive antismooth muscle or ANA, etc.). “A” and “D” are both noninvasive scores using easily obtained labs and patient data. The NAFLD fibrosis score (NFS) takes into account the patient’s age, BMI, glucose, platelet count, albumin, and transaminase levels. The Fibrosis-4 (FIB-4) includes transaminase levels, platelet count, and age. Both NFS and FIB-4 are useful to categorize patients as low-to-moderate fibrosis (F1-2) or near cirrhosis and cirrhosis (F3-4) (see mdcalc.com). “B,” elastography, was discussed previously and is useful in determining fibrosis levels in NAFLD as well as HCV infection. Higher fibrosis scores require additional management including surveillance for HCC and esophageal varices.

► **Objectives: Did you learn to ...**

- Evaluate a patient with abnormal liver tests?
- Recognize the clinical and laboratory presentation of Gilbert syndrome?
- Describe findings of nonalcoholic liver disease?
- Manage a patient with fatty liver disease?

► **CASE 7.15**

A 70-year-old female presents to the emergency department complaining of mid-epigastric pain associated with vomiting. This started approximately 12 hours ago and now she notes vomiting, fever, and myalgia. Her vital signs are blood pressure 110/70 mm Hg, pulse 115 bpm, and temperature 38.5°C. On examination, the patient is quite tender in the mid-epigastric region with guarding and some rebound. Her past history is significant for lone atrial fibrillation and a seizure disorder. Her only medication is phenytoin.

Question 7.15.1 Your next steps in the diagnosis of this patient should include all of the following EXCEPT:

- A) Chest radiograph
- B) CBC
- C) Liver enzymes
- D) Abdominal CT with contrast
- E) Amylase

Answer 7.15.1 The correct answer is “D.” An abdominal CT is not indicated in this patient as part of the initial workup. “A,” an upright chest radiograph, is the single best *plain* radiograph for finding free abdominal air and is indicated for this reason. In addition, the etiology of abdominal pain may also include pneumonia (especially consider this in the elderly) and other thoracic pathology that may be evident on a chest radiograph. Liver enzymes, amylase, and CBC are indicated since mid-epigastric pain with fever can be related to pancreatitis, acute cholecystitis, etc.

Her chest x-ray is normal and her laboratory results are as follows: elevated AST and ALT (both mild), normal amylase, mildly elevated white count (13.5×10^3 cells/mm³), and elevated GGT.

Question 7.15.2 The correct interpretation of these results is:

- A) The patient does not have pancreatitis
- B) The elevated GGT is specific for biliary outlet obstruction
- C) The elevated AST and ALT may indicate biliary outlet obstruction
- D) None of the above

Answer 7.15.2 The correct answer is “C.” Early in the course of biliary outlet obstruction (e.g., biliary colic and common duct stone), AST and ALT may be mildly elevated. “A” is incorrect because amylase is only 80% sensitive for pancreatitis, meaning 20% of patients with pancreatitis have a normal amylase—a false-negative test. “B” is incorrect because GGT is nonspecific. GGT helps differentiate biliary tract disease from bony disease, but is an inducible enzyme and can be elevated in response to alcohol and various medications including phenytoin.

HELPFUL TIP:

In alcohol-related liver disease, AST is generally twice the level of the ALT. Part of this is due to decreased breakdown of AST, and part of this is from mitochondrial toxicity and AST leak from skeletal muscle. Rhabdomyolysis will also present with elevated AST-to-ALT ratio. When you encounter an elevated AST-to-ALT ratio, consider checking CK—in the right clinical scenario, of course.

We still don’t know what is causing this patient’s pain. You consider your differential. The patient has a history of atrial fibrillation and is not on anticoagulation (appropriately, given her CHA2-DS2-VASc score). You are concerned that there may be bowel ischemia from an embolism.

Question 7.15.3 Which of the following is true of mesenteric thrombosis and bowel ischemia?

- A) Patients generally have guarding and rebound early in the course
- B) The pain is out of proportion to the examination and patients may have a normal initial examination
- C) A serum lactate level is helpful and specific for the diagnosis of bowel ischemia
- D) The best study to diagnose this disease entity is CT with contrast

Answer 7.15.3 The correct answer is “B.” Patients with small bowel ischemia from either embolism or mesenteric thrombosis will generally present with severe abdominal pain and an examination that is unremarkable. Late in the course there will be guarding, rebound, and other peritoneal signs as the bowel perforates. However, early in the course of the illness, severe pain with a relatively benign examination is consistent with the presentation of bowel ischemia. “A” is incorrect for the reasons stated above. “C” is incorrect because the serum lactate can be elevated in a number of states, not just bowel ischemia. However, abdominal pain plus lactic acidosis should raise the suspicion that there may be bowel ischemia. “D” is incorrect because radiographic findings on CT scan are present in only about 65% of patients with mesenteric thrombosis/embolism. The **best** study remains angiography or CT angiography, which has largely replaced traditional angiography.

Since the patient’s examination includes guarding and rebound that is not out of proportion to your exam, you put the diagnosis of bowel ischemia lower in your list of possibilities. Based on the elevated white count, ALT and AST, you order an ultrasound of the right upper quadrant, which shows evidence of a common duct stone. There is thickening of the gallbladder wall but no pericolic fluid noted. You decide that there is a mild cholecystitis and want to admit the patient to the hospital. Clearly, this patient needs to be started on antibiotics.

Question 7.15.4 Which antibiotic is the most appropriate choice for this patient?

- A) IV clindamycin
- B) IV vancomycin
- C) IV gentamicin
- D) IV ampicillin/sulbactam

Answer 7.15.4 The correct answer is “D.” The most appropriate antibiotic choice of those provided is ampicillin/sulbactam (Unasyn). The main organisms that need to be covered are Gram-negative organisms and anaerobes (*E. coli*, *Enterococcus*, *Klebsiella*, and *Enterobacter*). Ampicillin/sulbactam will cover all of these organisms. You might also choose piperacillin/tazobactam (Zosyn), which includes pseudomonal coverage, or metronidazole with either ceftriaxone or levofloxacin. “A” is incorrect because clindamycin covers Gram-positive organisms and anaerobes, but does not cover most Gram-negative organisms. In addition, many enterococci are resistant to clindamycin. “B” is incorrect because vancomycin only covers Gram-positive organisms and even then it is a relatively weak antibiotic for such (e.g., mortality is higher for MSSA than with nafcillin). “C” is incorrect because gentamicin does not cover anaerobic organisms. Other antibiotic options for treating this patient include cefotetan and cefoxitin, among others.

The patient is admitted to the hospital. She is treated with ampicillin/sulbactam, IV fluids, and pain medication.

Question 7.15.5 The next step for this patient is:

- A) Percutaneous “T” tube placement to drain the gallbladder
- B) 2 weeks of IV antibiotics followed by cholecystectomy
- C) Endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy
- D) Lithotripsy

Answer 7.15.5 The correct answer is “C.” The patient should have an ERCP with sphincterotomy in an attempt to retrieve the stone in her common bile duct. “A” is incorrect because in this healthy patient, percutaneous drainage would certainly be a third-line procedure. “B” is incorrect because the patient essentially has a closed abscess (the gallbladder blocked by a stone), which requires drainage. If the patient had cholecystitis **without** obstruction, prolonged antibiotics followed by cholecystectomy would be an option—but not the best one. In patients with cholecystitis without obstruction, outcomes are

overall better with an early cholecystectomy. “D” is also incorrect and would be a less desirable approach than is ERCP with sphincterotomy.

HELPFUL TIP:

Studies have shown improved outcome in patients with severe gallstone pancreatitis and/or cholangitis that receive early (within 72 hours after admission) ERCP with biliary sphincterotomy.

The ERCP is successful but the patient develops worsening pain in the mid-epigastric region.

Question 7.15.6 Which of the following is the most common adverse consequence of ERCP?

- A) Pancreatitis
- B) Contrast allergy
- C) Perforation
- D) Bleeding
- E) Sepsis

Answer 7.15.6 The correct answer is “A.” Of the complications listed, pancreatitis is the most common, with an incidence of about 5% of patients after ERCP. In fact, elevations in pancreatic enzymes (mostly not significant) occur in up to 75% of patients post-ERCP. The others are less common and in order of descending incidence are bleeding, perforation, sepsis, and contrast allergy (rare).

Although you suspect that this patient has pancreatitis secondary to the ERCP, you also consider other potential causes of pancreatitis.

Question 7.15.7 All of the following are causes of pancreatitis EXCEPT:

- A) Viral infection
- B) HMG-Co A reductase inhibitors (statins)
- C) Alcohol
- D) Indinavir
- E) Bee stings

Answer 7.15.7 The correct answer is “E.” The most common causes of acute pancreatitis in the United States are ethanol ingestion, biliary tract disease, and endoscopic procedures with biliary tract disease. “A” is true. Common viruses that can cause pancreatitis include HIV, hepatitis viruses, EBV, and Coxsackieviruses. “B” and “D” are true. Many other drugs can also cause pancreatitis: of note are didanosine, some diuretics, some NSAIDs, some antibiotics, etc. See Table 7-5 for more on drugs that cause pancreatitis. The venom of a scorpion sting can result in pancreatitis, as can brown recluse spider bites but not bee stings (OK, there are one or two cases with wasps).

TABLE 7-5 DRUGS ASSOCIATED WITH PANCREATITIS

Drugs with Definitive Association	Drugs with Probable Association
Thiazide diuretics	Acetaminophen
Sulfonamides	Salicylates
Azathioprine	Metronidazole
6-Mercaptopurine	Nitrofurantoin
Furosemide	Erythromycin
Estrogens	NSAIDs
Tetracycline	ACE inhibitors
Valproic acid	Methyldopa
Pentamidine	Steroids
Valproic acid	
Dideoxyinosine	

The patient unfortunately develops worsening pancreatitis from the ERCP. You have the patient’s pain well managed with morphine. However, over the next couple of days, her condition worsens. The patient begins to vomit and have increased pain as well as tachycardia and fever. Repeat labs are pending.

Question 7.15.8 Which of the following are helpful in assessing prognosis?

- A) Hematocrit
- B) BUN
- C) SIRS criteria
- D) All of the above

Answer 7.15.8 The correct answer is “D.” Scores including the Ranson (no longer used), APACHE II, and newer scores like the Bedside Index of Severity in Acute Pancreatitis are not particularly helpful as early prognostic tools. They basically tell you that sick patients are sick after they are sick! Markers of severity include elevated or rising BUN, creatinine and/or hematocrit, and SIRS criteria and help identify who is sick without the cumbersome scoring of the Ranson criteria. Evidence of organ dysfunction, pleural effusions, pulmonary infiltrates, and altered mental status all suggest a more severe disease state. Patients with persistent tachycardia or tachypnea warrant close monitoring in the ICU including vitals, I’s and O’s, and serial evaluation for other organ system failure.

Baseline characteristics including advanced age (>55 years old), elevated BMI, and multiple comorbidities are associated with worse outcomes, and clinicians should remain vigilant in these patients.

HELPFUL TIP:

Fluid resuscitation in acute pancreatitis is important. Aggressive fluid resuscitation in the first 24 hours has been associated with reduced morbidity and mortality. Some experts recommend up to 5 to 10 mL/kg/hour with either normal saline or lactated ringers. In such patients—as with all patients with acute

pancreatitis—fluid status must be monitored frequently, and fluids adjusted as the clinical scenario dictates.

There are concerns about the patient's nutrition status. A spirited debate erupts on rounds regarding route, type, and timing of nutrition with a rather gray-haired doctor droning on about central venous nutrition (CVN).

Question 7.15.9 Which of the following IS NOT a complication of CVN?

- A) Infection
- B) Cholestasis
- C) Hypoglycemia
- D) Ileus

Answer 7.15.9 The correct answer is “D.” Infection, cholestasis, and hypoglycemia can all be a result of CVN. Hypoglycemia generally occurs when stopping CVN because of increased levels of circulating insulin. This can be mitigated by tapering CVN or administering IV dextrose.

HELPFUL TIP:

In acute pancreatitis, enteral nutrition is preferred. CVN is now discouraged unless absolutely necessary. Increasingly, early feeding in the first 24 hours with a low-fat diet is gaining traction over waiting 24 hours and advancing from a clear liquid diet. Refeed patients early who are free of nausea/vomiting (and other signs of ileus) and have decreasing pain and improving inflammatory markers (*Curr Opin Gastroenterol.* 2018;34(5):330–335). Early refeeding is not harmful and decreases bowel permeability and bacterial translocation to the circulation.

Since the patient has continued to do poorly, you order a CT scan of the abdomen that shows evidence of a pseudocyst.

Question 7.15.10 Which of the following IS NOT true about a pancreatic pseudocyst?

- A) Pseudocysts occur in 10% of patients with pancreatitis
- B) Pseudocysts can be drained by forming a fistula with the stomach endoscopically
- C) Pseudocysts can lead to the formation of arterial pseudoaneurysms that can cause severe bleeding
- D) Open drainage is the preferred method of treatment
- E) Not all pseudocysts require drainage

Answer 7.15.10 The correct (and untrue) answer is “D.” The formation of a fistula with the stomach using an endoscope (“B”) is actually the preferred method of drainage. The one major contraindication to endoscopic treatment is a pseudoaneurysm (“C”). Injury to an artery can cause significant bleeding that is

difficult to control. Not all pseudocysts may require drainage (“E”) and can be observed.

HELPFUL TIP:

CT scan can be used to look for a pseudoaneurysm before endoscopic drainage. An aneurysm should also be suspected in these circumstances: evidence of an upper GI bleed, a drop in the HCT, or a sudden expansion of the pseudocyst. Uncomplicated pseudocysts can be observed with serial imaging. Indications for drainage include infection, a rapidly enlarging cyst, or patients who are symptomatic from the pseudocyst. It is best to let the pseudocyst “mature” to have a well-defined “wall” for several weeks before drainage.

► **Objectives: Did you learn to ...**

- Recognize and diagnose mesenteric thrombosis?
- Identify causes of acute pancreatitis?
- Diagnose and manage a patient with acute pancreatitis?
- Manage the complications of pancreatitis?
- Describe some side effects of parenteral nutrition in a hospitalized patient?
- Describe the principles of narcotic choice in patients with pancreatitis?

QUICK QUIZ: GALLSTONES

A 40-year-old female presents to you with gallstones found on a “full body CT scan” performed at Live4Ever Imaging Technologies, Inc. She is anxious that she will become sick like her sister who had an emergent cholecystectomy for her gallstone pancreatitis. She asks you if she should have her gallbladder removed. She is asymptomatic and her liver enzymes are normal.

Which of the following should you recommend?

- A) Laparoscopic cholecystectomy because of family history of severe gallstone pancreatitis
- B) Ultrasound to confirm gallstones and to check for common bile duct stones
- C) No treatment or follow-up is needed unless she develops symptoms
- D) ERCP with sphincterotomy to allow stones to pass without obstructing common bile duct or compressing pancreatic duct
- E) Recheck liver enzymes and if elevated recommend cholecystectomy

The correct answer is “C.” Asymptomatic gallstones do not need special attention since 70% to 80% remain asymptomatic. Only 2% to 3% of patients will present with acute cholecystitis or other complications and therefore prophylactic cholecystectomy is not indicated. American-Indian populations have high risk of stone-associated gallbladder cancer and are an exception to this rule. Diabetics or sickle cell disease patients have higher

risk of complications from gallstones but still **should not** have their gallbladder removed if asymptomatic. Family history of complication from gallstones is not an indication for prophylactic cholecystectomy.

► CASE 7.16

A 58-year-old woman with type 2 diabetes mellitus comes to your clinic with nausea, vague epigastric abdominal pain, bloating, early satiety, and intermittent vomiting for 3 weeks. Her past medical history is significant for hypertension and hyperlipidemia and her diabetes is complicated by retinopathy and neuropathy. She is on metformin, glyburide, lisinopril, aspirin, and atorvastatin.

She is afebrile and not ill appearing on examination. She has gained 5 kg in the last year. She has mild epigastric tenderness without rebound or guarding. Bowel sounds are normal and there is no abdominal distention. Laboratory results show normal CBC and differential with HbA1c of 9.4%. You suspect diabetic gastroparesis.

Question 7.16.1 Which statement is FALSE regarding diagnosis of gastroparesis?

- A) On scintigraphy (gastric emptying study) >60% of the standard meal present in stomach at 2 hours suggests gastroparesis
- B) On scintigraphy >10% of the standard meal present in the stomach at 4 hours suggests gastroparesis
- C) EGD looking for evidence of food after an uncontrolled restaurant meal is a good test for diagnosing gastroparesis
- D) Gastroparesis can be diagnosed by exhaled radiolabeled CO₂ measurement

Answer 7.16.1 The correct answer (the false statement) is "C." Simply looking for retained gastric contents at an unspecified time after an unspecified ingestion is not the way to diagnose gastroparesis. The most widely used test for diagnosing gastroparesis is radionuclide scan. The patient is given standardized meal containing 99m technetium sulfur colloid in low-fat eggs, and nuclear activity is measured at 2 and 4 hours, respectively. If radioactivity in the stomach is >60% at 2 hours or >10% at 4 hours, the patient is considered to have delayed gastric emptying. You can do a liquid phase gastric emptying study if you suspect dumping syndrome, but it is not a test for gastroparesis. "D," radiolabeled CO₂ breath test, correlates well with nuclear scintigraphy and is easier to perform in the community setting. However, a radiolabeled CO₂ breath test requires normal small bowel, pancreas, liver, and lung function.

You order a radionuclide gastric emptying study, and it shows that 75% of the meal was present in the stomach at 2 hours and 20% at 4 hours. You diagnose gastroparesis.

Question 7.16.2 The best long-term treatment option for her is:

- A) Cisapride
- B) Domperidone

- C) Erythromycin
- D) Metoclopramide
- E) Improved glucose control

Answer 7.16.2 The correct answer is "E." The treatment of diabetic gastroparesis is often difficult and frustrating for patients and clinicians. Although not proven in prospective trials, most experts believe improved glucose control with dietary and lifestyle modification is the key to long-term success in diabetic gastroparesis. All of the above medications ("A"–"D") have shown benefit in the *short term* to reduce symptoms associated with diabetic gastroparesis. Cisapride was removed from the market because of prolongation of the QT interval. Domperidone is not available in the United States and causes a prolonged QT interval but is used in other countries for gastroparesis. Erythromycin and metoclopramide are effective and available. However, both can cause cramps, and erythromycin can cause nausea, prolonged QT interval, and often rapidly becomes ineffective (tachyphylaxis), while metoclopramide may cause tardive dyskinesia, dystonia, and a prolonged QT. Other macrolides are not effective. Liquid metoclopramide is suggested for gastroparesis and seems to work better than tablets (leaves the stomach faster and is better absorbed).

You add insulin to the diabetic regimen in an attempt to tighten glucose control and prescribe metoclopramide 5 mg, 30 minutes before meals.

Question 7.16.3 In addition to this you recommend all of the following dietary and life style modifications EXCEPT:

- A) Increase dietary fiber
- B) Change from four large to six small meals daily
- C) Moderate exercise
- D) Decrease dietary fat
- E) ADA 1,800 kcal diet

Answer 7.16.3 The correct answer is "A." Fiber and raw vegetables can form gastric bezoars (phytobezoar) in gastroparesis and this is often seen on endoscopy. Bezoars cause early satiety and bloating and add to the symptom burden of gastroparesis. If a bezoar is found, it can be dissolved using cellulase (Kanalase[®]) or mechanically broken up. More frequent, smaller meals help with symptoms; and moderate exercise can be helpful but excessive exercise may slow gastric emptying. Your patient is gaining weight, so it is important to reinforce the ADA diet. Fat slows gastric emptying; therefore, dietary fat should be reduced to less than 40 g/day.

Question 7.16.4 Which of the following medications can exacerbate preexisting gastroparesis?

- A) Fluoxetine
- B) Oxycodone
- C) Angiotensin converting enzyme (ACE) inhibitors
- D) Metformin
- E) Insulin

Answer 7.16.4 The correct answer is “B.” Oxycodone and all narcotics reduce GI motility and are rarely tolerated by patients with gastroparesis. This can be clinically challenging, and attention to the cause of pain and alternative management options should be explored. Fluoxetine does not have significant effects on gastric motility, but tricyclic antidepressants and other drugs with anticholinergic activity do and are not good options for pain syndromes in gastroparesis. ACE inhibitors do not affect GI motility. Although metformin is associated with GI side effects, it does not affect GI motility. Insulin has no adverse effect on GI motility. Other medications that reduce gastric emptying are dopaminergic agents, antiadrenergic antihypertensives, calcium channel blockers, and anticholinergic agents. All drugs known to affect gastric motility should be stopped prior to obtaining a gastric emptying study.

HELPFUL TIP:

There are multiple causes of gastroparesis other than diabetes. Some of these include: postviral syndrome after gastroenteritis (may persist for >1 year), thyroid disease, neurologic diseases, and autoimmune diseases. Forty percent of gastroparesis is idiopathic. So, consider this in your differential of the patient with any of the following: postprandial fullness, upper abdominal pain, nausea, vomiting, early satiety, and regurgitation of food hours after intake (yum!).

► Objectives: Did you learn to ...

- Diagnose gastroparesis?
- Identify medications that can exacerbate gastroparesis?
- Manage gastroparesis?

QUICK QUIZ: GI BLEED

You admit a 65-year-old woman with end-stage renal disease on hemodialysis. She is being admitted because of recurrent episodes of melena requiring transfusions. She is anemic with low ferritin, iron, and iron saturation. The gastroenterologist performs an upper and lower endoscopy without any bleeding source found. Subsequently, a capsule enteroscopy shows multiple small angiodysplasias throughout the small bowel, without any large, endoscopically treatable lesions.

Your patient is discharged after a blood transfusion. Her hemoglobin is 11 g/dL. At follow-up 1 month later, her hemoglobin is 9 g/dL. The patient is on maximum doses of erythropoietin with dialysis and is still having guaiac positive stools. She refuses to take oral iron because of constipation.

Which of the following is the next best step in the management of this case?

- Prescribe iron dextran or sucrose IV with dialysis to maintain her iron stores
- Try to convince the gastroenterologist to repeat the endoscopy and treat any angiodysplasia lesions that can be reached

- Prescribe octreotide
- Order a Meckel scan
- Prescribe estrogen–progesterone

The correct answer is “A.” This is an appropriate situation for the administration of IV iron. It is safer than blood transfusions and can be given on an outpatient basis during hemodialysis. There are rare occurrences of anaphylaxis with iron dextran, and a test dose should be given. Some reports suggest iron sucrose is safer. “B,” repeat endoscopies with treatments of angiodysplasias, may help but should be adjunctive therapy to maintenance of iron stores. The scope only reaches the proximal jejunum and the patient has lesions throughout the small bowel. “C,” octreotide, has been reported in case series to have a beneficial effect, but no randomized trials have been performed and it cannot be recommended at this time. “D,” a Meckel scan (done to look for Meckel diverticula), would be redundant as another cause has been found and the patient does not fit the most likely age group. “E,” hormone replacement therapies initially seemed effective at reducing bleeding from angiodysplasia but randomized trials failed to show benefit.

HELPFUL TIP:

Angiodysplasias are commonly missed and are associated with increasing age, end-stage renal disease, aortic stenosis, hereditary telangiectasias (autosomal dominant), and are more likely to bleed in patients on long-term anticoagulation and antiplatelet therapies. Other commonly missed lesions include Cameron lesions (small ulcers caused by rubbing of hiatal hernia sac against diaphragm) and peptic ulcer disease.

HELPFUL TIP:

Capsule endoscopy of the small bowel using a small camera can be helpful if a small bowel follow-through does not show a source of bleeding. Other possible studies include tagged red blood cell (RBC) scan and angiography, but these are only really useful in overt bleeding. The tagged RBC scan needs 0.1 mL/min bleeding rate and angiography requires 0.5 mL/min bleeding rate to detect bleeding sites. Finally, double balloon enteroscopy can allow visualization and treatment of small bowel lesions.

QUICK QUIZ: HEMATOCHESIA

A 30-year-old female comes to your clinic with the complaint of intermittent blood on toilet paper for 3 years. She says she always has been constipated and takes polyethylene glycol (MiraLax) on regular basis. She has no family history of colorectal cancer and is asymptomatic and has no weight loss. On examination, she does not appear anemic and abdominal examination is normal. Rectal examination is normal and nontender. Anoscopy is normal.

What is the most appropriate action?

- A) Reassurance
- B) Hydrocortisone suppositories three times/week for 6 weeks; follow up as needed
- C) Flexible sigmoidoscopy
- D) Colonoscopy
- E) Anorectal manometry

The correct answer is "C." The message is that everybody reporting persistent blood in stools without lesions seen on anoscopy warrants endoscopic evaluation. Colon cancer is rare in this age group but can happen. The symptom of red blood per rectum suggests that the cause could be found distal to descending colon and likely in the rectum. If there is only a single episode of bleeding, some would argue for a more conservative approach in patients less than 50 years of age without other alarm symptoms (constitutional symptoms or change in bowel habits). In this young patient, a full colonoscopy is not necessary unless there is a strong family history of colorectal cancer or other symptoms suggestive of colitis such as urgency, weight loss, or diarrhea. Anorectal manometry is not useful in the evaluation of rectal bleeding. Hydrocortisone suppositories can be helpful in reducing pain associated with hemorrhoids, but if bleeding is the only symptom, fiber supplements and stool softeners are sufficient. If the patient is older than 50 years with rectal bleeding, full colonoscopy is indicated.

▶ CASE 7.17

A 73-year-old male comes to your office with a 3-day history of left lower quadrant abdominal pain. He has felt cold and clammy at times but has not checked his temperature. He has had no nausea, vomiting, or diarrhea. The pain does not worsen after meals, but his appetite has been poor since this started. On review of systems, he reports increased urinary frequency and urgency for the same amount of time. He has had no abdominal surgeries. He has diabetes mellitus type 2 and is on metformin. He also takes aspirin 81 mg/day. He has always declined screening colonoscopy, stating, "If it ain't broke, don't fix it"—apparently, his family motto. On examination, he is in no distress with blood pressure 125/75 mm Hg, pulse 90 bpm, respirations 15, and temperature 38.5°C. His heart sounds are normal, and his chest is clear bilaterally. He has moderate left lower quadrant tenderness without rebound tenderness or guarding. There is no abdominal distention or organomegaly. Bowel sounds are normal, and the rectal examination is normal without stool in the rectal vault. Urinalysis is normal.

Question 7.17.1 What is the most likely diagnosis?

- A) Ischemic colitis
- B) Colon cancer with large bowel obstruction
- C) Irritable bowel syndrome (IBS)
- D) Pyelonephritis
- E) Diverticulitis

Answer 7.17.1 The correct answer is "E." Diverticulitis is the most likely cause of the patient's pain. Fever associated with acute onset abdominal pain located in left lower quadrant makes this pain more likely to be due to diverticulitis. Diverticulitis can, however, occur in any part of the colon. Ischemic colitis ("A") can present with disproportionate abdominal pain in this location, but is usually associated with bloody diarrhea, so it is less likely. IBS ("C") almost never initially presents in this age group, is not associated with fevers unless there is a fistula or megacolon, and is a chronic condition, not acute. Pyelonephritis ("D") was a good thought until the urine dipstick returned normal. Urinary symptoms are common in diverticulitis because of bladder irritation. Colon cancer with large bowel obstruction ("B") would present with severe abdominal pain and distention. In obstruction, bowel sounds are typically hyperactive with intermittent rushing.

Question 7.17.2 The most appropriate next step in the workup of the patient is:

- A) CT scan of abdomen and pelvis
- B) Surgical consult
- C) Gastroenterology consult
- D) Abdominal ultrasound
- E) Colonoscopy

Answer 7.17.2 The correct answer is "A." CT scan is very sensitive and specific for diverticulitis and can simultaneously evaluate for other causes of abdominal pain. Radiocontrast (oral or IV) does not add to the diagnostic accuracy for diverticulitis or appendicitis (*Ann Emerg Med.* 2010;55(1):51–59), but try telling that to your radiologist. Compromise with them and use IV contrast alone if they insist. In general, CT scan is indicated if the patient has peritoneal signs or mass suggesting diverticular abscess formation. In a patient who has had previously documented attacks and who has none of the above symptoms, empiric treatment is appropriate. Surgical and/or GI consults may be indicated but are premature at this point. Abdominal ultrasound can diagnose diverticulitis and/or abscess, but it is less sensitive than a CT scan. Colonoscopy is only indicated in the acute setting if obstruction is present or if colitis is thought to be more likely. In the setting of acute diverticulitis, the risk of perforation during colonoscopy is increased, and colonoscopy is preferably delayed until inflammation has subsided. Note that you specifically do not want to use rectal contrast if there is a question of a perforation (or that you may cause a perforation).

You get the CT scan the same day (with only IV contrast ... you partially win this round with the radiologist) and have the patient return to your office to discuss the results. The CT scan shows inflammation in the sigmoid colon with some outpouching structures suggesting diverticulosis. There is a 1.5 cm fluid collection posterior to the sigmoid colon suggesting pericolic abscess. No other findings were noted, and the colon above sigmoid appeared normal. No free air was seen.

Question 7.17.3 Which of the following is the most appropriate next step in management?

- A) CT-guided drainage of the abscess
- B) Surgical consult for immediate diverting colostomy and abscess drainage
- C) Admission to the hospital for IV antibiotics and serial abdominal examinations
- D) Discharge to home on levofloxacin and metronidazole
- E) GI consult for endoscopic ultrasound guided transcolonic drainage of abscess

Answer 7.17.3 The correct answer is “C.” This patient should be admitted for IV antibiotics. Mild attacks of diverticulitis can be managed on an outpatient basis. Our patient has small abscess that requires inpatient therapy. In addition, he is immunosuppressed by his diabetes, and all immunosuppressed patients with diverticulitis should be admitted for IV antibiotics since they are more likely to develop complications and need surgery. “A” is not the best choice. It is reasonable to ask the radiologist if this abscess can be drained, but the likely answer is no, because it is very small and is posterior to colon. “B” is also incorrect. The patient does not have peritoneal signs, and the abscess likely will respond to IV antibiotics. Thus, immediate surgery is not indicated. As discussed above, colonoscopy (and by extension endoscopic ultrasound) is relatively contraindicated in the setting of acute diverticulitis. Additionally, no gastroenterologist has been found crazy enough to try to drain abscesses by a transcolonic approach to our (and Pubmed’s) knowledge. However, maybe the emerging Natural Orifice Transluminal Endoscopic Surgeons (NOTES) will attempt this in the future but not on our patient today. (Editor’s note: we didn’t make this one up either They have been doing cholecystectomies via a transvaginal approach ... don’t ask us why ...)

HELPFUL TIP:

Antibiotic regimens for diverticulitis must include both Gram-negative and anaerobic coverage. Some common regimens include ciprofloxacin + metronidazole, ampicillin/sulbactam, amoxicillin/clavulanate, ampicillin + gentamicin + clindamycin, and ceftriaxone + metronidazole.

Question 7.17.4 Which of the following is true of diverticulosis?

- A) The majority of patients with this disease will develop symptoms at some time
- B) The condition is associated with a high malignant potential
- C) The condition has peak incidence of occurrence in sixth, seventh, and eighth decades of life
- D) The condition primarily affects the ascending colon

Answer 7.17.4 The correct answer is “C.” Diverticulosis is an acquired disease that peaks in the sixth, seventh, and eighth decades with about 50% of octogenarians having the condition. “A” is incorrect. Most are **asymptomatic** with only 10%

to 20% going on to develop symptomatic diverticulitis. Acute diverticulitis has a variety of presentations. Peri-diverticular inflammation occurs when a fecalith becomes entrapped in a diverticular wall resulting in a localized, contained, microperforation. Pain is typically acute and located in the left lower quadrant. Examination may reveal only a mildly tender abdomen without any masses. A peri-diverticular abscess and phlegmon will typically result in worsening left lower quadrant abdominal pain, and *may* have an associated palpable mass.

HELPFUL TIP:

Epiploic appendagitis (not appendicitis, yes, it is spelled correctly) can mimic both appendicitis and diverticulitis. It generally will present similarly to appendicitis but on the left. It occurs mostly in people in their thirties. It occurs when there is torsion or infarction of an epiploic appendage on the peritoneal aspect (“outside”) of the colon. Diagnosis is by CT scan and it generally resolves on its own without surgical intervention.

The patient is admitted and he responds to IV antibiotics and supportive measures. A repeat CT scan 2 weeks later shows resolution of the abscess. The local gastroenterologist performs colonoscopy 2 months after the attack and confirms left-sided diverticulosis with otherwise normal colonoscopy.

Question 7.17.5 Which of the following statements is true about this patient’s prognosis?

- A) When the patient has his second attack of uncomplicated diverticulitis, a resection of the diseased segment is always indicated (sigmoid colectomy)
- B) 50% of patients will have a repeat attack within 5 years
- C) He has 20% to 30% chance of diverticular perforation in the next 2 years
- D) He has 30% chance of diverticular bleeding in the next 2 years
- E) 33% of patients will have a second attack

Answer 7.17.5 The correct answer is “E.” Only 33% of patients with an episode of diverticulitis will have a second episode. There is no set rule for the number of attacks needed before partial colectomy is indicated. The commonly used rule of three attacks is not based on prospective evidence. The decision has to be individualized, but the tendency is to operate on healthy young people with frequent attacks while opting for observation of elderly patients with comorbidities (even if they have more than three attacks). Diverticular perforation is rare and occurs in only 5% to 10% of patients within 2 years of the initial event. Diverticular bleeding happens in 3% to 5% of patients with diverticulosis and the risk is not increased with diverticulitis; if GI bleeding occurs during an episode of presumed diverticulitis, other diagnoses should be strongly considered.

On a weekend call 6 months later, your patient presents to the emergency department after experiencing sudden onset of bright red blood per rectum mixed within stools. He has passed five stools in last 3 hours and the last one had blood clots. He feels dizzy but has not passed out. He stopped taking his aspirin after his last illness, but otherwise his health and medications are unchanged. His abdomen is nontender and bowel sounds are normoactive. Rectal examination reveals fresh blood on the glove but no masses in rectum. Hemoglobin is 10 g/dL, and you place two large-bore IVs and admit him to the hospital. He has no more bowel movements overnight, his hemoglobin is 8.2 g/dL the next morning, and he is feeling well. You assume that the bleeding was diverticular.

Question 7.17.6 Which of the following statements is true?

- A) Urgent colonoscopy is needed to localize and treat the lesion
- B) Colonoscopy is needed but can be done on an outpatient basis
- C) Tagged RBC scan followed by angiography is indicated to prevent rebleeding
- D) No further workup is indicated at this point
- E) Sigmoid colon resection is indicated because of the dynamic diverticular duo (diverticular bleed and diverticulitis)

Answer 7.17.6 The correct answer is “D.” The patient has classic presentation of diverticular bleeding with rapid onset and spontaneous resolution of bleeding (75% stop spontaneously). The patient underwent colonoscopy recently and the only finding was diverticulosis. Since the patient has stopped bleeding, colonoscopy is unlikely to help in the management of his condition. For the same reason, colonoscopy does not need to be done as an outpatient. If the patient had continued to bleed, there would be two options for managing this patient, and both are acceptable. One approach is to perform rapid colonic lavage by placing an NG tube and giving 6 L (1.5 gallons) of polyethylene glycol (GoLyte) over 4 hours and perform colonoscopy to try to find the bleeding site and treat it. Often multiple blood-filled diverticuli are seen, and the source of the bleed cannot be identified. The second approach is to perform a tagged RBC scan to confirm active bleeding, followed by selective angiography to identify the bleeding vessel and embolize it. The approach taken depends on the local expertise available. Without treatment, 25% of patients eventually rebleed and of those who rebleed, 50% will have a third bleed.

HELPFUL TIP:

The whole thing about avoiding seeds and nuts in those with diverticular disease is—pun intended—nuts. In fact, patients who eat popcorn, nuts, seeds, etc., have a lower incidence of recurrent diverticular disease (*JAMA*. 2008;300(8):907–914). Good thing, too, popcorn has helped fuel our book editing!

► **Objectives: Did you learn to ...**

- Identify signs and symptoms of diverticulitis?
- Appreciate the natural history of diverticular disease?
- Manage complications of diverticular disease?

QUICK QUIZ: CAN'T STOP PUKING

Mary Jane is a 27-year-old female who presents to your clinic complaining of recurrent abdominal pain and vomiting daily for the last 6 months. The only way that she can relieve the symptoms is to either sit in a hot bath or take a hot shower. She does this compulsively and is the cleanest patient you have ever seen; she literally shines. In this case, though, cleanliness may not be next to godliness. Social history is remarkable for daily use of marijuana, tobacco use of ½ pack per day, and about 1 to 2 alcoholic drinks per day. When her back hurts, she will take her boyfriend's oxycodone—about once per week.

This behavior is typical for which of the following disorders?

- A) Cyclic vomiting syndrome
- B) Cannabis hyperemesis syndrome
- C) Opioid bowel syndrome
- D) Catamenial cyclic vomiting syndrome
- E) Vomit-shower-vomit syndrome

The correct answer is “B.” This history is typical of cannabis hyperemesis syndrome. This occurs in patients who are frequent marijuana users. Cannabis hyperemesis syndrome is resistant to typical antiemetics, but patients will have an abatement of their symptoms while they are in a hot bath or shower (why is unknown). The syndrome resolves once they stop using marijuana. “A,” cyclic vomiting syndrome, **occurs in a stereotypical pattern**; for example, a patient may have onset at 3:00 AM (2:00 to 7:00 AM is the most common time) with preceding nausea, pallor, abdominal pain, and anorexia. Children usually have 12 cycles per year as compared to 4 in adults. Each cycle may last several days or more and the patient has normal health in between episodes. Cyclic vomiting syndrome may be a migraine variant, and antimigraine medications are worth trying. “C,” opioid bowel syndrome, refers to bloating, pain, distension, and vomiting found in opioid users (not just due to constipation). It is probably a hyperalgesia syndrome and resolves when opioids are stopped (good luck with that!). “D,” catamenial cyclic vomiting syndrome, is cyclic vomiting related to menses, which is not described in this case since it is occurring daily. “E” sounds silly and fictional—which it is.

QUICK QUIZ: ALL BOUND-UP

A 64-year-old male who is a long-time patient with a history of constipation-predominant irritable bowel disease (at least that is the diagnosis he came to you with) presents to your office complaining of worsening constipation. He tells you that he is taking psyllium (Metamucil), senna (a stimulant laxative), and

polyethylene glycol (MiraLax). His regimen is not working quite as well as it had in the past. He is once again having to strain.

Which of the following is/are FALSE?

- A) You should review his medicine list with an eye toward eliminating anticholinergic drugs
- B) He has become resistant to senna since resistance develops to stimulant laxatives
- C) Increasing exercise may help regulate his bowel movements
- D) Opioid-induced constipation is best treated with an antiopioid such as naldemedine as first line
- E) Both B and D are false

The correct (and false) answer is “E.” “A” is true. You should try to eliminate constipating medications if possible, including anticholinergics and opioids. “B” is false. Despite what we have been taught, there is no tolerance developed to stimulant laxatives (*J Clin Gastroenterol.* 2003;36(5):386–389). “C” is true. Exercise will help. Finally, “D” is false. The initial treatment of opioid-induced constipation should be a “traditional” laxative (especially an osmotic laxative such as polyethylene glycol). If the patient fails usual laxatives, peripheral mu-opioid receptor antagonists such as naldemedine (Symproic), methylbuprenorphine (Relistor), and naloxegol (Movantik) can be used (*Gastroenterology.* 2019;156(1):218–226). As an aside, did you notice that we didn’t mention docusate (Colace)? It tends to be ineffective long-term (*Gastroenterology.* 2013 Jan;144(1):218–238).

HELPFUL TIP:

The definition of constipation requires two of the following: straining to pass stools >25% of the time, lumpy or hard stools >25% of the time, sensation of incomplete evacuation >25% of the time, relying on manual maneuvers to promote defecation, and having fewer than three unassisted bowel movements per week. Prior criteria were difficulty passing stools, incomplete passage of stool, or fewer than three bowel movements per week.

Clinical Pearls

- All patients 50 years old or older with at least a 10-year life expectancy should undergo routine colon cancer screening; various methods are acceptable.
- Do not refer patients for cholecystectomy if they have asymptomatic cholelithiasis.
- Do not refer patients for upper endoscopy (EGD) if they have typical heartburn and no alarm symptoms (e.g., dysphagia, weight loss).
- Feed patients with pancreatitis once their nausea begins to subside. Early feeding is associated with better outcomes. There is no need for a jejunal tube if they tolerate oral feedings.

- Gastroparesis can be caused by diabetes and also by viral GI infections, thyroid disease, and autoimmune disease. Postviral gastroparesis can last for up to a year.
- If a screening colonoscopy is completely negative, do not repeat colon cancer *screening* of any kind for 10 years.
- Most pancreatitis is caused by gallstones or alcohol; other causes (viral, drug induced, elevated triglycerides, scorpion stings, etc.) are much less common.
- Screen for hepatitis C at least once in all U.S. adults aged 18–79 years (per USPSTF draft recommendation published for public comment in 2019).
- There is no absolute number of episodes of diverticulitis that mandates surgery. Tailor the treatment to the patient.
- Titrate proton pump inhibitor therapy to the lowest tolerable dose—or discontinue, if possible—after initial therapy for GERD. Remember that there is rebound hyperacidity when stopping PPIs or H₂ blockers.

Infectious Diseases

A. Ben Appenheimer

▶ CASE 8.1

Flu season is right around the corner and you are preparing your clinic for the onslaught. First things first ... you need to know how much vaccine to order and who will be receiving it. The Centers for Disease Control and Prevention (CDC) annually publishes recommendations for administering influenza vaccine to the American public.

Question 8.1.1 The CDC recommends vaccination for all of the following groups EXCEPT:

- A) Health care workers
- B) Nursing home residents
- C) Febrile neonates
- D) Diabetics
- E) The elderly

Answer 8.1.1 The correct answer is “C.” We start this chapter with an easy one. Patients 6 months of age or younger should not be vaccinated nor should children who are febrile. *Egg allergy is no longer a contraindication to any influenza vaccine product.* Also, patients with egg allergies no longer need to be observed for 30 minutes. Those who have more than hives as an egg allergy should be given the vaccine in a health care facility able to treat anaphylaxis, which seems prudent (CDC 2018).

HELPFUL TIP:

Vaccinate all persons older than 6 months annually. There are **several types** of vaccine available: trivalent and quadrivalent inactivated influenza vaccines (the old-fashioned flu shot, e.g., Fluzone) for patients 18 to 64 years of age, high-dose intramuscular vaccine for the elderly, and the intranasal live attenuated influenza vaccine (e.g., FluMist). However, the intranasal live attenuated influenza vaccine was not recommended for the 2017–2018 influenza season due to concerns about efficacy against the circulating strains. It was once again recommended for the 2018–2019 season. Check annually.

Oh, no! The virus has struck. Like a zombie apocalypse, it started with just a few cases, but now it's out of control. (For fun, google “zombie apocalypse CDC”—it's a real thing, an educational tool for patients.) Every other patient who calls complains of influenza-like illness and there have been a few cases noted in the local nursing home.

Question 8.1.2 During this outbreak, what intervention(s) is/are most appropriate for all your unvaccinated, frail nursing home patients who have no symptoms of febrile respiratory illness?

- A) Antiviral prophylaxis with oseltamivir
- B) Antiviral prophylaxis with amantadine
- C) Influenza immunization
- D) A and C given together
- E) B and C given together

Answer 8.1.2 The correct answer is “D.” Persons at high risk for complications of influenza can still be vaccinated after an outbreak of influenza has begun in the community, but development of antibodies in adults can take up to 2 weeks. Thus, for those patients who have not been vaccinated but are at high risk for complications, chemoprophylaxis should be considered. These include children <5 years old, adults > 65 years old, pregnant or recently postpartum women, immunosuppressed patients, those with significant comorbidities, etc. In an outbreak setting, oseltamivir prophylaxis is recommended for all nursing home residents *regardless of their immunization status*. “A” alone might be appropriate for individuals who have a contraindication to vaccination and wish to protect themselves from influenza. “B” is not correct because influenza A is increasingly resistant to M2 drugs (e.g., amantadine, rimantadine) and influenza B has never been sensitive to them. Vaccination alone (“C”) can be used in individuals **without** known high-risk conditions such as asthma, diabetes, renal dysfunction, immunodeficiency, or cardiovascular disease. But, as noted above, vaccine alone is inadequate for those who are institutionalized or have significant

comorbidities. These higher risk patients also need to be covered by oseltamivir until immunity has developed (2 weeks).

HELPFUL TIP:

Sensitivity of rapid antigen tests for influenza is low, estimated at 62%. Therefore, a negative rapid antigen test should not preclude treatment in those patients in which a high clinical suspicion is maintained. However, newer PCR testing has a much higher sensitivity of around 92%. Both tests have relatively high specificity.

HELPFUL TIP:

For a specific patient, tests of the virus for susceptibility to specific antivirals are not clinically useful due to the time required to get results. However, trends in the community guide empiric therapy. Resistance varies by year. Resistance of influenza A H1N1 to oseltamivir was 99% in 2009. However, in 2013 to 2014 98.2% of influenza A H1N1 isolates tested were **susceptible** to oseltamivir. The CDC monitors and reports annual influenza antiviral sensitivity results on their website, <https://www.cdc.gov/flu/>.

Question 8.1.3 Which of these patients would qualify for antiviral therapy during an influenza outbreak?

- A) A healthy 29-year-old male who presents 72 hours after onset of symptom **and** has a positive rapid test for influenza
- B) A 70-year-old patient hospitalized with influenza who presents 72 hours after onset of symptoms
- C) A pregnant woman who presents within 48 hours of symptom onset and has a positive rapid test for influenza
- D) B and C
- E) All of the above

Answer 8.1.3 The correct answer is “D.” In outpatients, antiviral drugs are reserved for high-risk groups including pregnancy, age >65 years, significant underlying medical illness (DM, immunosuppression, morbid obesity, asthma, etc.), nursing home residents, and children age <2 years. Normal risk outpatients should be prioritized lower on the treatment ladder. However, the CDC does recommend that antiviral drugs be considered for otherwise healthy outpatients with confirmed influenza who can start medication *within 48 hours* of symptom onset. All hospitalized patients should be treated even if it is >48 hours after onset of symptoms.

The director of nursing at your community nursing home calls about an outbreak of febrile respiratory infections. In the last 24 hours, three patients have become ill on the dementia care unit. All residents of the home were vaccinated with the current year’s influenza vaccine 2 months ago in November. Several of the aides have not been vaccinated and two recently left work after complaining of feeling tired, feverish, and achy.

Question 8.1.4 You suspect an influenza outbreak and take the following actions EXCEPT:

- A) Quarantine the nursing home and restrict access for visitors, new admissions, and ill staff
- B) Hospitalize all patients suspected of having influenza
- C) Limit the interaction of ill residents with non-ill residents
- D) Administer antiviral prophylaxis to all well residents
- E) Provide influenza vaccine to any unvaccinated residents and staff

Answer 8.1.4 The correct answer is “B.” Moving sick patients only risks spreading the infection to the hospital. In addition to measures above, employees should be assigned to one work area only to prevent spread via the staff. Activities, visits, and gatherings in central common areas should be curtailed during the outbreak.

HELPFUL TIP:

Influenza vaccine is only about 50% effective in nursing home patients (thus the admonition to treat with prophylaxis during an outbreak in the nursing home regardless of vaccination status). Still, there is some herd immunity, and vaccination is recommended as the primary way to prevent an influenza outbreak. Considering all the options, vaccinating staff may be the most effective method to prevent nursing home outbreaks.

QUICK QUIZ: THE NEW KID ON THE BLOCK

Baloxavir (Xofluza®) has the advantage of:

- A) Being effective even 72 hours after the onset of influenza symptoms
- B) Influenza viruses having very little resistance *and* very little chance of developing resistance
- C) Being recommended for treatment of all inpatients with influenza
- D) Being available in an IV form
- E) None of the above

The correct answer is “E,” “none of the above.” Baloxavir is a single-dose agent active against influenza A and B that is equivalently effective to oseltamivir and should be started within the first 48 hours of symptoms to be effective. It is given orally only (not IV), and there is about a 10% rate of resistance development *after a single dose*. Although it is not clear, this may also reduce communicability (so *that* is a plus). Its role in therapy is not currently well-defined and it is not necessary for inpatients with influenza. There seems to be no role at this point in using it in combination with oseltamivir. As to “D,” you are thinking of peramivir (Rapivab®). It also has no well-defined role but may be used IV for hospitalized patients who cannot take PO; it reduces symptoms by 4 hours when compared to oral oseltamivir at several times the cost (close to \$1,000).

Question 8.1.5 Time to update the pneumococcal vaccine protocol at your nursing home! In accordance with 2015 CDC recommendations for older adults, you institute the following schedule for all patients at age 65 who have not yet received a pneumococcal vaccination:

- A) 23-valent pneumococcal polysaccharide vaccine (PPSV23) once only
- B) 13-valent pneumococcal conjugate vaccine (PCV13) once only
- C) PPSV23 followed by PCV13 one year later
- D) PCV13 followed by PPSV23 one year later
- E) Cowpox ... lots and lots of cowpox

Answer 8.1.5 The correct answer is “D.” Indications for pneumococcal vaccination include patients with chronic illness at high risk for invasive pneumococcal disease (e.g., diabetes, chronic pulmonary disease, and cardiovascular disease), institutionalization, age 65 or older, immunocompromised state, and **tobacco use**. Note that the tobacco use applies to all patients age 19 to 64 years old. There are two pneumococcal vaccinations, the 23-valent pneumococcal polysaccharide vaccine (PPSV23 or Pneumovax) and 13-valent pneumococcal polysaccharide conjugate vaccine (PCV13 or Prevnar-13). While the PPSV23 covers more serotypes than the PCV13 (23 vs. 13), the PCV13 induces a stronger immune response. Therefore, all adults aged 65 or older should receive both vaccines. PCV13 should be administered before PPSV23 when practical. PCV13 is also recommended for patients with end-stage renal disease, asplenia, HIV, and many other conditions. As opposed to PPSV23, **PCV13** vaccine is **NOT** indicated for those <age 65 only on the basis of smoking or the presence of lung disease (as of 2019).

HELPFUL TIP (AND BREAKING NEWS):

It turns out that Prevnar-13 is not needed in most adults: Adults are protected by herd immunity secondary to children getting vaccinated. Thus, by the time you read this, the CDC will recommend shared decision making when deciding whether or not to give Prevnar-13 in adults over 65 without an immunocompromising condition. Continue to suggest both Prevnar-13 and Pneumovax 23 to those >65 or with chronic disease that might effect immunity (DM, CKD, etc.). We don't know what the answer on the exam will be.

HELPFUL TIP:

The most common cause of bacterial pneumonia complicating influenza is *S. pneumoniae*. However, *Staphylococcus aureus* pneumonia (usually uncommon in the community) is an important entity during influenza outbreaks and generally presents with more severe symptoms.

► Objectives: Did you learn to ...

- Describe who should receive influenza and pneumococcal vaccines?
- Identify appropriate interventions to halt the transmission of influenza in community and care facility outbreaks?
- Lead a successful influenza prevention program in a health care setting?
- Prescribe influenza antivirals appropriately?

QUICK QUIZ: THE COMING PLAGUE

The clinic triage nurse comes to you with a concern about a patient who has just walked into clinic and is at the front desk. She is a 28-year-old Peace Corps worker who returned 10 days ago from a western African country in the midst of an Ebola epidemic. She is otherwise healthy but started having a fever suddenly last night. She describes fatigue, night sweats, myalgia, and temperature of 38.5°C. This morning she notes vomiting and diarrhea with blood in the stool. The patient thinks that she has a benign viral illness (“everyone was coughing on the plane”) and does not recall any contacts with persons with Ebola.

You tell the nurse:

- A) “We will work her in. Just have her hang out in the waiting room.”
- B) “Give her any mask you can find and send her to the ER. Pronto.”
- C) “Isolate the patient immediately in an examination room (preferably negative laminar flow if available) and call the health department.”
- D) “Shut down the whole clinic! We’re on lockdown!”

The correct answer is “C.” This patient has been in an area of Ebola epidemic, has the classic symptoms of Ebola (fever, diarrhea, vomiting, bleeding [in this case in her stools]). Other symptoms include meningoencephalitis, diffuse rash, and a relative bradycardia for the degree of fever (similar to that seen with typhoid). Treat her as though she has Ebola until proven otherwise. Ebola is highly contagious and is spread by contaminated body fluids, including aerosolized droplets. You should endeavor to limit exposure of others to the ill patient, so “A” and “B” are incorrect, as both options expose more persons. The health department in your area should be involved immediately, and they would be in contact with the CDC. The CDC recommends symptomatic patients at risk for Ebola exposure be isolated (a private examination room with doors closed is likely sufficient) and treated at the direction of public health authorities. “D” is incorrect. Despite its contagious nature, casual exposure to a patient with Ebola (e.g., sitting 10 ft away in the reception area as she walks by) is unlikely to result in transmission. Remember that the persons at highest risk during the 2014–2015 Ebola outbreak in West Africa were health care workers and caregivers of the Ebola patients. The incubation period of Ebola is 2 to 21 days. The virus can persist in the sperm, eye, breast milk, and CNS for months after symptoms have resolved (so quit eating eyeballs and you will be fine).

CASE 8.2

An 80-year-old female fell, broke her hip, and underwent intraoperative repair with pinning of the fracture. She developed a local infection at the site of the repair and was treated with a 10-day course of oral clindamycin. She was transferred to the nursing home for rehabilitation and has developed loose, watery stools. Today when you visit her, she reports feeling diffuse abdominal discomfort and has had 10 bowel movements. She is very concerned because she cannot work with the therapist and risks losing her Medicare benefit for skilled nursing.

Question 8.2.1 You plan to do the following:

- A) Begin loperamide (Imodium) as needed to prevent diarrhea during the therapy sessions
- B) Obtain stool specimens for *Clostridium difficile*
- C) Obtain an abdominal CT scan looking for evidence of obstruction
- D) Ask your favorite gastrointestinal (GI) doctor to perform emergency endoscopy for evaluation of lower GI bleed
- E) Obtain stool specimens for ova and parasites

Answer 8.2.1 The correct answer is “B.” *C. difficile* is the most common bacterial cause of infectious diarrhea in hospitalized patients in the United States (*Campylobacter jejuni* is the most common bacterial cause overall). Multistep diagnostic algorithms using polymerase chain reaction (PCR) for the toxin gene(s) have the best test performance characteristics (sensitivity 68–100% and specificity 92–100%). Testing should be performed on only symptomatic patients. There is no benefit from testing more than one stool specimen or for checking for test of cure. Although symptomatic therapy is important, “A” is incorrect because antiperistaltic agents should be avoided in patients with *C. difficile*. Although other causes of diarrhea are possible, the most cost-effective approach in this patient would be laboratory testing for *C. difficile* according to local laboratory protocol prior to any other more invasive procedure. As an aside, *Clostridium difficile* is no more. The new nomenclature is “*Clostridioides difficile*.” We are using the old nomenclature in this book due to the general familiarity with it among physicians—either way, “*C diff*” still works!

HELPFUL TIP:

Testing for *C. difficile* infection has become more complicated. Therefore, the specifics of testing are not likely to be on the boards. However, the following information could be clinically useful depending on your lab’s testing algorithm for *C. difficile*. Different labs test for *C. difficile* using different assays (see Table 8-1). The simplest approach (and one used by many labs) is to use PCR to test for the presence of the gene encoding the toxin responsible for *C. difficile* disease. However, this is not specific as not all *C. difficile* with this gene are actively producing toxin. Other labs have recently started utilizing an algorithm that incorporates three different assays. These include the GDH antigen (present on all *C. difficile*) which

picks up all *C. difficile*, even the nontoxigenic strains that cannot cause disease. This is coupled with an assay that looks directly for the toxin responsible for *C. difficile* disease. If GDH and the toxin assay are both positive, the patient has *C. difficile* infection. If both are negative, the patient does not have *C. difficile*. If the patient has a positive GDH but **negative** toxin assay, then the PCR for the toxin gene is used to see if the patient’s *C. difficile* is capable of producing toxin (see Table 8-2). The gold standard test for detecting *C. difficile* in the stool is the tissue culture cytotoxicity assay, but it is not commonly performed because it takes up to 2 days to perform and is more costly.

TABLE 8-1 CLOSTRIDIUM DIFFICILE DIAGNOSTIC TESTS

Test Name	What It Tests For	Comments
GDH assay	Presence of any <i>Clostridium difficile</i> bacteria	This test does not differentiate between toxigenic strains (that are capable of causing disease) and nontoxigenic strains that are asymptomatic. If negative, the patient does not have <i>Clostridium difficile</i> . Only used in conjunction with other tests
Toxin PCR	Presence of the gene responsible for producing toxin	This test identifies infection with <i>C. difficile</i> that has the gene to produce toxin (i.e., it is capable of causing disease). It does not detect the toxin itself. Many labs use this as the sole diagnostic test for <i>C. difficile</i> . It has a high sensitivity at detecting disease but its specificity is questionable
Toxin assay	Detects presence of the toxin itself	This test confirms the diagnosis of <i>C. difficile</i> disease as it directly detects the toxin. The specificity of this test is high but it is not highly sensitive

A stool specimen reveals the presence of *C. difficile* toxin A gene. The patient is nontoxic with a normal complete blood count (CBC) and creatinine.

Question 8.2.2 The preferred, first-line, treatment of this patient should include:

- A) Fecal microbiota transplantation (i.e., stool transplant)
- B) Lactose restriction and acidophilus milk products
- C) Metronidazole 500 mg PO TID for 10 days
- D) Vancomycin 125 mg PO QID for 10 days
- E) B and C

TABLE 8-2 INTERPRETING *CLOSTRIDIUM DIFFICILE* MULTISTEP TESTING

Initial Result	Follow-Up Testing	Interpretation
GDH assay – Toxin assay –	None	Negative for <i>C. difficile</i> disease
GDH assay + Toxin assay +	None	Definitive positive for <i>C. difficile</i> disease
GDH assay + Toxin assay –	Toxin PCR –	Negative for <i>C. difficile</i> disease. Patient is colonized with nontoxigenic <i>C. difficile</i>
GDH assay + Toxin assay –	Toxin PCR +	Interpret based on clinical scenario ^a

^aThere are two potential interpretations of this scenario. Presuming all testing is accurate, this represents colonization with a strain of *C. difficile* that has the gene to produce toxin but is not actively producing the toxin (as indicated by the negative toxin assay). Interpreted literally, this is a negative test. However, the toxin assay has variable sensitivity and is therefore prone to false-negative tests. Therefore, the alternative possibility with this testing result is that the patient has true *C. difficile* disease but the toxin assay was a false negative. In the correct clinical scenario, these patients should be treated, but other causes of diarrhea should be considered if they do not respond to therapy.

Answer 8.2.2 The correct answer is “D.” Treatment of *C. difficile* infection (CDI) includes supportive care, discontinuation of the offending antimicrobial agent, and initiation of an oral antibiotic. The previous recommendation in this setting was metronidazole. However, the Infectious Disease Society of America (IDSA) guidelines were updated in 2018 and removed metronidazole as a preferred option for initial, nonsevere *C. difficile*. There are currently two favored choices for an initial episode of *C. difficile* disease: oral vancomycin at 125 mg every 6 hours for 10 days or fidaxomicin (Dificid[®]) 200 mg twice daily for 10 days. Randomized studies demonstrate similar cure rates between fidaxomicin and oral vancomycin, with fewer recurrences with fidaxomicin. However, fidaxomicin has a much higher cost (potentially over \$3,000 for a course), and therefore vancomycin is used more often as first-line therapy. Fecal microbiota transplantation is associated with resolution of recurrent CDI, but its role in primary and severe CDI has not been established. There is limited evidence that use of probiotics is effective in the treatment of *C. difficile* infection and prevention of recurrence. See helpful tip below.

Question 8.2.3 Risk factors for *C. difficile* infection in nursing home patients include:

- A) Advanced age
- B) Recent acute hospitalization
- C) Proton pump inhibitor (PPI) use
- D) Long-term residence in a chronic care facility
- E) All of the above

Answer 8.2.3 The correct answer is “E.” Risk factors for acquisition of CDI in nursing home patients are similar to that of hospitalized patients and include hospitalization, advanced age, GI surgery/procedures, antibiotic exposure, and importantly **PPI use**. H₂ blockers are much less likely to contribute to *C. difficile* colitis.

**HELPFUL TIP:**

C. difficile diarrhea and colitis can be caused by **any** antibiotic, including metronidazole and vancomycin. The probability of diarrhea seems highest with clindamycin. Fluoroquinolones and broad-spectrum cephalosporins are increasingly associated with *C. difficile* infection, including a highly toxigenic strain. Simply stopping the antibiotic can lead to resolution in 25% of the mild cases.

Recurrence of *C. difficile*-associated diarrhea after a 10-day course of antibiotic therapy is common. Guess what? Your patient’s diarrhea has recurred shortly after discontinuation of her vancomycin.

Question 8.2.4 The most reasonable treatment approach is to:

- A) Repeat a course of oral vancomycin
- B) Treat with a prolonged vancomycin pulse-taper regimen
- C) Treat with a course of intravenous (IV) vancomycin
- D) Treat with a course of fidaxomicin
- E) B or D

Answer 8.2.4 The correct answer is “E.” Relapse and/or recurrence are very common. Typically, about 20% of patients have a recurrence of symptoms, often within about 1 week of completing therapy. These patients usually respond to retreatment. The new IDSA guidelines have changed the recommendations for how to treat an initial recurrence. Previous recommendations included either metronidazole or oral vancomycin. However, the new guidelines suggest treating an initial recurrence with a “step-up” in therapy. If metronidazole was used initially (despite the new guidelines), a 10-day course of vancomycin is recommended. If oral vancomycin was used, recommendations include either a prolonged vancomycin pulse-taper or fidaxomicin. For additional recurrences, guidelines suggest either fidaxomicin, vancomycin pulse-taper, vancomycin followed by rifaximin, or fecal microbiota transplantation. IV vancomycin is **ineffective** treatment of *C. difficile* since vancomycin does not enter into the GI tract from the vascular space.

**HELPFUL TIP:**

Klebsiella oxytoca and *Clostridium innocuum* can produce an antibiotic-related diarrhea that is indistinguishable from *C. difficile*. In those with a negative stool for *C. difficile* antigen, consider (1) false-negative test (some of the newer strains of *Clostridium* toxin are not detected by traditional stool antigen), (2) *K. oxytoca* or *C. innocuum*, (3) inappropriate care of the stool sample; since *C. difficile* toxin degenerates rapidly at room temperature (no toxin may be detectable after 2 hours of exposure to room temperatures) or (4) ELISA tests generally only test for Type A antigen. The patient

may have an antigen Type B producing strain **or** there may be a mutation of antigen Type A. Know the type of test your laboratory does: enzyme immunoassay (EIA) may miss type B toxin; glutamate dehydrogenase (GDH) assay is sensitive *for the organism*, but does not prove it is causing disease; and nucleic acid amplification test (NAAT) is prone to overdiagnosis.

HELPFUL TIP:

Although frequently used in the prevention and treatment of CDI, the effectiveness of probiotics is uncertain. Gut flora is amazing (about 10^{14} bacteria from 1,200 different species live in symbiosis with you—we are actually about 50% bacteria), and adding a little acidophilus might not cut it. In particularly recalcitrant cases, fecal microbiota (stool, basically) transplantation can be performed. Patients are given “healthy” stool via NG tube or colonoscopy to reestablish normal GI flora. Yum. Although it sounds a little yucky, it appears quite safe and effective (and tastes fine with a little ketchup). Finally, bezlotoxumab is a monoclonal antibody against *C. difficile* toxin that can reduce recurrences. Added to antibiotics it reduces recurrence rate (17% vs. 28% for placebo). May be worth a try if you have a patient with recurrent disease.

► Objectives: Did you learn to ...

- Recognize the presentation of *C. difficile* infection?
- Identify risk factors for the development of *C. difficile* diarrhea and colitis?
- Treat patients with initial and recurrent *C. difficile* infections?

► CASE 8.3

You are called to the emergency department (ED) to examine a 40-year-old man with fever (temperature of 39°C) and headache. His past history is remarkable only for a splenectomy secondary to trauma at age 10. He is not allergic to any antibiotics. Upon examination you note that he has meningeal signs. Nondilated fundal examination shows sharp disc margins, and he is neurologically intact with a nonfocal examination.

Question 8.3.1 The most appropriate action is:

- Obtain a head CT so that you can safely proceed with lumbar puncture (LP)
- Order IV penicillin as you prepare to perform LP
- Perform an LP immediately and begin antibiotic therapy empirically
- Order IV erythromycin as you prepare to perform LP
- Order IV vancomycin and IV ceftriaxone as you wait for the CBC. If the CBC is abnormal, you will do the LP

Answer 8.3.1 The correct answer is “C.” Once you suspect bacterial meningitis, rapid diagnostic evaluation and emergent

treatment are imperative, including LP and blood cultures. **If LP is going to be delayed, then appropriate empiric antimicrobial and adjunctive therapy should be given without delay.** Head CT is necessary only in those who are immunocompromised (HIV/AIDS, those receiving immunosuppressive drugs, transplant recipients), have a history of CNS disease (brain tumor and stroke), develop new-onset seizures, display papilledema on examination, or who have an abnormal/focal neurologic deficit or abnormal level of consciousness. Antibiotics for a 40-year-old male should cover *Neisseria meningitidis* and *S. pneumoniae* and would include vancomycin and ceftriaxone with pneumococcus predominating in this age group (“E”). However, “E” is not the best choice. Never wait for a CBC to determine if an adult needs an LP. The decision to do an LP is a clinical one.

HELPFUL TIP:

If the preponderance of initial clinical and laboratory data indicate that bacterial meningitis is likely and the LP cannot be done immediately, draw blood cultures and administer dexamethasone and appropriate antibiotics. You won’t change the CSF culture results (in most cases) if you give a single dose of antibiotics before the LP. However, it is considered prudent to do the LP within 2 hours of administering IV antibiotics. Although *not* used routinely, PCR and immunochromatographic studies of the CSF can be used to diagnose bacterial meningitis if needed. The standard of care for suspected meningitis is to administer antibiotics within 30 minutes of the patient presenting to the ED.

Results of the cerebrospinal fluid (CSF) obtained after LP are as follows: cloudy, WBC count $5,000\text{ cells/mm}^3$, 95% neutrophils, glucose 20 mg/dL, and Gram-positive cocci in pairs (see Figure 8-1).

FIGURE 8-1. Gram positive bacteria with polymorphonucleocytes. Courtesy of Dr. Bradley Ford.

Question 8.3.2 The most likely pathogen is:

- A) *S. pneumoniae*
- B) *Listeria monocytogenes*
- C) *S. aureus*
- D) *N. meningitidis*
- E) *Pseudomonas* species

Answer 8.3.2 The correct answer is “A.” Gram stain examination of CSF may permit rapid identification of the causative organism in bacterial meningitis with a sensitivity of 60% to 90%. Prior antibiotic therapy (e.g., a partially treated meningitis ... not a single dose of antibiotics in the ED) may reduce the sensitivity by 20%. The likelihood of a positive Gram stain is highest in cases of *S. pneumoniae* (a Gram-positive diplococcus). Only about one-third of *L. monocytogenes* meningitis cases demonstrate a positive Gram stain. “D” requires special mention. *N. meningitidis* is a diplococcus but is Gram negative. As you can see in Figure 8-1, there are numerous dark blue (Gram positive) organisms in pairs and chains among the polymorphonucleocytes.

Question 8.3.3 An adjunctive therapy that has been shown to improve neurologic outcomes in pneumococcal meningitis is:

- A) Dexamethasone
- B) Activated protein C
- C) Vasopressors
- D) CSF shunt implantation
- E) Monoclonal antibody directed against the capsule antigen of the bacterium.

Answer 8.3.3 The correct answer is “A.” The IDSA guideline recommends adjunctive dexamethasone to be administered to all adult patients with pneumococcal meningitis. No other adjunctive therapy has proven benefit. However, benefit is only proven if given with (or just prior to) the first dose of antibiotics. Since the organism is not usually known at the time of initiation of therapy, dexamethasone should be given empirically until the causative organism is identified. If the meningitis is not due to *S. pneumoniae*, dexamethasone should be discontinued. Additionally, patients should receive standard supportive therapies in an intensive care setting. Complications, when they occur, usually develop within the first 2 to 3 days of therapy. Complications include sepsis, mental status changes, neurologic complications, and electrolyte abnormalities.

Question 8.3.4 Highly resistant *S. pneumoniae* infections of the CNS should be treated with:

- A) Third-generation cephalosporin
- B) Vancomycin and a third-generation cephalosporin
- C) High-dose penicillin G
- D) Ampicillin
- E) Vancomycin, gentamycin, and rifampin

Answer 8.3.4 The correct answer is “B.” Vancomycin should be combined with a third-generation cephalosporin (e.g., ceftriaxone and cefotaxime) for highly resistant pneumococcus. It

is important to understand that the use of empiric vancomycin in community-acquired meningitis is to cover for highly resistant *S. pneumoniae* as opposed to MRSA (which doesn't generally cause community-acquired meningitis). Therefore, even when *S. pneumoniae* meningitis is definitively diagnosed, you should continue vancomycin until susceptibilities are available. If it is highly resistant to beta-lactams, both vancomycin and ceftriaxone should be continued. Do not use vancomycin alone. The newer generation fluoroquinolones have enhanced in vitro activity against *S. pneumoniae* and may be used as alternative agents in very specific situations but should not be used routinely in this setting. Fluoroquinolones are not recommended unless the patient cannot tolerate or is allergic to standard drugs. In general, empiric coverage for community-acquired meningitis in adults includes vancomycin and ceftriaxone. Ampicillin is added for certain patient groups where *Listeria* is more common (infants, age > 50, or immunocompromising condition).

**HELPFUL TIP:**

You may be asking yourself why we need to add vancomycin to cover for highly resistant *S. pneumoniae* in the setting of meningitis, but not when covering for community-acquired pneumonia. The answer has to do with drug penetration. Ceftriaxone reaches high enough levels in the lungs to overcome this resistance. However, levels of ceftriaxone in the CSF are not high enough for this, even when used with the standard CNS dosing of 2 g every 12 hours.

**HELPFUL TIP:**

The combination of Kernig and Brudzinski signs carries a sensitivity and specificity of 5% and 95%, respectively. Thus, the great majority of patients do not manifest these signs when they have meningitis, and they are useless to rule out meningitis. The sensitivity and specificity of nuchal rigidity (stiff neck) is 30% and 68%, respectively. In adults, the classic triad of fever, nuchal rigidity, and altered mental status was found in only 46%, with 85% having fever, 70% having neck stiffness, and 67% having mental status changes. If they have **none** of these, you have effectively ruled out meningitis.

► Objectives: Did you learn to ...

- Diagnose meningitis?
- Identify the most likely causative organism based on epidemiology and patient characteristics?
- Describe proper use of empiric antibiotics and steroid therapy for bacterial meningitis?

**QUICK QUIZ: BIG MENINGITIS ON CAMPUS**

What is the most common bacterial cause of meningitis in college-aged patients who live in dormitories?

- A) *N. meningitidis*
- B) *S. pneumococcus*
- C) *L. monocytogenes*
- D) *Haemophilus influenzae*
- E) *Escherichia coli*

The correct answer is "A." Although *S. pneumococcus* is the most common cause of bacterial meningitis in the adult population in the United States, *N. meningitidis* remains the leading cause in adolescents despite vaccination and is particularly prevalent in the setting of dormitory living (e.g., college or military). The presence of petechial (or purpuric) rash in the lower extremities and pressure points is typical of *N. meningitidis*. The advent of vaccination has made *H. influenzae* a less common cause. *L. monocytogenes* is more prevalent in those over age 50, infants, and the immunocompromised. *E. coli* is a common cause for meningitis in neonates and infants, but is very uncommon in adolescents and adults (see Table 8-3).

QUICK QUIZ: SPLEENLESS IN SEATTLE

Patients undergoing elective splenectomy should receive all of the following EXCEPT:

- A) PCV13 followed by PPSV23 at least 8 weeks later
- B) *H. influenzae* type B conjugate vaccine
- C) Influenza vaccine
- D) Meningococcal vaccine
- E) Oral polio vaccine

TABLE 8-3 RECOMMENDED EMPIRICAL ANTIBIOTIC THERAPY FOR PURULENT MENINGITIS BASED ON PATIENT AGE

Age	Most Likely Bacterial Pathogens	Recommended Antibiotics
<1 month	<i>Streptococcus agalactiae</i> <i>Escherichia coli</i> <i>Listeria monocytogenes</i> <i>Klebsiella</i>	Ampicillin + Cefotaxime or Ampicillin + Aminoglycoside
1–23 months	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Streptococcus agalactiae</i> <i>Haemophilus influenzae</i> <i>Escherichia coli</i>	Vancomycin + Ceftriaxone ^a
2–50 years	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i>	Vancomycin + Ceftriaxone ^a
>50 years	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Listeria monocytogenes</i> Aerobic Gram-negative rods	Vancomycin + Ceftriaxone ^a + Ampicillin

^aOr cefotaxime.

Adapted from Tunkel AR, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis*. 2004;39:1267–1284.

The correct answer is "E." Oral polio vaccine is no longer recommended in the United States for anyone. The risk of developing polio from the live vaccine outweighs the benefit of oral administration. All patients undergoing elective splenectomy should receive preoperative vaccination against encapsulated organisms at least 14 days prior to splenectomy; this includes vaccines against *S. pneumoniae*, meningococcus, and *H. influenzae* type B (all encapsulated bacteria). New recommendations for all pneumococcal vaccine-naïve immunosuppressed adults, including those with asplenia, advise vaccination with a dose of PCV13 first, followed by a dose of PPSV23 at least 8 weeks later. Splenectomized individuals should be re-immunized against pneumococcus in 5 years with a second PPSV23. Patients who have undergone splenectomy need to be educated about seeking prompt medical attention for fever.

CASE 8.4

A 74-year-old woman is in your office for a complete physical. As part of her routine labs, you obtain a urinalysis (although why is beyond us ... there is no recommendation for a screening urinalysis for any nonpregnant patients). On further questioning, she has actually had stress urinary incontinence for a number of years, which is unchanged. She reports no fevers, hematuria, dysuria, flank pain, or other symptoms. The urinalysis shows 10 to 20 WBC/hpf and is nitrite positive on dipstick. A culture of the urine shows 100,000 cfu/mL of *E. coli*.

Question 8.4.1 How should you treat this patient?

- A) Trimethoprim–sulfamethoxazole DS 1 tab PO BID for 10 days
- B) Erythromycin 500 mg PO q 6 hours for 14 days
- C) Ampicillin 250 mg PO q 6 hours for 10 days
- D) Ceftriaxone 1 g IM every day for 3 days
- E) With courtesy and respect, but not with antibiotics

Answer 8.4.1 The correct answer is "E." A positive urine culture in an asymptomatic patient (i.e., asymptomatic bacteriuria) should not be treated with antibiotics except during pregnancy. Asymptomatic bacteriuria is a very common finding, especially in elderly females, persons with indwelling catheters, and institutionalized persons. Treatment does not reduce the incidence of symptomatic infection or sequelae. Treatment also does not reduce mortality in frail elderly patients and does not improve chronic urinary incontinence symptoms. Persistent asymptomatic bacteriuria does not result in renal insufficiency or the development of hypertension.

Question 8.4.2 Which statement is true of asymptomatic bacteriuria?

- A) The finding of pyuria in a urinalysis distinguishes urinary tract infection (UTI) from asymptomatic bacteriuria and guides treatment decisions
- B) The prevalence of asymptomatic bacteriuria in women is unrelated to age, function, or hormonal status

- C) Asymptomatic bacteriuria need not be treated in the pregnant patient
 D) None of the above

Answer 8.4.2 The correct answer is “D.” None of the statements are true. “A” is incorrect because the finding of pyuria with low numbers of WBCs in a urinalysis specimen is nonspecific, common, and frequently unrelated to infection. “B” is incorrect. The prevalence of asymptomatic bacteriuria in women increases with age, declining functional capabilities, and institutionalization. More than 10% of community-dwelling women over the age of 65 and up to 50% of elderly women in nursing homes will have asymptomatic bacteriuria. “C” is incorrect. Pregnancy is one state in which treating asymptomatic pyuria/bacteriuria is indicated. The risk of infection from asymptomatic bacteriuria is high in pregnant patients.

HELPFUL TIP:

Treat asymptomatic bacteriuria in the following patients: those with urinary tract obstruction (functional or anatomic), pregnancy, transplanted kidney (only within the first 3 months after transplant ... though we always call the transplant surgeon), or planned urinary instrumentation. In the past, **men** with asymptomatic bacteriuria were considered candidates for treatment. This is no longer the case. **Men** with asymptomatic bacteriuria should not be treated; it does not improve outcomes and leads to resistant organisms (see <http://www.choosingwisely.org/societies/infectious-diseases-society-of-america/>).

HELPFUL TIP:

Not all pyuria is from UTI. Other pathologic causes of pyuria include vaginitis (infectious and atrophic), urethritis (*Chlamydia trachomatis*, *Neisseria gonorrhoeae*), and genital herpes infections.

A few years later, the same patient is now 80 years old (you're still paying off your med school loans and will probably work until you're 80), and she is admitted to a nursing home. Her initial tuberculin skin test (TST) with 5-tuberculin unit injection of purified protein derivative was interpreted as 0 mm diameter of induration after 48 hours.

Question 8.4.3 What is your next step?

- A) Repeat a TST now
 B) Repeat a TST in 2 weeks
 C) Repeat a TST in 1 year
 D) Declare the patient free of TB
 E) Obtain a chest x-ray

Answer 8.4.3 The correct answer is “B.” This is called a two-step TST test. If many years have passed since a patient became infected with latent TB, they can have an initial false-negative due to immune senescence. However, the initial TST stimulates

their ability to react to the test, prompting a positive second test. This type of testing is recommended at the time of *initial* testing for individuals who will thereafter be tested periodically (e.g., persons living in nursing homes CDC recommendations have changed for health care workers). If the first TST is negative, a second test should be performed approximately 2 weeks later in order to detect this “booster phenomenon.” Without this two-step approach in this setting, the patient might react in their 1-year routine screen and may be incorrectly labeled as a recent converter (as opposed to long-standing, latent TB).

HELPFUL TIP:

False-positive TSTs can be due to Bacille Calmette–Guerin (BCG) vaccine and infection with other mycobacteria. However, most patients who had the BCG vaccine will experience a decline in immunity (a maximum of 20% will have a positive TST due to BCG 10 years after the vaccine was given). Therefore, the CDC recommends interpreting a positive skin test as a true positive, even in the presence of a prior BCG, saying, “TST reactions should be interpreted based on risk stratification regardless of BCG vaccination history.” To remove this variable from the equation, Interferon Gamma Release Assays (IGRAs) are considered the preferred testing in patients who have received the BCG vaccine previously (see the following).

HELPFUL TIP:

In general, once the decision is made to test with either the TST or IGRA, the result should be trusted. An IGRA test should not be viewed as a “confirmatory” test for a positive TST (or vice versa) as they have similar test characteristics. More information on the exceptions to this rule is available at <https://www.cdc.gov/tb/publications/litbi/appendixd.htm>.

The TST is repeated 2 weeks later and is interpreted again as 0 mm diameter of induration after 48 hours. You reassure the patient that her tuberculin test is negative.

Question 8.4.4 What would most accurately represent a positive TST in *THIS* patient?

- A) Erythema 5 mm in diameter
 B) Induration 5 to 10 mm in diameter
 C) Erythema of 10 mm in diameter
 D) Induration 10 mm in diameter
 E) Erythematous induration of any size

Answer 8.4.4 The correct answer is “D.” Here is the bottom line. Routine screening is not recommended for low-risk patients (e.g., community dwelling individuals from a low-risk country) unless they are at high risk for reactivation (such as with initiation of TNF-inhibitor). Screen only the following: close contacts of those with TB, HIV-infected patients, IV drug users, those with predisposing factors to TB infection (diabetes, immunosuppressive drugs, lung

TABLE 8-4 INTERPRETATION OF TUBERCULIN SKIN TESTS

Diameter of Induration	Positive in These Situations
>5 mm	Chest x-ray consistent with past TB infection HIV positive Recent close contact of person with active TB Organ transplant recipients Other immunosuppressed conditions (>15 mg/day prednisone, TNF inhibitor, etc.)
>10 mm	Employees or residents of high-risk congregate settings (hospitals, nursing homes, etc.) IV drug users Recent immigrants (<5 years) from high-prevalence countries Children <5 y/o or those exposed to high-risk adults TB lab personnel
≥15 mm	Persons without risk factors. These are people who probably should not have been tested in the first place (e.g., the general public without any exposure to TB)

cancer, etc.), foreign-born individuals arriving in the United States within the last 5 years, nursing home and other institutionalized individuals, and the homeless. Measure the **induration** and not the erythema. The definition of a positive TST changes with the population tested. A general rule is that the cutoff for immunosuppressed people or those with very high-risk exposures (e.g., known close contact with known case of active pulmonary TB) is 5 mm. For other people at risk the cutoff is 10 mm. For people who shouldn't have been tested in the first place the cutoff is 15 mm. See Table 8-4 for specific details. A note about health care workers: As of 2019 the CDC no longer recommends annual screening for health care workers unless they are at high risk (pulmonologists, respiratory therapists, some emergency department staff, etc.). (<https://www.cdc.gov/tb/topic/testing/healthcareworkers.htm>)

**HELPFUL TIP:**

Whole blood interferon-gamma release assays, or IGRAs (e.g., QuantiFERON-TB Gold test, T-SPOT) are Food and Drug Administration (FDA)-approved for use in any situation in which the TST is currently employed. IGRAs are more expensive and should not be the front-line screening test, but may help in certain situations such as with prior BCG vaccination or in someone who may not reliably return for their TST read. Similar to TSTs, IGRAs are **not 100% sensitive and should not** be used in patients who are symptomatic to attempt to confirm a diagnosis of active TB; they are for asymptomatic screening only and cannot differentiate latent from active infection.

is 12 mm. The patient denies cough, weight loss, fever, or chills.

Question 8.4.5 The most appropriate next step in this case is to:

- Obtain a chest radiograph and, if *normal*, initiate isoniazid 300 mg and pyridoxine for 9 months
- Obtain a chest radiograph and, if *normal*, observe the patient annually for signs of active TB (weight loss, cough, fever, etc.)
- Obtain a chest radiograph and, if *abnormal*, initiate isoniazid 300 mg and pyridoxine for 9 months
- Obtain sputum specimens for acid-fast bacilli (AFB) stains and mycobacterial culture and sensitivity testing, and initiate therapy with isoniazid, pyridoxine, pyrazinamide, and rifampin for 6 months
- Obtain an interferon-gamma release assay, and if negative, observe the patient annually for signs of active TB (weight loss, cough, fever, etc.)

Answer 8.4.5 The correct answer is “A.” The patient lives in a high-risk setting (nursing home). The results of her TST 1 year ago suggest that she was not infected with *Mycobacterium tuberculosis* at that time. She has newly converted—probably due to exposure to an active case of TB in the facility. The risk of developing active disease following TB infection is greatest in the first 2 years following infection. The risk/benefit ratio favors prophylactic therapy with isoniazid (INH) for the patient who has converted within the last 2 years, regardless of age, as long as there is no sign of active disease and the chest x-ray is negative. Pyridoxine should also be given to prevent peripheral neuropathy from isoniazid. A negative chest x-ray does not mean that you can forego prophylactic therapy, and thus “B” is incorrect. “C” is incorrect because an **abnormal** chest radiograph must be followed with collection of sputum specimens for AFB staining and culture. “D” is incorrect because a chest radiograph is necessary to evaluate all patients with a positive TST to evaluate for active TB. Sputum specimens should be collected and multiple drug regimens initiated only in patients with signs and symptoms of active disease based on clinical history, examination, and radiographic findings. “E” is incorrect. Since this patient has converted from 0 to 12 mm induration in 1 year, her pretest probability is high enough that performing an IGRA adds nothing.

**HELPFUL TIP:**

It is extremely important to understand the difference between latent TB and active TB. People with latent TB are **asymptomatic** and without any imaging findings concerning for TB disease. They are infected with TB but their immune system has the infection contained. These people are **not infectious** and cannot transmit TB. Treating them for latent TB will lower the risk of converting to active TB in the future. In contrast, in people with active TB, the infection has overcome the patient's immune system. These people are symptomatic and usually have radiographic findings. People with untreated active pulmonary TB are infectious and should be isolated.

A year later, the nursing home calls about her annual TST. You examine the patient and find the diameter of induration

**HELPFUL TIP:**

A directly observed 3-month course of isoniazid (INH) plus rifapentine (RIF) once weekly may be an equal alternative to a 9-month course of daily self-supervised INH in otherwise healthy patients of at least 12 years of age. Contraindications to this regimen include persons <2 years of age, people with HIV, women who are pregnant or who may become pregnant, or those with presumed INH- or RIF-resistant TB.

**HELPFUL TIP:**

If active disease is diagnosed, appropriate therapy should be initiated with a four-drug regimen for 6 to 8 weeks followed by a simpler regimen for 4 to 7 months once sensitivities are known (average 6 months total). A number of regimens are available, and all include isoniazid (INH) and rifampin. INH alone is never appropriate for active TB because of resistance. First-line drugs used for active TB include isoniazid, rifampin, pyrazinamide, and ethambutol. Ethambutol may be dropped if the organism is sensitive to isoniazid, rifampin, and pyrazinamide. Second-line drugs include levofloxacin, streptomycin, and others. Regimens vary by location and local resistance patterns. Contact your local health department.

The patient's son is somewhat distraught that his mother has TB. He asks if she should have received a vaccine before coming into the nursing home.

Question 8.4.6 Regarding the BCG vaccine, which of the following statements is true?

- A) Foreign-born persons who received the BCG vaccine should never have a TST administered
- B) The BCG vaccine is most efficacious for older adults, and children benefit much less from the vaccine
- C) A TST in an individual with a remote history of BCG vaccine should be interpreted as if the BCG had not been given
- D) The BCG vaccine is made from killed *M. tuberculosis*
- E) People who have received the BCG vaccine are not at risk for developing active TB

Answer 8.4.6 The correct answer is "C." Of course, you have been paying attention and know that the TST should be interpreted exactly the same way whether or not the patient has received the BCG. "B" is incorrect. BCG is most efficacious in children but protection from the vaccine wanes over a few years. Even in children, it is a poor vaccine, protecting children from TB only about 50% of the time, making "E" incorrect. Persons vaccinated with BCG should still be evaluated by TST when appropriate and an induration of >10 mm (age <35 years) or >15 mm (age ≥35 years) is considered positive. "D" is incorrect. The BCG vaccine is made from attenuated *Mycobacterium bovis*.

Prior to starting INH, you measured the patient's aminotransferase levels, which were normal. Now, 3 months into treatment, her alanine aminotransferase (ALT) is 42 IU/L (about twice the upper limit of normal).

Question 8.4.7 Your next step is to:

- A) Stop her INH since she has had a few months of treatment
- B) Continue the INH as scheduled and follow up with clinical and laboratory monitoring
- C) Switch to rifampin and pyrazinamide
- D) Refer her to a hepatologist for liver biopsy
- E) Start her on milk thistle

Answer 8.4.7 The correct answer is "B." While liver injury is a significant problem with INH, the drug need not be stopped unless the liver enzymes rise to more than three times the upper limit of normal in the presence of associated symptoms or five times the upper limit of normal if asymptomatic. "A" is incorrect because she should have 9 months of prophylactic therapy. "C" is incorrect because rifampin and pyrazinamide have potentially more hepatotoxicity than INH. Finally, "D" and "E" are incorrect. Neither liver biopsy nor milk thistle (touted for its benefit in liver disease) is likely to be useful.

**HELPFUL TIP:**

Unfortunately, TB has developed resistance to numerous first-line agents. There is drug-resistant TB, multidrug-resistant TB (MDR-TB), and extensively drug-resistant TB (XDR-TB). The differences:

- Drug-resistant TB is resistant to one of the first-line drugs (INH, rifampin, ethambutol, streptomycin, pyrazinamide).
- MDR-TB is resistant to at least INH and rifampin and possibly more drugs.
- XDR-TB is resistant to at least INH, rifampin, fluoroquinolones, and aminoglycosides or capreomycin or both. A new drug for XDR-TB, pretomanid (2019), is approved for use with bedaquiline (approved 2012) and linezolid for highly resistant TB with about a 90% response rate.

► **Objectives: Did you learn to ...**

- Determine who needs to be treated for asymptomatic bacteriuria?
- Interpret TST results?
- Describe the BCG vaccine and how patients who receive it should be approached?
- Recommend appropriate treatment of a positive TST?
- Recognize complications of isoniazid therapy?
- Define and recognize the importance of drug-resistant TB?

► **CASE 8.5**

A 37-year-old woman with a history of mitral valve prolapse and mitral regurgitation presents for evaluation. She reports no symptoms of shortness of breath or exercise intolerance.

She plans to undergo health-screening procedures, including dental exams for routine cleaning and filling of several caries, pelvic examination with removal of an intrauterine device (IUD), and colonoscopy in the next year (for a family history of polyps and early colon cancer).

Question 8.5.1 According to the American Heart Association (AHA) 2007 guidelines (and focused update in 2017) on prevention of infective endocarditis, what should she receive prior to these procedures?

- A) Amoxicillin 2 g orally
- B) Azithromycin 500 mg orally
- C) Clindamycin 600 mg orally
- D) Nothing

Answer 8.5.1 The correct answer is “D.” Even now it seems the news has not made it to every corner of the world. In 2007 there were major changes to the AHA guidelines on infective endocarditis prevention which were affirmed in 2017. The one change that would seem to affect the greatest number of patients in primary care practices is the “downgrading” of mitral valve prolapse with regurgitation, which is no longer considered a high-risk condition. If the patient had a condition for which prophylaxis was warranted, all of the other regimens (“A,” “B,” “C”) are options depending on the patient’s allergies and other medications, conditions, etc.

Question 8.5.2 According to the AHA 2007 guidelines on the prevention of infective endocarditis, which of the following conditions is NOT a high-risk condition for the adverse outcome of infective endocarditis?

- A) Bioprosthetic aortic valve
- B) Mechanical aortic valve
- C) Congenital heart disease completely repaired with prosthetic material
- D) Bicuspid aortic valve
- E) Previous history of infective endocarditis

Answer 8.5.2 The correct answer is “D.” The guidelines recommend antibiotic prophylaxis for conditions considered to be high risk for adverse outcomes of infective endocarditis. High-risk conditions include prosthetic valves (bioprosthetic homograft and allograft valves and mechanical valves), previous infective endocarditis, and complex cyanotic congenital heart disease.

HELPFUL TIP:

Moderate-risk conditions, for which prophylaxis is **not** indicated, include acquired valvular dysfunction, such as rheumatic heart disease, hypertrophic cardiomyopathy, bicuspid aortic valve, and mitral valve prolapse with auscultatory evidence of valvular regurgitation and/or thickened leaflets. **Joint replacement is also not a reason for routine dental prophylaxis** (but that doesn’t stop orthopedists from prescribing antibiotics).

HELPFUL TIP:

Infective endocarditis is much more likely to result from transient bacteremia that occurs with routine dental care at home, like brushing and flossing, than from dental, GI, and GU procedures. Accordingly, good oral hygiene to lower the risk of bacteremia is more important than prophylactic antibiotics.

Question 8.5.3 If your patient had a mechanical aortic valve, appropriate endocarditis prophylaxis might include:

- A) Ampicillin IV 2 hours prior to colonoscopy if biopsy of lesions is anticipated
- B) Ampicillin IV 2 hours prior to pelvic examination and IUD removal
- C) Amoxicillin PO 2 hours prior to routine dental cleaning
- D) Amoxicillin PO 2 hours prior to any injection of local anesthesia and filling of caries
- E) All of the above

Answer 8.5.3 The correct answer is “C.” For high-risk conditions (e.g., mechanical aortic valve), antibiotic prophylaxis is recommended by the AHA prior to cleaning of teeth and removal of plaque. The risk of endocarditis is highest for dental procedures that might traumatize the oral mucosa and periapical tissue, such as tooth extractions, periodontal procedures, and cleaning of teeth with removal of adherent plaque. “A,” “B,” and “D” are incorrect. Prophylaxis is not recommended prior to these procedures. The risk of endocarditis is low for procedures such as upper endoscopy, colonoscopy, and pelvic examination with IUD removal, because the microorganisms likely to cause transient bacteremia following these interventions are not capable of adhering to cardiac valve tissues. Antibiotic prophylaxis is NOT recommended for restorative dental procedures (e.g., fillings). Other procedures where prophylaxis *may* be indicated include procedures involving the respiratory tract with incision or biopsy of mucosa (e.g., tonsillectomy or adenoidectomy, incision and drainage of peritonsillar abscess) or other procedures including *actively infected* areas (e.g., skin, musculoskeletal, gastrointestinal, or genitourinary tracts) in those individuals at highest risk of infectious endocarditis as per above.

HELPFUL TIP:

Catheter-based cardiac valve prostheses (e.g., TAVR/TAVI, annuloplasty rings) should be treated like any other prosthetic valve from the standpoint of endocarditis prophylaxis, according to the AHA 2017 update.

All of the evaluations, including the dental examination, seem to go well. However, 1 month later, she returns to see you for gradually (perhaps even subacutely?) worsening fever, malaise, and night sweats. You are concerned that she may have developed infective endocarditis.

Question 8.5.4 The evaluation of a patient suspected of having subacute bacterial endocarditis (SBE) should include all of the following EXCEPT:

- A) Three sets of blood cultures before starting antibiotics
- B) Auscultation of chest for evidence of new or changing murmur
- C) Transthoracic or transesophageal echocardiogram
- D) Spiral chest CT
- E) Electrocardiogram

Answer 8.5.4 The correct answer is “D.” Endocarditis is on the rise because of the opioid epidemic. Spiral chest CT is NOT indicated in the diagnosis of SBE. History is important: onset of infection can sometimes be related to a recent dental extraction, IV drug abuse, or invasive medical procedure. Symptoms generally begin insidiously and may include weakness, fatigue, fever, night sweats, arthralgia/myalgia, and hematuria. “C,” echocardiography, is indicated. The yield for visualization of vegetations for transthoracic echocardiography is 60% to 77% and increases to 96% with transesophageal echocardiography. A prolongation of the PR interval on an electrocardiogram, “E,” may suggest involvement of the cardiac conduction system while a new or changing heart murmur, “B,” may be suggestive of newly turbulent flow over a vegetation.

You carefully examine the patient and find that she is febrile and slightly tachycardic.

Question 8.5.5 You look for signs of infective endocarditis, paying particular attention to all of the following EXCEPT:

- A) Osler nodes
- B) Painless erythematous macules on the palms and soles
- C) Splinter hemorrhages
- D) Painless nodules over bony prominences
- E) Roth spots

Answer 8.5.5 The correct answer is “D.” Classical physical examination findings of SBE include: intermittent fever; petechiae; conjunctival hemorrhage; splinter hemorrhages under the nails; erythematous painful nodules on the pads of fingers, and toes (Osler nodes); fundic hemorrhages (Roth spots); painless erythematous macules on the palms and soles (Janeway lesions); and a new diastolic murmur. “D” is not a physical examination finding in SBE. Painless nodules over bony prominences are observed in *rheumatic fever* and are a Jones criterion. Remember that in a modern medical practice, most patients with SBE will not present with these findings, and you must maintain a high degree of suspicion for SBE in the appropriate clinical scenario.

HELPFUL TIP:

Laboratory evaluation in endocarditis may be remarkable for anemia, leukocytosis, elevated erythrocyte sedimentation rate (ESR), and microscopic hematuria.

TABLE 8-5 DUKE CRITERIA FOR BACTERIAL ENDOCARDITIS

Definite endocarditis is established by the presence of two major criteria, OR one major and three minor criteria, OR five minor criteria. Probable endocarditis is established by the presence of one major and one minor criterion, or three minor criteria.

Major Duke criteria	<ul style="list-style-type: none"> • New valvular regurgitation • Echocardiographic evidence of vegetations • Two positive blood cultures of a typical organism known to cause endocarditis (<i>Streptococci viridans</i>, <i>Staphylococcus aureus</i>, <i>Streptococci bovis</i>, <i>Enterococcus</i>, HACEK organism) • Persistently positive blood cultures with other, nontypical, organisms drawn at least 12 hours apart • Single blood culture or antibody evidence of <i>Coxiella burnetii</i> (Q fever)
Minor Duke criteria (not an exhaustive list but these are the most common manifestations)	<ul style="list-style-type: none"> • Fever >38°C • Vascular phenomena (e.g., Janeway lesions, splinter or conjunctival hemorrhages, and septic emboli) • History of predisposing illness (e.g., IV drug abuse, heart lesion, and artificial valve) • Immunologic phenomena (e.g., glomerulonephritis and Osler nodes) • Microbiologic finding not meeting major criteria

Question 8.5.6 Which of the following is/are included in the major criteria of the modified Duke criteria for endocarditis?

- A) Positive blood cultures
- B) Janeway lesions (painless macules on palms and soles)
- C) Echocardiographic evidence of valvular vegetation
- D) A and B
- E) A and C

Answer 8.5.6 The correct answer is “E.” The modified Duke criteria were developed to provide clinicians with standardized criteria for the diagnosis of endocarditis. They have been validated by pathologic examination and are more sensitive than other endocarditis criteria systems. See Table 8-5.

You draw a CBC, which shows leukocytosis with a “left shift” (e.g., a high percentage of bands and other immature neutrophils). Chest x-ray and urinalysis are unrevealing. You draw blood cultures and admit her to the hospital and start antibiotics (vancomycin). The next morning two blood cultures are reported to grow Gram-positive cocci in clusters. You order a transesophageal echocardiogram. Indeed, the echocardiogram shows a small vegetation on her mitral valve. Blood cultures return (wow—that was fast!) showing methicillin-sensitive *S. aureus*.

Question 8.5.7 What is the most appropriate treatment of this patient now?

- A) Nafcillin IV for 4 to 6 weeks
- B) Penicillin G IV for 4 to 6 weeks
- C) Vancomycin IV for 4 to 6 weeks

- D) Ceftriaxone IV for 2 weeks
E) Levofloxacin 500 mg IV for 4 to 6 weeks

Answer 8.5.7 The correct answer is “A.” Nafcillin is the drug of choice for the treatment of methicillin-sensitive *S. aureus* endocarditis. The next best agent for severe MSSA infections would be cefazolin. Vancomycin should be reserved for patients with a penicillin allergy or patients with methicillin-resistant *S. aureus* (MRSA) as it has been shown to be inferior to both nafcillin and cefazolin for severe MSSA infections. Neither ceftriaxone nor levofloxacin would be considered appropriate first-line therapy for staphylococcal endocarditis.

HELPFUL (AND IMPORTANT) TIP:

Patients who have a sensitive organism (MSSA) actually have better outcomes (fewer deaths, etc.) with nafcillin or cefazolin than with vancomycin. While providing broad coverage for Gram-positive organisms, vancomycin is actually a relatively weak antibiotic, so save vancomycin for MRSA or other resistant organisms. Other options for hospital-acquired MRSA include linezolid and daptomycin.

While hospitalized, the patient develops symptoms of heart failure and worsening mitral regurgitation by echocardiogram. The heart failure is managed medically, but the regurgitation is now categorized as “severe.” She has had 3 days of antibiotics and is currently hemodynamically stable.

Question 8.5.8 Which of the following is the most appropriate course of action?

- A) Complete 6 weeks of antibiotics and manage her heart failure medically for the foreseeable future
B) Complete 6 weeks of antibiotics and manage her heart failure medically, if possible; plan for valve replacement after 6 weeks of antibiotics
C) Refer her for emergent valve replacement surgery, while being treated with the course of antibiotics
D) Refer her for heart transplant

Answer 8.5.8 The correct answer is “C.” Progressive heart failure due to moderate-to-severe valvular dysfunction is an indication for surgery. There is evidence that early surgery reduces mortality and embolic complications especially in patients who have left-sided endocarditis associated with large vegetations and severe valvular dysfunction. This is true even in the absence of congestive heart failure and in the presence of less virulent pathogens. Thus, “B” is incorrect. Also, “A” is incorrect, as the patient should have surgery. “D” is incorrect, as there is no indication for heart transplant at this time.

HELPFUL TIP:

Other indications for surgery in cases of endocarditis include multiple embolic events, infections that are

difficult or impossible to treat adequately with medications (e.g., fungal infections), cardiac conduction abnormalities due to infection, persistent bacteremia, partially dehiscence prosthetic valve, and perivalvular infection (e.g., cardiac abscess and fistula).

Question 8.5.9 Which of the following organisms is most often responsible for causing infective endocarditis?

- A) *E. coli*
B) *Streptococcus viridans*
C) *Proteus mirabilis*
D) None of the above

Answer 8.5.9 The correct answer is “B.” Of all these choices, *S. viridans* is the most likely organism to cause endocarditis. Gram-negative organisms, such as *E. coli* and *P. mirabilis*, are infrequent causes of infective endocarditis. Other organisms that cause endocarditis include the HACEK organisms (*Haemophilus* species, *Actinobacillus actinomyces comitantes*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella kingae*). In summary, organisms typically found causing endocarditis are *S. aureus*, *S. viridans*, enterococci (aerobic, Gram-positive organisms in chains that are GI or vaginal flora), *Streptococcus bovis*, and HACEK organisms.

► **Objectives: Did you learn to ...**

- Determine who is an appropriate candidate for infective endocarditis prophylaxis?
- Recognize signs and symptoms of infective endocarditis?
- Diagnose infective endocarditis?
- Prescribe appropriate treatment for infective endocarditis?

QUICK QUIZ: DRUG INTERACTIONS

Which of the following medications is/are contraindicated in patients taking linezolid?

- A) MAOIs
B) SSRIs
C) Gentamicin
D) Vancomycin
E) A and B

The correct answer is “E.” Linezolid can cause serotonin syndrome when combined with SSRIs, lithium, MAOIs, and other serotonergic drugs.

► **CASE 8.6**

A 10-year-old boy presents with his mother, complaining of intense itching, worse at night, since the first week of school. He has numerous excoriations in the interdigital web spaces, wrists, and anterior axillary folds (see Figure 8-2). His infant sister (10 kg) has recently developed intensely pruritic linear lesions on her palms, soles, face, and scalp. Their mother

FIGURE 8-2. Scabies rash often occurs between the fingers.

works in a nursing home and has developed pruritus and red-dish-brown nodular lesions in her axillae and perineum that have persisted several months after she treated herself with a lotion that was provided at her place of work. As you examine the patient, your skin begins to itch—you need to solve this puzzle quickly.

Question 8.6.1 The most likely ectoparasite affecting this family is:

- A) Head lice (pediculosis)
- B) Chiggers (mites)
- C) Ticks
- D) Fleas
- E) Scabies

Answer 8.6.1 The correct answer is “E.” Scabies’ mites (*Sarcoptes scabiei*) burrow into the epidermis, lay eggs, and hatch larvae in cycles of 3 to 4 days. The most notable clinical symptom is intense pruritus that is worse at night. The typical lesion is small, erythematous, and papular and may resemble eczema in quality and distribution. About 7% of individuals develop a nodular variant (like the mother in this case). Transmission is typically by direct contact and infestations may appear as epidemics in institutions like nursing homes. The organism may be spread by fomites as well, although to a lesser extent. Young children and infants often have involvement of palms, soles, face, and scalp. A clinical diagnosis may be made in the setting of pruritic rash, typical distribution, and multiple family members affected.

Question 8.6.2 What is the next best step in this case (remember that one child weighs 10 kg)?

- A) Removal of the individual organisms
- B) Tetracycline 10 mg/kg divided TID for all affected family members
- C) Single-dose oral ivermectin 200 µg/kg, repeated in 2 weeks for all affected family members
- D) Symptomatic treatment with topical steroids and oral antihistamines

- E) Single-dose oral ivermectin 200 µg/kg repeated in 2 weeks for the mother; one application of 5% permethrin cream for all family members for 8 to 14 hours, followed by bathing

Answer 8.6.2 The correct answer is “E.” Permethrin 5% cream is the topical medication of choice. Ivermectin, an antihelminthic medication, is indicated for adults with nodular disease (like the mother in this case), in epidemic settings and for treatment of scabies crustosa. “B” is incorrect because tetracycline is not helpful in this situation and should be avoided in children. “C” is incorrect because oral ivermectin should be avoided in infants weighing <15 kg due to concerns about increased penetration of the blood–brain barrier. Finally, “D” is incorrect because scabies should be treated with specific therapy rather than simply symptomatic therapy. Oh, and “A” is just insane—how could you do that? Is there even a CPT code for that?

HELPFUL TIP:

All household members should be treated, regardless of the presence or lack of symptoms. Microscopic examination of a skin scraping may identify the mite but has **poor sensitivity (46–90%)**. Other viable treatment alternatives include crotamiton 10% solution precipitated sulfur in petroleum and lindane but avoid lindane in children <10 years old per the FDA. Additionally, lindane hasn’t been manufactured in the United States for several years. Launder or isolate any worn/suspect bedding, clothing, etc. for 1 week (although scabies mites generally die within 3 days away from human skin). You can instruct patients to put bedding into a garbage bag outside for a week and then wash it. Patients will continue to itch for 2 to 4 weeks after treatment. This does not mean you have failed (although some providers routinely retreat at 1–2 weeks).

You successfully treated the whole family. They are now comfortable, happy, and totally confident in your abilities. The mother returns with her girl, who is now 3 years old, with a new complaint. Apparently, the girl’s “bottom” is hurting, a symptom that her mother has interpreted to mean perineal pain. The pain is worse at night, even waking her at night with vaginal pain. The mother thinks that she may have a bladder infection, but there are no urinary symptoms. In the office, the patient complains only of “itchy butt” and her examination is normal.

Question 8.6.3 What is the next best step in diagnosis of this problem?

- A) Reassurance that this is “just a stage”
- B) Vaginal speculum examination with cultures
- C) “Scotch tape” test
- D) Stool collection for ova and parasites
- E) Psychiatry consultation for the mother who obviously has Münchausen by proxy syndrome

Answer 8.6.3 The correct answer is “C.” The presentation is consistent with pinworm (*Enterobius vermicularis*) infection. Clinical manifestations of pinworm infection are related to the life cycle of the parasite, in which the adult worm resides in the colon, exits the anus at night, lays eggs in the perianal skin, and may also infest the female genitourinary tract. Typical symptoms include pruritus ani, vulvitis, vaginal pain, poor sleep, and—rarely—abdominal pain (pinworms can migrate and cause appendicitis and other intra-abdominal illness). The diagnostic test of choice is the “Scotch tape” test. Clear cellophane tape is wrapped around a tongue depressor, sticky side up, and used to sample the perianal area first thing in the morning before bathing. Multiple specimens should be obtained and stored in a refrigerator (it’s a good thing OSHA has no jurisdiction in the home). The tape is then examined microscopically for the characteristic ova.

Your “Scotch tape” test is a success, proving your clinical suspicions.

Question 8.6.4 The best intervention is to:

- A) Treat the patient with mebendazole 100 mg orally once, repeat in 2 weeks, and encourage good hand washing for the whole family
- B) Treat the patient and the entire family with mebendazole 100 mg orally daily for 14 days
- C) Treat the patient and the entire family with mebendazole 100 mg orally once, and repeat in 2 weeks
- D) Treat the patient with metronidazole 500 mg orally once, and repeat in 2 weeks

Answer 8.6.4 The correct answer is “C.” As with scabies, the entire family should be treated. Mebendazole is the agent of choice, although other antiparasitic agents (e.g., albendazole, pyrantel pamoate) may also be used. Pyrantel pamoate is second-line and only has a 90% response rate. “D,” metronidazole, is not used for helminthic infections but is effective against protozoal infections, including amebiasis and trichomoniasis. Make sure to wash all of the bed linens and clothing; eggs can stay viable for 20 days (although 3 days is more typical).

► **Objectives: Did you learn to ...**

- Diagnose and treat scabies infestations?
- Diagnose and treat pinworm infections?

QUICK QUIZ: SWEATING IN SAVANNAH

A 54-year-old construction worker with no significant travel history presents with a fever. He developed the fever 4 weeks ago and has been febrile daily since. He saw another doctor recently. He was evaluated but received no antibiotics or other treatment. His evaluation, including history, physical examination, CBC

with differential, urinalysis, serum chemistries, and chest x-ray, has been unrevealing. Today his temperature is 38.5°C.

Which of the following is the most appropriate next step in the evaluation and management of this patient?

- A) ESR and/or CRP
- B) PET CT
- C) Bone scan
- D) PSA
- E) Vancomycin IV daily and ceftriaxone IV daily for 2 weeks

The correct answer is “A.” This patient has a fever of unknown origin (FUO). FUO in adults is defined as fever greater than 38.3°C of at least 3 weeks duration with no obvious cause despite extensive evaluation. Infections are the most common source of FUO in children and young adults. The most common infections worldwide include tuberculosis and abscesses. In older adults (sorry to say that this patient’s age of 54 counts!), collagen-vascular diseases, such as giant cell arteritis and rheumatoid arthritis, are more likely sources of FUO. Therefore, tests for inflammatory markers, like ESR and CRP, are indicated. Other tests to consider at this point include ANA, rheumatoid factor, creatine kinase (CK), and blood and urine cultures. Although malignancy is a consideration, PSA (“D”) should not be ordered without other symptoms associated with underlying prostate disease. A bone scan (“C”) would be indicated to look for osteomyelitis, which is an unlikely occult source of fever in this patient with no other reason to believe he has a bone infection. PET CT can be part of the workup for FUO, but is usually reserved until after a broad initial workup has returned as negative. There is no indication for antibiotics (“E”) at this point—wait until you have something to treat.

HELPFUL TIP:

The most common malignancies that present with an FUO are lymphoma, leukemia, renal cell carcinoma, and hepatoma. A CT scan of the abdomen should pick all of these up, except leukemia, of course. However, the diagnostic yield of a CT scan is lower than the yield of FDG-PET/CT, which may detect active inflammation prior to any specific anatomic change. See Table 8-6 for a partial list of causes of FUO.

► **CASE 8.7**

A 45-year-old physician who has recently returned from an early summer fishing vacation (in reality he mostly studied for his upcoming board examination) in rural North Carolina presents for a febrile illness. He reports a 5-day history of fever, malaise, headache, and vomiting. Today, he has developed a nonpruritic rash that began on his extremities and has spread to his body. On examination he has a fever of 38.3°C with a pulse of 120 bpm and otherwise normal

TABLE 8-6 PARTIAL LIST OF ETIOLOGIES OF FEVER OF UNKNOWN ORIGIN**Infections**

- Tuberculosis
- Lyme disease
- HIV
- Endocarditis
- Dental abscess
- Abdominal/pelvic abscess
- CMV
- Epstein–Barr virus

Malignancies

- Metastatic cancer
- Lymphoma
- Leukemias
- Renal cell carcinoma

Autoimmune Conditions

- Polymyalgia rheumatica/giant cell arteritis
- Rheumatoid arthritis
- Inflammatory bowel disease
- Lupus
- Vasculitides

Drug-induced Fever**Factitious fever****Venous thrombosis****Sarcoidosis**

vitals. The rash is maculopapular and generalized, involving his palms and soles. Oral mucosa is dry but intact, and the examination is otherwise nonspecific.

Question 8.7.1 What is the most appropriate next step?

- A) Reassurance and symptomatic treatment
- B) CBC, electrolytes, BUN, creatinine
- C) Dermatology referral
- D) Punch biopsy of leading edge of rash
- E) Admission to the ICU

Answer 8.7.1 The correct answer is “B.” This gentleman is sick (febrile, pulse of 120 bpm, dry oral mucosa, headache, vomiting). We would be amiss to simply reassure (“A”) or refer (“C”) this patient. A CBC and electrolytes may give us an indication of the degree of dehydration and help us narrow the differential (bacterial, viral, etc.). Blood cultures would also be indicated at this time. While he is febrile and tachycardic, his other vital signs are stable and he does not appear to be ill enough to warrant ICU admission (“E”) given the information provided. “D,” punch biopsy of the rash may be warranted as part of the evaluation but would not provide timely diagnosis or treatment; therefore, this would not be the most appropriate next step.

The test results return quickly. CBC shows mild thrombocytopenia and leukopenia but is otherwise normal. BUN and creatinine are at the upper limits of normal, and the electrolytes are normal aside from mild hyponatremia.

Question 8.7.2 The most likely diagnosis is:

- A) Chicken pox
- B) Syphilis
- C) Parvovirus B19
- D) Rocky Mountain spotted fever (RMSF)
- E) Human monocytic ehrlichiosis

Answer 8.7.2 The correct answer is “D.” RMSF is a tick-borne (dog or wood tick) disease caused by *Rickettsia rickettsii*. It presents with a prodrome of fever and headache several days before the onset of the characteristic rash—a maculopapular eruption that begins at the wrists and ankles and spreads centrally. Eventually, the rash becomes petechial. While the rash is characteristic, most patients present to medical care before the development of the rash and up to 10% of patients never develop a rash. Therefore, the lack of a rash does not rule out RMSF. Despite its name, RMSF is endemic in the southeastern United States, the Atlantic states, and the northern Rocky Mountains. Laboratory manifestations of RMSF are generally nonspecific: mild thrombocytopenia (rarely becoming severe), hyponatremia, azotemia, elevated transaminases, and prolonged PTT and PT. WBC count is variable and can be low, normal, or elevated.

“B” is incorrect because the secondary stage of syphilis is characterized by a generalized maculopapular rash (including the palms and soles) and is **not** associated with systemic symptoms.

“E” is also incorrect. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis*, and other related bacteria, and presents with a fever and nonspecific “flu-like” symptoms (headache, fever, myalgias, chills, cough). Rarely a rash, maculopapular or petechial, is seen. Thus, it may be easily confused with RMSF (and in fact some physicians refer to ehrlichiosis as “Rocky Mountain *Spotless* Fever”). Patients are often leukopenic and thrombocytopenic. The disease is tick-borne and endemic to midwestern, south central, and southeastern states. So, if you think you have a case of RMSF but there is no rash, consider human monocytic ehrlichiosis.

Regarding distribution, a quick general rule (albeit an oversimplification) is that Lyme, Babesiosis, and Anaplasmosis cover similar geographic areas including the Atlantic states and upper Midwest. Likewise, Ehrlichiosis and RMSF cover similar geographic areas, focused on the southeastern US and southern Midwest. Outside of Babesiosis, all others should respond to doxycycline. See Table 8-7 for more details on tick-borne illnesses. Yeah ... we know ... *everything* presents with fever, headache, and myalgias. They all sound the same to us too ...

Question 8.7.3 What is the appropriate next step for this patient?

- A) Obtain serologic studies and await results while treating symptomatically
- B) Obtain skin biopsy and await results while treating symptomatically

TABLE 8-7 TICK-BORNE ILLNESSES

Disease	Etiologic Agent	Geographic Distribution	Clinical Findings
Babesiosis	<i>Babesia species</i>	New England, upper Midwest, California	Fever, sweats, myalgias, arthralgias, red urine, hemolytic anemia (most severe cases occur in splenectomized patients). Similar to malaria , in that there are periodic fever spikes. Diagnosis is by Giemsa stain
Human monocytic ehrlichiosis	<i>Ehrlichia chaffeensis</i> and <i>ewingii</i>	South, Midwest	Fever, headache, myalgias (similar to RMSF but rarely a rash). Diagnosis is by buffy coat examination, clinical presentation, PCR
Human granulocytic anaplasmosis	<i>Anaplasma phagocytophilum</i>	Atlantic states, upper Midwest	Fever, headache, myalgias. Similar to Ehrlichia but often milder presentation. Diagnosis is by buffy coat examination, clinical presentation, PCR
Lyme disease	<i>Borrelia burgdorferi</i>	Northeast, upper Midwest	Erythema migrans, myalgias, arthralgias, arthritis, fever, headache. Diagnosis is by serology
Rocky Mountain Spotted Fever (RMSF)	<i>Rickettsia rickettsii</i>	Southeast, Atlantic coast states	Fever, headache, GI symptoms, maculopapular rash that may involve wrists, ankles, palms, and soles of feet→petechiae, myalgias. Diagnosis: clinical, serology (but not + early)
Tularemia	<i>Francisella tularensis</i>	South, Midwest	Fever, headache, cough, myalgias, GI symptoms, tender lymphadenopathy with rare skin ulceration. Diagnoses by agglutination or ELISA. Exposure history (rabbits, ticks, flies)

- C) Obtain serologic studies and start doxycycline 100 mg orally BID
- D) Obtain skin biopsy and start levofloxacin 500 mg orally daily
- E) Hospitalize and start ceftriaxone 1 g IV daily until fever has resolved

Answer 8.7.3 The answer is “C.” Early treatment for RMSF is essential. Individuals treated after 5 days of symptoms have worse outcomes than those treated earlier. Awaiting serologic studies is inappropriate and treatment should not be delayed. The drug of choice in the treatment of RMSF is doxycycline 100 mg PO BID for 14 days. **This is true for children as well!** Despite prior concerns, doxycycline does not stain the teeth of children (per FDA). Pregnant women should be treated with chloramphenicol. Agents such as penicillin, fluoroquinolones, and cephalosporins are inappropriate in this situation.

The following year the patient returns from another fishing trip, this time in Northern Wisconsin. Three weeks after returning, he notices an erythematous rash behind his knee with central clearing. He then develops low-grade fevers and eventually becomes short of breath and fatigued. An EKG is notable for third-degree heart block.

Question 8.7.4 In addition to ordering further testing, what should be your next step in management?

- A) Start IV ceftriaxone
- B) Start oral doxycycline
- C) Emergent permanent pacemaker placement
- D) Start an anti-arrhythmic

Answer 8.7.4 The answer is “A.” This patient likely has Lyme carditis with AV block. His prior rash was likely erythema

migrans. In this setting, IV therapy is indicated, at least until the heart block resolves. Therefore, “B” is incorrect. While hospitalized patients with Lyme-related heart block occasionally require a *temporary pacemaker*, the heart block resolves with effective therapy and it would be premature to place a permanent pacemaker (“C”) at this time.

Your patient is started on ceftriaxone and improves significantly. His Lyme disease titers (you need BOTH a positive ELISA and Western Blot) come back as positive. His fever resolves and his heart block disappears. He completes a full course of therapy targeting his Lyme disease. However, his fatigue persists. He comes back to see you 7 months after completing his therapy and is asking about additional antibiotics.

Question 8.7.5 What should you do at this visit?

- A) Send additional studies to look for co-infection with other tick-borne diseases
- B) Re-prescribe a course of doxycycline
- C) Consider noninfectious causes of his symptoms
- D) A and C
- E) All of the above

Answer 8.7.5 The correct answer is “D.” Occasionally someone with a prior diagnosis (or presumed diagnosis) of Lyme disease will develop chronic symptoms which is referred to as post-Lyme disease syndrome. This syndrome is **not** related to active infection and patients **do not** respond to re-treatment with doxycycline (“B”). However, other explanations for his symptoms are possible and should be investigated. Babesia is carried in the same species of tick as Lyme disease and co-infection can occur. Unlike the other tick-borne infections, Babesia does not respond

to doxycycline (or ceftriaxone in this case), and therefore infection can persist despite treatment for Lyme disease. While much is not currently known about post-Lyme disease syndrome, the IDSA guidelines state, “There is no convincing biologic evidence for the existence of symptomatic chronic *B. burgdorferi* infection among patients after receipt of recommended treatment regimens for Lyme disease [and] antibiotic therapy has NOT proven to be useful and is NOT recommended for patients with chronic (> 6 months) subjective symptoms after administration of recommended treatment regimens for Lyme disease.”

HELPFUL TIPS:

The CDC has approved doing TWO ELISAs (AKA EIA) either at the same time or sequentially to diagnose Lyme Disease. Use an FDA approved test. See: <https://www.cdc.gov/mmwr/volumes/68/wr/mm6832a4.htm>.

HELPFUL TIPS ABOUT LYME:

- Prophylaxis after a bite requires ALL of the following be true:
 - Attached tick identified as an adult or nymphal *I. scapularis* tick (deer tick now known as the “black legged tick”).
 - Tick is estimated to have been attached for ≥ 36 hours (by degree of engorgement or time of exposure).
 - Prophylaxis is begun within 72 hours of tick removal.
 - Local rate of infection of ticks with *B. burgdorferi* is ≥ 20 percent—basically, only New England, parts of the mid-Atlantic States, and parts of Minnesota and Wisconsin.
 - Use a single, 200 mg dose of doxycycline for those 8 years of age and older.
- Only 20–40% of patients will have positive serology for Lyme at the time of the rash (erythema migrans); so, labs cannot be used to rule out infection in these patients.
- Lyme symptoms can include: Rash, neuropathy (Bell’s palsy, others), arthritis, heart block. But there is no chronic Lyme disease, only untreated disease, which progresses to include the above manifestations. There is “Post-Lyme Syndrome” which is subjective aches, fatigue, etc. There is no evidence that this is related to persistent infection.

► Objectives: Did you learn to ...

- Identify and diagnose RMSF?
- Initiate treatment of RMSF?
- Identify complications of Lyme disease?
- Recognize other tick-borne illnesses?

QUICK QUIZ: FLUCTUANCE IN FLINT

A 27-year-old male carpenter presents with pain, redness, and swelling of the distal aspect of the right index finger. He reports

getting a splinter in the site 2 days ago while working. The pain is now so severe that he cannot work. On examination, the patient is afebrile, the right index fingertip is extremely tender, and there is an area of fluctuance at the palmar aspect of the finger. All of the redness and warmth are distal to the proximal interphalangeal joint.

What is the most appropriate diagnosis?

- A) Paronychia
- B) Felon
- C) Whitlow lesion
- D) Tenosynovitis
- E) Achy-breaky-finger

The correct answer is “B.” A felon is an abscess of the distal fingertip (not the person convicted of grand theft auto), and it most commonly occurs in the index finger and thumb. It can be distinguished from paronychia (“A”) because a felon is located in the fat pad of the finger and not the tissue around the nail. Often, an area of fluctuance is palpable. A felon can spread quickly and can involve the tendon sheath, periosteum, and bone. Appropriate management includes x-ray of the finger (to rule out osteomyelitis), antibiotics, and incision and drainage. “C” is incorrect because a whitlow lesion results from inoculation of broken skin of the hand with type 1 or 2 herpes simplex virus. The whitlow lesion is often typical of herpes (vesicles on erythematous papules), but can also be confused with paronychia or felon if at the distal finger. “D” is incorrect as well. Tenosynovitis should involve the tendon sheath. “E” is just silly but could be another big country hit!

► CASE 8.8

The Smith family presents to your office in December seeking travel vaccines for a trip to Nigeria. John (34) and Jane (35) Smith have two children, Jack (7) and Jill (5). They will be in Nigeria for a month and will be living in a suburb of Lagos, Nigeria’s largest city (Boko Haram notwithstanding). They expect to take sightseeing trips into less developed areas. John has no previous medical problems. Jane is currently taking venlafaxine (Effexor) for depression and is known to have a sulfa allergy. Jack has had occasional bouts of reactive airway disease and also has a sulfa allergy. Jill is healthy. Everyone in the family is up-to-date on all routine North American vaccines.

Question 8.8.1 Regarding pathogens they might encounter in Africa, which of the following is caused by a virus?

- A) *Plasmodium ovale*
- B) *Plasmodium falciparum*
- C) Dengue fever
- D) *Entamoeba histolytica*
- E) All of the above

Answer 8.8.1 The correct answer is “C.” Dengue fever (aka “break bone” fever) is a viral infection caused by *Flavivirus* (more later). “A” and “B,” *P. falciparum* and *P. ovale*, are two species of malaria parasites. *P. falciparum* tends to produce

more severe infections that can be rapidly fatal in malaria naïve patients. “D,” *E. histolytica*, is the intestinal protozoan parasite responsible for amebiasis.

Question 8.8.2 Mr. Smith asks for advice on the use of insect repellent. What do you recommend?

- A) Any repellent will do, they’re all the same. Just use the cheapest
- B) Pleasant-smelling repellents, such as Avon Skin So-Soft™, are just as effective as any DEET-containing formulation
- C) Use repellent with DEET concentrations of at least 50% for the children, since their protection is so vital
- D) Apply permethrin insecticide to the skin to enhance any other repellent’s efficacy
- E) Use DEET or picaridin-containing repellents, as they are the most efficacious insect repellents available, but avoid DEET concentrations greater than 30% in children

Answer 8.8.2 The correct answer is “E.” Repeated experiments clearly show DEET- and picaridin-containing repellents to be the most effective for deterring bites and these are the two recommended by the CDC. Picaridin-containing insect repellents do not cause neurotoxicity. The American Academy of Pediatrics recommends not exceeding 30% DEET concentration in repellants for children, due to a slight risk of toxicity seen in frequent applications over a long period of time. Applying DEET to clothing rather than skin reduces the risk of toxicity. Adults can theoretically use any concentration, but 30% is usually sufficient for most situations and you do not get more “bang for your buck” with concentrations above 50%. Often, more cosmetically pleasing products (“B”) are less effective and last a mere fraction of the duration of DEET compounds. Permethrin insecticide, *when applied to clothes, tents, and bed nets*, is synergistic with insect repellent, but permethrin itself is not formulated for use as an insect repellent on skin. Even if permethrin does not kill a tick or mosquito, it makes them incapable of biting. Of note, many countries have a combination DEET-Permethrin product available for use on clothes.

Mrs. Smith reports that her friends get sick with diarrhea every time they travel abroad. She would like to avoid this.

Question 8.8.3 Which of the following is (are) true about traveler’s diarrhea?

- A) Enterotoxigenic *E. coli* (ETEC) is the most common cause of this condition
- B) Even carefully avoiding the consumption of tap water or unwashed vegetables may not be sufficient to prevent the disease
- C) Fluoroquinolones can help to rapidly cure this condition but are contraindicated in pregnancy and young children
- D) The use of loperamide is effective in reducing the duration of symptoms but is contraindicated in children <2 years of age
- E) All of the above are true

Answer 8.8.3 The correct answer is “E.” In most parts of the world, including Africa, ETEC is the most common cause of travelers’ diarrhea followed by other pathogens such as *Campylobacter*, *Salmonella*, and *Shigella*. Although it is advisable to avoid tap water, unwashed foods, and raw foods, these measures are usually insufficient to completely eliminate the risk of contracting the disease. A traveler may drink only bottled liquids but might not realize that the ice in the glass is made from tap water. Although the disease is self-limited, a single dose of ciprofloxacin 750 mg (**see following note**) may shorten the course of symptoms: use ciprofloxacin 500mg BID for 2-3 days for more severe disease. A patient’s symptoms can be further shortened by adding loperamide, which is safe in the absence of bloody stools and fever. Loperamide is potentially toxic to infants and toddlers.

HELPFUL (AND VERY IMPORTANT) TIP:

The CDC no longer recommends fluoroquinolones for travelers’ diarrhea acquired in Southeast Asia because of resistance, seen in *Campylobacter* and increasingly in *Shigella* and *Salmonella*. The current recommendation is to use azithromycin for travelers’ diarrhea in Southeast Asia.

HELPFUL TIP:

The FDA has continued to issue new warnings regarding potentially serious side effects of fluoroquinolones to include: increased risk of tendinopathies, development of *C. difficile* infection, CNS side effects, mental health side effects, and aortic dissection that may cause more risk than benefits with their use. However, the very short duration of fluoroquinolone use for traveler’s diarrhea is not felt to pose significant risk. Moral of the story: use fluoroquinolones sparingly and stay tuned for emerging recommendations.

HELPFUL TIP:

The CDC maintains a user-friendly and up-to-date travel website at <https://wwwnc.cdc.gov/travel>. Always check here first to assure you are giving the right vaccines and advice.

Finally, you discuss the medication options for malaria prophylaxis.

Question 8.8.4 Which of the following is TRUE?

- A) Mefloquine (Lariam) is relatively contraindicated for Jane due to her history of psychiatric illness
- B) Doxycycline would be a safe and effective option for the whole family
- C) Although malaria is resistant to chloroquine in many parts of the world, it can still be used for prophylaxis in West Africa

- D) Atovaquone/proguanil (Malarone) is contraindicated for Jane and Jack due to their sulfa allergy
- E) A month is too long a time to use malaria prophylaxis safely; recommend against it

Answer 8.8.4 The correct answer is “A.” Mefloquine is an effective, once-a-week prophylaxis for malaria. However, it carries a significant risk of CNS side effects including vivid or disturbing dreams. There have been case reports of the medication inducing psychosis, so the drug is relatively contraindicated for patients with a history of psychiatric illness (such as Jane Smith ...careful with that axe, Jane). “B,” doxycycline, may be a good option for the parents, but is not recommended for children < 8 years. “C” is incorrect. Malaria throughout Africa, India, Southeast Asia, and South America is now assumed to be resistant to chloroquine. Finally, “D” atovaquone/proguanil is relatively contraindicated in patients with G6PD deficiency due to a risk of hemolysis, but it does not contain sulfa. Of particular note is answer “E.” Medications used to provide malarial chemoprophylaxis have been shown to be well-tolerated for at least a year or more (<http://www.cdc.gov/malaria/about/faqs.html>). Therefore, 1 month is not too long to use malaria prophylaxis safely, and it should be recommended to the family for their travel. The main cause of long-term travelers getting malaria is poor compliance with antimalarials.

Weeks pass, and you hear nothing more until you are called to the acute care clinic, where Jack Smith has been brought in by his parents for fever and lethargy. Jack’s father had been treated in Lagos, Nigeria, for malaria with an unknown medication, and he subsequently recovered. Jack was apparently well until 10 days after returning home, when he developed rapid onset of a fever and shaking chills. He also complained to his parents of generalized abdominal pain and watery, nonbloody diarrhea. The parents treated him at home for a day with ibuprofen and acetaminophen, but he seemed to worsen. He became lethargic, stopped drinking and eating, and the fever continued.

Jack appears drowsy and listless but is arousable. He does not respond to questions about current symptoms but cooperates with an examination. Findings are temperature 39.1°C, pulse 136 bpm, blood pressure 100/50 mm Hg, and respiratory rate 24. His neck is supple with mild lymphadenopathy. He is tachycardic with a mild flow murmur. His abdomen is nontender with a palpable spleen. No rash or petechiae are noted. The rest of the examination is unremarkable. Malaria is suspected.

Question 8.8.5 What is the best method for confirming this diagnosis?

- A) Blood culture
- B) Malaria serology
- C) Malaria PCR
- D) Thin and thick blood smears
- E) Stool ova and parasite

Answer 8.8.5 The correct answer is “D.” Malaria is usually diagnosed by blood smear. The thick blood smear is the more sensitive screening test, and the thin blood smear is used to identify the species of parasite. There are rapid antigen tests that are often important in resource-limited settings but should be **used in conjunction** with the thin and thick smears. While many rapid antigen tests can distinguish *P. falciparum* from other species, they do not allow specific identification of the other species. If one suspects malaria and the rapid test is negative, thick and thin smears are still indicated and remain the gold standard. Malaria will not grow in blood cultures (“A”), and malaria serologies (“B”) are used only in research experiments and are not clinically helpful for diagnosis of an individual patient. The PCR-based testing (“C”) has excellent sensitivity and specificity but is expensive and not widely available. The malaria parasite cannot be identified in stool (“E”).

HELPFUL TIP:

It is important to determine the species of malaria for a few reasons. First, *P. falciparum* is the most aggressive species of malaria and has a higher mortality rate than the other species. These patients often require closer monitoring. Second, there are two species of malaria that have hypnozoite forms that can remain dormant in the liver, *ovale* and *vivax*. In addition to routine therapy for malaria, these species require an additional agent, primaquine, to clear the dormant parasites in the liver. Because of this dormant stage, infection with these species can cause relapses of malaria weeks, months, or even years after travel if left untreated.

You begin IV fluids and arrange hospital admission. The relevant laboratory tests are drawn and sent, including CBC, blood cultures, tests for malaria, chemistry profile, blood type and screen, and urinalysis. LP is performed and the CSF is normal. In the meantime, the laboratory calls with the report that *P. falciparum* has been identified.

Question 8.8.6 What antimicrobial should be chosen as initial therapy?

- A) Oral hydroxychloroquine (Plaquenil), since many hospitals do not stock chloroquine
- B) Oral mefloquine (Lariam)
- C) Oral quinine
- D) IV quinidine, since IV quinine is not generally available in the United States
- E) IV atovaquone/proguanil (Malarone)

Answer 8.8.6 The correct answer is “D.” This is a difficult question. For severe malaria such as this, IV therapy is generally indicated. In the US, quinidine is the best option available but is sometimes used in conjunction with other therapy. For uncomplicated or outpatient treatment of malaria, atovaquone/proguanil is an option along with artemether-lumefantrine (Coartem) which works well but may prolong the QT interval. In patients

from chloroquine-sensitive zones (currently Central America and the Middle East), treatment with chloroquine is acceptable. Hydroxychloroquine is an option if chloroquine is not available.

HELPFUL TIP:

Artesunate, another antimalarial, clears parasitemia faster than quinidine but is not approved by the FDA. It is available from the CDC on protocol. The CDC maintains a 24-hour hotline for malaria advice that will connect you directly to a real, live clinician for assistance in managing patients with malaria.

Despite a frightening hospital course that included generalized seizures, hypoglycemia, hematuria, renal insufficiency, and an exchange transfusion, Jack eventually recovers completely. The Smith family thanks you for your help and hopes you'll accompany them on their next trip to Africa.

► Objectives: Did you learn to ...

- Identify important elements of a patient's travel plans and unique risks when providing counseling for overseas travel?
- Identify preventative measures for malaria, including chemoprophylaxis and insect bite avoidance?
- Diagnose travelers' diarrhea and describe its prevention and treatment?
- Recognize the signs and symptoms of malaria, describe methods of diagnosis, and initiate therapy?

QUICK QUIZ: CRITTERS IN CLEVELAND

A family comes to see you because the two children, ages 7 and 4, have developed itchy scalps. The parents seem unaffected. So far, they have not tried any treatments. On examination of both children, you find erythematous papules on the occiput and small white eggs firmly attached to the hair shaft about 1 cm from the scalp. Upon leaving the room, you head straight for the shower and scrub your scalp for 5 minutes.

The most appropriate treatment for the suspected diagnosis is:

- Application of 1% permethrin cream to all family members for 10 minutes followed by rinsing, combing out all nits with a special louse comb, and decontaminating affected garments and bed linens. Repeat in 7 days
- Elimination of animal or fomite sources of infestation and use of insect repellents
- Removal of any adherent organisms and oral doxycycline for 14 days
- Application of 5% permethrin cream to all family members for 8 to 14 hours, followed by showering
- Shave everyone's head

The correct answer is "A." These are head lice. Pediculosis infestations of the hair and scalp are usually asymptomatic but can present with itching. The diagnosis is made by demonstration

of the louse or nits, which fluoresce a pale blue under a Wood's light. Treatment with topical agents such as permethrin cream for two applications and wet combing to remove nits is recommended by the CDC. Ivermectin may be effective in cases of resistant organisms. It is reasonable to recommend washing clothing and bedclothes of an infested person, but head lice do not survive off the scalp longer than 48 hours. "B" is appropriate for chiggers (mites) or fleas. "C" is appropriate for ticks (see above for management of Lyme). "D" is a treatment of scabies (note the difference in strength of permethrin). Of note, *there is no benefit to keeping children with head lice out of school*. Avoid sharing hats, etc. But just try to get this one past the school nurse.

► CASE 8.9

A 19-year-old female college student presents to student health services with "the flu." She has noted a fever of 38.9°C and myalgia. She is treated with symptomatic care and discharged back to her dormitory. Three hours later her roommate finds her lethargic and difficult to arouse, so she calls 911. On examination, her blood pressure is 70/30 mmHg with a pulse of 145 bpm. Her neck is supple, but she is lethargic and complaining of severe muscle aches. She denies headache. There is a fine macular rash over her abdomen.

Question 8.9.1 You need to obtain a little more history. The most important historical factor in this case is:

- History of splenectomy
- Previous history of acetaminophen overdose
- History of tobacco use
- History of alcohol abuse

Answer 8.9.1 The correct answer is "A." "A" is important since patients with a splenectomy can get sick rather rapidly from pneumococci and other encapsulated bacteria. The rest are much less important. Shock is not a prominent feature of acetaminophen overdose ("B")—if it occurs at all. In addition, acetaminophen overdose is not associated with a rash. "C" and "D" are incorrect. These elements of social history, while important to her overall care, will not aid you in the diagnosis and immediate management. Another very pertinent historical feature would be tampon use, which is important because this patient may have toxic shock syndrome.

The patient is able to give you the additional history that she does not use tampons and has not taken any medication except for occasional acetaminophen and ibuprofen in recommended doses. She has her spleen ... in a jar in her dorm room—no, wait, we mean in her left upper quadrant.

Question 8.9.2 On the basis of this information you decide that:

- It is unlikely that this is toxic shock syndrome given that she does not use tampons

- B) The combination of acetaminophen and ibuprofen in this patient with the flu has led to hypotension
- C) Given that she is immunocompetent and has her spleen intact, this cannot be sepsis since it started so quickly
- D) Toxic shock, which was a big problem in the 1980s and early 1990s, no longer occurs since the advent of less absorbent tampons
- E) None of the above

Answer 8.9.2 The correct answer is “E.” “A” is incorrect because up to 50% of cases of toxic shock occur as the result of staphylococcal infections unrelated to tampons. These may be ingrown toenails, infected abrasions, etc. “B” is incorrect. Acetaminophen and ibuprofen are frequently combined without difficulty (but likely no benefit either). “C” is also incorrect. Splenectomized patients are more prone to sepsis from encapsulated organisms, but the fact that the patient has a spleen does not grant invincibility. Sepsis obviously occurs in the normal host as well. Finally, “D” is incorrect. While absorbent tampons are a major culprit in toxic shock syndrome, as noted earlier, there are other causes. Thus, toxic shock syndrome is not going away anytime soon.

Question 8.9.3 The organism(s) responsible for toxic shock syndrome is (are):

- A) *Staphylococcus*
- B) *H. influenzae*
- C) *Streptococcus*
- D) A and B
- E) A and C

Answer 8.9.3 The correct answer is “E.” There are two major types of toxic shock syndrome, one caused by *Staphylococcus* and the other by *Streptococcus*. There are certain subtypes of these bacteria that make the toxin responsible for toxic shock syndrome and only certain hosts are thought to be susceptible. Of note, most patients with streptococcal toxic shock are bacteremic, whereas those with staphylococcal toxic shock are not.

Question 8.9.4 Which of the following lab abnormalities is NOT part of the criteria for suspected toxic shock syndrome?

- A) Creatinine of 2 mg/dL (normal 1 mg/dL)
- B) Elevated ALT/AST
- C) Platelets of 900,000/mm³
- D) Elevated CPK

Answer 8.9.4 The correct answer is “C.” By the definition of toxic shock syndrome, the platelet count should be <100,000/mm³ in staphylococcal-related toxic shock. All of the other findings are representative of the multisystem dysfunction that categorizes toxic shock syndrome. Since Staphylococcal Toxic Shock Syndrome is a clinical diagnosis, the clinical criteria are as follows: fever (temperature > 38.9°C), rash, desquamation, hypotension, and three or more of the following: vomiting or diarrhea, severe myalgia or CPK > 2x upper limit of normal (ULN), mucous membrane involvement, Cr > 2x ULN or pyuria in the absence of UTI, LFTs > 2x ULN, platelets < 100,000/mm³, or altered mental status (AMS).

Your patient is a little more alert, most likely NOT due to your charming wit. A second set of vitals shows: blood pressure 72/44 mm Hg, pulse 140 bpm, respirations 24, temperature 39°C. Labs are pending.

Question 8.9.5 What is the single best next step in the care of this patient?

- A) Start IV nafcillin
- B) Place two large-bore IV lines and start aggressive fluid replacement
- C) Start IV norepinephrine
- D) Give a single dose of IV dexamethasone
- E) Transfuse two units of packed red cells

Answer 8.9.5 The correct answer is “B.” Treatment is mainly supportive. She’s in shock. Two large-bore IV lines should be placed with fluids running wide open, and norepinephrine (or other pressor) should be available if her blood pressure does not improve rapidly. “A” is of special note. Patients with classic toxic shock syndrome (staphylococcal) are not bacteremic. They are suffering from the effects of a localized infection that has produced a toxin that is the causative agent in their illness. Therefore, while an anti-staphylococcal drug is important (as is locally treating the site of infection with incision and drainage, toenail removal, etc.), the anti-staphylococcal drug is not to treat bacteremia. However, the patient should receive empiric antibiotics (IV clindamycin and vancomycin) to treat a suspected localized infection, with narrowing of the spectrum when more data (e.g., cultures and susceptibilities) become available. Since we have not ruled out sepsis you might consider broader spectrum antibiotics including piperacillin/tazobactam (Zosyn). “A,” nafcillin alone, would be inappropriate, however. Of note, the clindamycin in this setting is used more to *limit toxin production* than as an anti-staphylococcal agent. “D” and “E” are incorrect since neither steroids nor blood products are currently indicated.

HELPFUL TIP:

Norepinephrine is the initial pressor of choice in most shock situations. It has superior survival when compared to dopamine in sepsis and is clearly better in cardiogenic shock.

► Objectives: Did you learn to ...

- Identify signs and symptoms of toxic shock syndrome?
- Describe the pathophysiology of toxic shock syndrome?
- Initiate management for a patient with sepsis and toxic shock syndrome?

QUICK QUIZ: BOILS IN BOSTON

A 15-year-old male presents with his mother who had to drag him in to your clinic. He won’t look up from his iPhone as his mother gives an exasperated history. He’s had “boils” several times on his buttocks and legs that he prefers to “pop” rather

than to have treated by a medical professional. (“Darn,” you think, “I’d really like to pop those.”) Today he has a large red lump on his anterior left thigh. On examination, you find a healthy-looking male with normal vital signs and a 3 cm area of erythema with central pustule and fluctuance. You incise the lesion, obtain a sample for culture and drain it completely (just in time for lunch).

If the culture returns with MRSA as you suspect it will, you must treat with:

- A) Good local wound care
- B) Packing the wound daily
- C) Chlorhexidine baths and mupirocin to nares daily
- D) Cephalexin orally for 2 weeks
- E) Oritavancin (Orbactiv®) 1,200 mg IV, single dose

The correct answer, and the only thing you must do for this patient, is “A.” You have already treated the local infection, the abscess on his skin, with incision and drainage. Packing a small abscess after incision and drainage (“B”) is a time-honored method of inflicting mild torture on patients. This practice is grounded in tradition and perceived benefits of packing large, deep soft tissue wounds. However, wound packing has not been shown to benefit small skin abscesses (e.g., less than 5 cm), but it has been shown to increase pain, prolong healing, and result in greater health care utilization. “C” sounds good for a patient who has a history of skin abscesses and is probably worth a try in patients with recurrent MRSA skin infections; but the benefits are minimal at best. Even after clearing MRSA, the little bugger has a tendency to recur; re-colonization rates are as high as 75% several months after decolonization. “Bleach baths” have also been tried, and these seem to be marginally effective if they are effective at all (*Clin Infect Dis.* 2014;58:679).

As to “D”, cephalexin does not cover MRSA, and this patient is not systemically ill so IV antibiotics are not necessary. Antibiotics do seem to improve cure rates after drainage of an abscess of 2 cm or greater (NNT 14, NNH 23) (*Ann Emerg Med.* 2018 Mar 9). For abscesses >2 cm, antibiotics are not unreasonable especially if there is surrounding cellulitis. Other factors may push your hand including indwelling medical devices/lines, prior history of endocarditis, immunosuppression, multiple lesions, etc.

If treating a MRSA cellulitis, many options are available. Antibiotic therapy should be dictated by culture and susceptibility when available. Empiric oral antimicrobials that are generally regarded as effective against MRSA include trimethoprim-sulfamethoxazole, tetracyclines (e.g., doxycycline), and linezolid. Clindamycin can be effective as well, but resistance rates are much higher than for the other agents and this should not be used unless susceptibility data is known and resistance is less than 10–15%. For more serious MRSA infections and those failing to respond to empiric oral antibiotics, vancomycin is still first-line IV therapy. Other options include daptomycin and cefaroline. For isolated skin infections, the newer lipoglycopeptides (e.g. oritavancin and dalbavancin) are long-acting antimicrobials that have the advantage of infrequent administration-- in fact, oritavancin

is given as a single dose. The lipoglycopeptides are expensive and have no medical advantage over less expensive options. Remember that they are only approved for skin infections, not systemic infections.

▶ CASE 8.10

One of your patients has recently been in Indonesia for a prolonged period of time. Upon return to the United States, he develops a febrile illness 5 days after landing in Iowa (yes, we have airports). When he presents to the ED, he recalls being bitten by a particularly large and persistent mosquito just before boarding the airplane. On arrival to the ED, he complains of severe, diffuse body pain, headache, and eye pain and eye redness. Vitals show a temperature of 38.5°C, pulse 145 bpm. After taking his blood pressure, you note a few petechiae under the location of the blood pressure cuff (the so-called “tourniquet test”). Labs show a low white count and thrombocytopenia. He does NOT report cyclic fevers. His eosinophil count is normal. A Giemsa stain of the blood shows no organisms.

Question 8.10.1 The most likely cause of this illness is:

- A) Pneumococcal sepsis
- B) Dengue fever
- C) Malaria
- D) Filariasis
- E) Kuru

Answer 8.10.1 The correct answer is “B.” This patient likely has Dengue fever. Dengue fever is most common in Asia but also occurs in Africa, South and Central America, and the Caribbean (and may eventually occur in the southern United States if global temperatures continue to rise). Patients typically present with fever, conjunctivitis, headache, retro-orbital pain, leukopenia, and thrombocytopenia. The *sine-qua-non* of Dengue fever is severe myalgia and arthralgia, hence the moniker “break bone fever.” More mild forms do occur, however. “A” is incorrect since patients with pneumococcal sepsis will *generally* not have thrombocytopenia and a low WBC count (yes, we know there are exceptions). “C” is incorrect because the patient does not have cyclic fevers and a blood smear is negative (plus, we’ve already had our malaria case—why would we repeat it?). Filariasis, “D,” presents with eosinophilia and microfilaria in the bloodstream. Again, this should be evident on the blood smear. “E,” kuru, is a prion-driven degenerative neurological disease found in Papua, New Guinea associated with eating brains and ritual cannibalism (another reason not to eat your family). This patient does not have any evidence of neurological disease, aside from a headache, which also makes this option less likely.

With supportive care, the patient recovers. However, not having learned his lesson he returns to Indonesia. When he comes home to Iowa again, he presents again to the ED, suspecting that he has another episode of Dengue fever.

Question 8.10.2 Signs and symptoms of a second occurrence of Dengue fever include all of the following EXCEPT:

- A) Capillary leak with hypovolemia and hemoconcentration
- B) Hemorrhagic complications including capillary fragility
- C) Onset of symptoms >14 days after exposure
- D) Severe thrombocytopenia

Answer 8.10.2 The correct answer is “C.” If a returning traveler presents more than 14 days after returning home, Dengue fever can be effectively ruled out. In this case, think of other infectious diseases including malaria. The incubation period of Dengue fever is 3 to 7 days. The rest are correct. Patients with their **second or subsequent** episode of Dengue fever can present with capillary leak syndrome, marked thrombocytopenia, and severe hemorrhage. It is usually the second or subsequent infection that leads to mortality.

**HELPFUL TIP:**

The treatment of Dengue fever is supportive care. In many countries, treatment is begun with albumin to replace the circulating volume (given the capillary leak syndrome). However, saline is just as good and a lot less expensive.

► Objectives: Did you learn to ...

- Describe the presentation of Dengue fever?
- Distinguish between the first and subsequent episodes of Dengue fever?

► CASE 8.11

Ahh... Spring Break...beaches in Mexico, palm trees, and margaritas (drug cartels be damned!). However, on return, a 20-year-old female patient presents to your clinic with a low-grade fever (37.8°C [100.4°F]), a pruritic rash on the body, face, hands, and feet, small joint arthralgia, and conjunctivitis (but no eye drainage). Her mother is on the phone demanding she be checked for STIs (spring break, you know).

Question 8.11.1 The most likely diagnosis is:

- A) Dengue
- B) Chikungunya
- C) Typhoid
- D) Zika
- E) MERS-CoV (Middle East Respiratory Syndrome-Corona Virus)

Answer 8.11.1 The correct answer is “D.” This is Zika. Consider Zika in a patient who has two of these and an appropriate travel history: often **pruritic** rash (“micro” papular) involving hands, feet, face, body; low-grade fever (generally <38.5°C); arthralgia, especially in the small joints of the hands and feet; conjunctivitis without evidence of drainage. Patients with two or more of these have a disease *consistent* with Zika. Only 20–25% of infected individuals are *symptomatic*. And

that comment about STIs? Zika can be transmitted both by mosquito (*Aedes* species) as well as sexually (male to male, male to female, and female to male). Zika can persist in semen for 6 months. “A,” Dengue, is discussed earlier. “B,” Chikungunya, which is also mosquito borne, presents similarly to Dengue with abrupt fever and malaise. Only 15% of Chikungunya cases are *asymptomatic*. Fever is often >39°C and patients have arthralgia (bilateral, symmetrical) in often >10 joints and edema (including facial edema). Rash is common as well as about every other nonspecific symptom: myalgia, headache, GI symptoms, adenopathy. Chikungunya is associated with lymphopenia and thrombocytopenia. Patients can have elevated transaminases and organ failure. *Thinking Dengue? Think also Chikungunya.* “C,” typhoid, caused by *Salmonella typhi*, is water borne and presents with fever, myalgias, and abdominal pain. Diarrhea is actually variable and often there is constipation. There is often pulse-temperature disassociation (low pulse, high temperature). It can go on to GI bleeding, bowel perforation, shock, and death. Diagnosis is by culture of *Salmonella typhi* (now called *Salmonella enterica* [thus the moniker “enteric fever”]) from blood or bone marrow (marrow has the best sensitivity at 90%). But bone marrow culture is not fun. We can say this from personal experience. Treatment for typhoid is with antibiotics (start with ceftriaxone while sensitivities are being obtained). The Widal test that you learned about in medical school is fairly useless with a high false-positive rate. Finally, “E,” MERS-CoV, is a coronavirus that presents with URI symptoms and may proceed to an influenza-like illness progressing to respiratory distress and renal failure. Avoid snogging with camels and other people with the illness.

Question 8.11.2 Your patient has an illness consistent with Zika. Which of the following is *not* associated with the Zika virus?

- A) Guillain–Barre like illness
- B) Microcephaly in newborns
- C) Acute tubular necrosis
- D) Increased risk of miscarriage

Answer 8.11.2 The correct answer (and what you don’t generally see with Zika) is “C,” acute tubular necrosis. All of the others are associated with the Zika virus.

Question 8.11.3 Which of the following is FALSE about diagnosing this patient with an illness consistent with Zika?

- A) You need do nothing else. She meets the case definition so that is enough
- B) You can perform PCR on the blood or urine collected within 14 days of symptom onset
- C) You can perform serum IgM but not IgG within first 14 days of symptom onset
- D) You can perform a PRNT (plaque reduction neutralization test)
- E) All of the above

Answer 8.11.3 The correct answer, and false statement, is “A.” You SHOULD do some further evaluation. Let’s look at

them each. Generally, you want to do some testing to confirm, especially if the patient is considering pregnancy—the results could have a huge impact on her life in the near-term. A PCR of blood and urine may be positive for the virus and clinches the diagnosis. However, a negative test does not rule out disease since the virus may be cleared. The next step might be an IgM which is often detectable within 3 days of the onset of symptoms. IgG is not generally recommended. If the IgM is anything but clearly positive (intermediate, etc.), do PRNT (plaque reduction neutralization test). This looks for neutralizing antibodies. Fourteen days after the onset of symptoms, typical testing with IgM and IgG is reliable.

Her tests for Zika come back positive. Her boyfriend, who is asymptomatic, was in Cancun with her on spring break. They are getting married in the next month and would like to start a family. Unfortunately, he is needle phobic and refuses to pee in a cup, saying, “I don’t think so, doc. What happened in Cancun might stay in Cancun, but the pee doesn’t lie.”

Question 8.11.4 What do you recommend?

- A) Avoid conception for the next month
- B) Avoid conception for the next 3 months
- C) Avoid conception for at least 6 months
- D) Test the female partner for Zika before conception using a nucleic acid test of urine and serum as well as IgM testing.
- E) C and D

Answer 8.11.4 The correct answer is “E.” This is for a couple of reasons. First, the virus is transmissible for up to 6 months in the semen. Since most infections are asymptomatic (remember that only 20% or so are symptomatic), we need to know the serostatus of the boyfriend. He is refusing testing. Thus, the best course of action is to wait 6 months before trying to conceive (unless she wants to get a new potential mate who isn’t such a whiner about getting tested). “D” is also correct. Viremia may persist in the female partner so checking her viral status before conception is prudent. Thus, testing for the presence of the virus with a nucleic acid test will help assure there is no active virus persisting.

► Objectives: Did you learn to ...

- Describe the presentation of Zika?
- Distinguish between Zika and some other tropical infections?
- Counsel a patient and partner exposed to Zika?

► CASE 8.12

A 50-year-old male presents to your clinic in summer. He has noticed a relatively abrupt onset of fever, myalgia, back pain, and anorexia. In the past 4 days he has noticed progressive weakness and headache along with fever. He was visiting Minnesota 1 week ago with his 30-year-old son on vacation doing a slow paddle through the Boundary Waters (very pretty). His son was bitten just as much by mosquitoes yet is asymptomatic. You are wondering what the problem might be.

Question 8.12.1 Highest on your differential is which of the following?

- A) West Nile Virus (WNV)
- B) Lead poisoning from drinking water in a polluted stream
- C) Poliomyelitis
- D) Zika Virus
- E) Bacterial meningitis

Answer 8.12.1 The correct answer is “A.” Summer, when adventure and mosquitos are in the air, is WNV season. You can rule out lead poisoning, “B”; this is an ID chapter after all. Plus, lead poisoning generally presents with a radial neuropathy (wrist drop) and should not have fever and systemic symptoms more commonly associated with infection. “C” is unlikely given his age and the fact he likely had immunizations, and, lest we forget, polio has been eradicated in North America. “D” is wrong; the *Aedes* mosquito does not live that far north—yet. Finally, you would expect him to be sicker with bacterial meningitis (“E”).

Question 8.12.2 Factors associated with an increased expression of systemic symptoms with WNV include which of the following?

- A) Advanced age
- B) Hematologic malignancies
- C) Genetic factors
- D) Female gender
- E) All of the above

Answer 8.12.2 The correct answer is “E.” All of the above increase the risk of systemic symptoms. *Male gender* may increase the risk of encephalitis, however. Large viral load, immunosuppression, and organ transplant round out the list. Only 20–40% of those infected with WNV become symptomatic.

Question 8.12.3 The symptoms of WNV include all of the following EXCEPT:

- A) A “Dengue-like” syndrome of sudden onset of headache, body aches, fever (+/–), nausea, vomiting
- B) Confusion perhaps progressing to loss of consciousness
- C) A “polio-like” syndrome with symmetric (or asymmetric) extremity weakness **with** reflexes preserved
- D) A “Guillain-Barre like” syndrome **with loss of** reflexes
- E) Hematuria

Answer 8.12.3 The correct answer is “E.” Hematuria is generally NOT seen in WNV. The symptoms of WNV are protean, necessitating a high index of suspicion among clinicians. WNV presentations may include a “Dengue-like” illness, encephalitis with meningeal signs and mental status changes, neurologic symptoms including Guillain-Barre, a poliomyelitis-type syndrome, neuropathies, meningitis, a rash, and rarely cranial nerve involvement, including a “Bell’s-like” illness. Of those with encephalitis only 30% recover entirely, with 50% having prolonged fatigue, memory issues, or parkinsonian-like syndrome. If you are thinking, “This could be Dengue, but they haven’t left the U.S.,” then you need to think of WNV. Treatment is supportive.

**HELPFUL TIP(S):**

- You may choose not to test for WNV in mild disease (bit of an ache, low-grade fever, etc.). To diagnose WNV: check an IgM which will be 90% positive at 4 to 10 days. This does NOT mean acute infection since the IgM can persist >12 months. If IgM is negative, consider repeating at a later date. IgG doesn't help rule out acute infection; the patient may have had an asymptomatic infection in the past, as IgG persists for years after infection.
- For those with neurological manifestations (encephalitis, weakness, etc.) a firm diagnosis should be made requiring an LP. With WNV encephalitis/meningitis, LP will show a pleocytosis with lymphocytes and, early on, perhaps PMNs will predominate. CSF IgM (MAC-ELISA) should be done. **IgM does not normally cross into the CSF.** Thus, if the CSF is positive for IgM, it is evidence of acute encephalitis (the IgM can cross the blood–brain barrier because of inflammation). If positive, this should be followed up by neutralizing antibodies (acute and convalescent).

**HELPFUL TIP:**

WNV is tracked by dead crows and sentinel chickens. Crows and blue jays seem susceptible to dying from WNV. Sentinel chickens (a real thing) have their blood drawn regularly to check for WNV antibodies in an attempt to track the distribution of WNV. Think of these sentinel chickens standing guard like brave heroes—it makes a great mental picture.

▶ Objectives: Did you learn to ...

- Differentiate WNV from similar illnesses?
- Describe symptoms of WNV, including the protean neurological manifestations?
- Recognize the long-term sequelae of WNV infection?
- List patient-specific factors that increase the potential for symptoms development in WNV?

Clinical Pearls

- Do not delay antibiotics in a suspected case of meningitis. If the lumbar puncture is going to be delayed, administer antibiotics first.
- Do not rely on Kernig and Brudzinski signs to rule out meningitis. The sensitivity is as low as 9%.
- Do not treat asymptomatic bacteriuria in most patients; it is not helpful and only leads to resistance. Pregnant females are one of the important exceptions to this rule.
- Do not treat Lyme disease with prolonged courses of antibiotics. Postinfectious complications are not due to persistent infection.
- Do not treat viral upper respiratory infections with antibiotics.
- Do not use pre-procedural prophylactic antibiotics for most valvular heart disease. Exceptions include: prosthetic valves,

previous infectious endocarditis, and some congenital heart diseases.

- Do not use vancomycin in patients who prove to have methicillin-sensitive *Staphylococcus aureus*; outcomes are worse with vancomycin than with targeted coverage such as nafcillin.
- Start fluids and antibiotics as soon as possible in cases of presumed sepsis. It may take 3 L or more of crystalloid to stabilize the septic patient.
- There is no need to exclude patients with head lice from school. Avoid sharing hats and head-to-head contact, however.
- Treat patients with a positive PPD who have had the BCG vaccine just the same as any other patient with a positive PPD. Age is not a limitation to treating with isoniazid.

HIV/AIDS

A. Ben Appenheimer

Note: The antiretroviral treatment of HIV/AIDS (HAART) continues to evolve, and guidelines for use are regularly updated (<https://aidsinfo.nih.gov/guidelines>). This chapter focuses on the primary care aspects of HIV/AIDS including initial evaluation, drug side effects, and infectious disease prophylaxis.

▶ CASE 9.1

A 23-year-old female presents to your clinic complaining of sore throat, fever, and body aches. She reports that the illness began about a week ago and has persisted despite therapy with NSAIDs, acetaminophen, and throat lozenges. She denies cough, abdominal pain, nausea, or vomiting, but reports a persistent headache. Her past medical and surgical history is unremarkable. The patient smokes about one pack of cigarettes a week, drinks occasional alcohol, and denies other drugs, including intravenous (IV) use. She is heterosexual and has had eight male sexual partners in the past year. She takes oral contraceptives, and her partners usually do not use condoms.

On examination, her vital signs are T 38.9°C, P 112 bpm, BP 115/68 mm Hg, R 20 bpm. She has pharyngitis and enlarged tonsils with exudates. There is diffuse cervical lymphadenopathy, but the neck is supple. There are enlarged lymph nodes in her axillae and inguinal areas as well. The spleen is palpable and nontender. The rest of the examination is unremarkable. You obtain a throat culture, CBC with differential, and heterophile antibody (Monospot) test. Given her history of unprotected intercourse with eight new partners within the last year, you also consider testing for HIV.

Question 9.1.1 The most appropriate laboratory test(s) to rule out the acute retroviral syndrome would be:

- A) HIV-1/2 antibody by ELISA followed by a confirmatory Western blot
- B) HIV-1/2 antibody by rapid detection method
- C) CD4 T lymphocyte count
- D) Combined HIV-1/2 antibody and antigen test by ELISA

Answer 9.1.1 The correct answer is “D.” This presentation is consistent with an acute retroviral syndrome, which occurs very early in the infection and is characterized by a mononucleosis-like illness that can last several weeks. Current HIV diagnostic ELISA methods include the option for both antibody and antigen detection. Since the antibody to HIV will not develop for at least 2 to 8 weeks after infection and the retroviral syndrome typically occurs before seroconversion, HIV antibody tests, including rapid detection methods (“B”), may well be negative. During the acute HIV infection, HIV viral loads are very high, and patients are more infectious compared to other times during their HIV infection. Consequently, the HIV antigen assay, which measures HIV p24 protein, is typically positive during this period. Not all laboratories have adopted the combined HIV antibody–antigen ELISA. If this option is not available, the alternative approach would be to measure the HIV RNA by PCR. However, the PCR test is more expensive and has a longer turnaround time, thus the antibody–antigen ELISA is preferred as the initial screen. The CD4 count (“C”) is not a reliable way of diagnosing HIV infection; it can become depressed with any acute illness or may be normal in early HIV disease.

HELPFUL TIP:

If your clinical suspicion is high and the antibody–antigen combination ELISA test is *negative*, the next step would be an HIV RNA PCR. This can be detected approximately 10 days after infection and is typically positive 5 to 7 days prior to the HIV p24 antigen, but this timing can vary (see Figure 9-1).

The ELISA returns positive for HIV-1 antigen and negative for antibody and confirmatory testing comes back positive. After appropriate counseling about her test results, blood is also sent for CD4 count, HIV RNA viral load testing, and drug-resistance (genotype) testing. Follow-up is arranged for the patient, and she returns in 4 weeks with no complaints or symptoms. A complete history and physical examination are performed. The patient has mild cervical lymphadenopathy

FIGURE 9-1. Sequence of appearance of laboratory markers for HIV-1 infection. Taken from Centers for Disease Control and Prevention and Association of Public Health Laboratories. Laboratory testing for the diagnosis of HIV infection: updated recommendations. Available at: <http://stacks.cdc.gov/view/cdc/23447>. Published June 27, 2014. Accessed August 22, 2018.

and no other findings. Laboratory studies are ordered and show:

WBC 3,200 cells/mm³
 HCT 42%
 Platelets 185,000 cells/mm³
 Chemistry panel (normal)
 Liver enzymes (normal)
 CD-4 lymphocytes 645 cells/mm³
 HIV viral load 5,000 copies/mL
 HIV genotype has K103 N mutation

Question 9.1.2 At her next visit, what baseline studies should be ordered?

- A) PPD or Quantiferon Gold testing
- B) Syphilis IgG
- C) Repeat HIV ELISA
- D) Hepatitis B and C antibody
- E) All of the above

Answer 9.1.2 The correct answer is "E." During the initial assessment of an HIV-infected person, all of these studies are important. A positive PPD (>5 mm induration in a person infected with HIV) warrants treatment for latent tuberculosis (TB) if the

patient is found to not have active disease. Since patients with any sexually transmitted infection (STI) are at risk for another STI, screening for syphilis with syphilis IgG (RPR, VDRL) testing is recommended. The same rationale applies for hepatitis B and C, which can be acquired via the same routes as HIV. The patient has documented HIV by virtue of the positive HIV antigen test and positive HIV RNA; however, documentation of seroconversion is important, and a repeat HIV antibody ELISA should be sent at 12 weeks with positives confirmed by HIV-1/HIV-2 antibody differentiation immunoassay. Genotype testing should also be done at this time. The K103 N mutation suggests that the virus will be resistant to efavirenz and nevirapine, two of the most commonly used non-nucleoside reverse transcriptase inhibitors (NNRTIs).

HELPFUL TIP:

Genotype testing for resistance against certain medications should be performed at baseline diagnosis regardless of whether antiretroviral (ARV) therapy will be initiated or deferred. See this Stanford University website at <https://hivdb.stanford.edu/> for a mutation-resistance database.

The patient is counseled appropriately about all her results.

Question 9.1.3 What is the most important factor in determining when to start highly active antiretroviral therapy (HAART)?

- A) A rising viral load
- B) A decrease in CD4 count
- C) The development of an opportunistic infection
- D) The patient's willingness and ability to maintain strict adherence to an antiviral regimen
- E) An undetectable viral load (<50 copies/mL)

Answer 9.1.3 The correct answer is "D." The decision to start HAART must be done on an individual basis. The most important consideration by far, however, is the willingness of the patient to strictly adhere to complicated medical regimens. Poor compliance puts the patient at risk for the development of resistance, hampers treatment of the patient in later stages, and risks the spread of resistant strains to other patients. The current recommendations are to start all HIV-infected individuals on HAART therapy regardless of CD4 count, although the strength of these recommendations varies depending on the CD4 count. Early HAART therapy helps prevent disease progression for HIV-infected individuals and is also an important step in helping prevent transmission of HIV. Evidence does not support using the viral load ("E") as an independent determinant of initiating therapy.

HELPFUL TIP:

HAART regimens have become increasingly complex with the addition of many new drugs, classes, and combination pills. However, the basics can be broken down and simplified. The backbone usually consists of two nucleoside reverse transcriptase inhibitors (NRTIs). There are a few popular combination pills used for this backbone, but the two often used are Truvada (tenofovir/emtricitabine) and Epzicom (abacavir/lamivudine). These are popular because they are both once daily and are combined with an additional medication for relatively simple regimens. To complete a regimen, an additional medication is added from a different class, usually either an NNRTI (e.g., efavirenz), protease inhibitor (e.g., darunavir/ritonavir), or integrase inhibitor (e.g., dolutegravir, raltegravir, bictegravir, or elvitegravir). Current guidelines favor using integrase inhibitors over the other classes. The three current one-pill once-daily recommended regimens combine an NRTI backbone with an integrase inhibitor. These are Triumeq (abacavir/lamivudine + dolutegravir), Stribild (tenofovir/emtricitabine + elvitegravir/cobicistat), and Biktarvy (tenofovir/emtricitabine + bictegravir). Common adverse effects of common antiretroviral drugs are listed in Table 9-1.

HELPFUL TIP:

Current guidelines recommend treatment immediately for pregnant women at any stage of HIV infection to prevent transmission to the fetus, including during the acute retroviral syndrome. HIV medications suitable for

use during pregnancy must be used. Although HIV itself is not associated with birth defects, it can be transmitted to the fetus during pregnancy, delivery, and breastfeeding. Use of antiretroviral drugs lowers the risk of transmission to the fetus from as high as 70% to 1–2%.

Question 9.1.4 Aside from considering HAART and stressing the importance of partner notification, what other intervention should be offered at this stage?

- A) 13-valent conjugated pneumococcal (Pneumovax) and hepatitis B vaccines (Engerix-B)
- B) Trimethoprim/sulfamethoxazole (TMP/SMX) DS one tablet per day for the prevention of *P. jiroveci* pneumonia (PCP)
- C) Azithromycin 1,200 mg per week for the prevention of *Mycobacterium avium* complex (MAC)
- D) Fluconazole 100 mg per day for the prevention of cryptococcal meningitis

Answer 9.1.4 The correct answer is "A." Adequate immunizations at a clinical stage when the patient is likely to benefit from the vaccines (i.e., CD4 > 200 cells/mm³) are important. Live vaccines, such as the MMR, Zostavax, and intranasal influenza should be avoided in immunocompromised persons, generally considered those HIV-infected persons with a CD4 count <200 cells/mm³. Pneumococcal vaccines are indicated for HIV-positive patients. While the polysaccharide 23-valent vaccine (Pneumovax) covers more serotypes, the 13-valent conjugate vaccine (Pneumovax) elicits a more robust immune response. If previously unvaccinated, the recommendation is to start with the 13-valent conjugate vaccine followed by the 23-valent polysaccharide pneumococcal vaccine after at least 8 weeks. After 5 years, boost with the 23-valent pneumococcal vaccine. The CDC makes no specific recommendation regarding the live shingles vaccine (Zostavax) in HIV patients with CD4 count > 200 cells/mm³ but does state that it is *contraindicated* in patients with CD4 count < 200 cells/mm³; and CDC states that the use of the recombinant vaccine (Shingrix) is "under review" as of 2019.

TMP/SMX ("B") for PCP prevention is indicated when the CD4 drops below 200 cells/mm³, and azithromycin ("C") is indicated for MAC prophylaxis when the CD4 count drops

TABLE 9-1 COMMON ADVERSE EFFECTS OF ANTIRETROVIRAL AGENTS

Medication	Adverse Effects
Tenofovir (component of Truvada)	Renal failure, decreased bone mineral density
Abacavir (component of Epzicom)	Hypersensitivity reaction
Efavirenz	CNS effects including increased suicidality, depression, vivid dreams
Atazanavir	Asymptomatic hyperbilirubinemia

below 50 cells/mm³. If the patient is started on HAART immediately, MAC prophylaxis can be deferred. Fluconazole (“D”) is used for chronic suppression after the treatment of cryptococcal meningitis or for the treatment of esophageal candidiasis; but it is **NOT currently used as primary prophylaxis**. There is no survival benefit to prophylaxis for cryptococcal meningitis. See Table 9-2 for recommended prophylaxis in patients with HIV.

HELPFUL (BUT CONFUSING) TIP:

PCP is no longer *P. carinii*. It is now *Pneumocystis jiroveci*. We didn’t do it, honest. It was some microbiologist-taxonomist who wanted to confuse us all. Just to add to the confusion, *P. jiroveci* pneumonia is still often abbreviated “PCP” as in **Pneumo Cystis jiroveci Pneumonia**.

HELPFUL TIP:

Partner notification is **VERY** important. State laws vary considerably regarding partner notification, and state health departments are usually very helpful in facilitating this. Some states have criminal transmission statutes for having sex without telling the partner of one’s HIV status. Prosecution may not require actual transmission.

After consultation with an HIV specialist, the patient elects not to start therapy at this time and is scheduled for follow-up with regular checks of her viral load and CD4 count. After 1 year, the patient’s lab values have changed: CD-4 lymphocytes

280 cells/mm³ and HIV viral load 75,000 copies/mL. In the past year, she has been treated three times for lobar pneumonia and once for oral candidiasis (without esophageal disease).

Question 9.1.5 Does this patient meet the CDC case definition for the acquired immune deficiency syndrome (AIDS)?

- A) No, because she has not had an AIDS-defining illness
- B) No, because her CD4 count is >200 cells/mm³
- C) No, because she has only been diagnosed with HIV infection for 1 year
- D) Yes, because she has had recurrent (two or more episodes) of lobar pneumonia
- E) Yes, because her viral load is >10,000 copies/mL

Answer 9.1.5 The correct answer is “D.” The CDC HIV classification system requires that a case of HIV infection be reported as AIDS if the CD4 count is less than 200 cells/mm³ **or** the patient develops an AIDS-defining illness. These AIDS-defining illnesses include esophageal (not oral) candidiasis, cryptococcal infection, disseminated histoplasmosis, invasive cervical cancer, tuberculosis, HIV wasting disease, and recurrent pneumonia (more than one episode per year). Other infections, Kaposi sarcoma, and certain lymphomas may also define AIDS in an HIV-infected person. Duration of infection and viral load are not currently criteria.

The patient is started on one of the current first-line regimens, a combination pill of tenofovir/emtricitabine/elvitegravir/cobicistat (Stribild). She does well with the treatment and tolerates the medications. Her laboratory results over several visits are listed in Table 9-3.

Question 9.1.6 Most HIV regimens include three active drugs. What is the benefit of the fourth medication (cobicistat) in the patient’s regimen?

- A) Adds a fourth active antiretroviral to increase efficacy of the regimen
- B) Counteracts a potential adverse effect of her regimen
- C) Inhibits metabolism of some of her regimen, allowing for once-daily dosing
- D) Increases the rate of CD4 increase

Answer 9.1.6 The correct answer is “C.” Most HAART regimens for HIV consist of three medications active against HIV. In this case, the active agents are tenofovir, emtricitabine, and elvitegravir. For specific regimens a fourth “boosting” agent is added to decrease metabolism of an active drug, allowing for easier dosing schedules. The two boosting agents that are

TABLE 9-2 RECOMMENDED PROPHYLAXIS IN HIV PATIENTS

CD4± Count	Organism	Recommended Prophylaxis
<200	<i>Pneumocystis jiroveci</i>	TMP/SMX, atovaquone, or dapsone (should make sure patient is not G6PD deficient)
<100	Toxoplasmosis ^a	TMP/SMX, combination of dapsone + pyrimethamine + leucovorin, or atovaquone
<50	<i>Mycobacterium avium</i> complex (MAC) ^b	Azithromycin, clarithromycin, or rifabutin

^aToxoplasmosis prophylaxis is only indicated if patient has documented positive toxoplasma IgG.

^bMAC prophylaxis is not needed if patient is already on ART or starting ART at that visit.

Adapted from Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents. Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from the Centers for Disease Control and Prevention, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. Available at: http://aidsinfo.nih.gov/contentfiles/lvguidelines/adult_oi.pdf. Accessed August 22, 2018. Table 1.

TABLE 9-3 CASE 1, LABORATORY RESULTS

	January	March	May
CD4 count	204 cells/mm ³	178 cells/mm ³	244 cells/mm ³
Viral load	5,500 copies/mL	<50 copies/mL	<50 copies/mL

used include cobicistat and ritonavir. Since these affect drug metabolism by design, they also have several important drug interactions. If you have someone on a boosted regimen, it is important to check for interactions with any new medications.

HELPFUL TIP:

If the virus is undetectable, HIV is NOT transmissible sexually (*Lancet HIV* 2018 Jul 16); While this is good news, both partners need to have undetectable virus levels (to prevent sharing of different strains), and there are always other STIs to worry about.

The patient comes at her 4-week follow-up and has been taking her tenofovir/emtricitabine/elvitegravir/cobicistat faithfully and not having any notable side effects. Her viral load is checked and is undetectable. However, she is complaining of headaches and nasal congestion thought to be secondary to uncontrolled allergies. She has tried over-the-counter oral antihistamines without effect. Every year she has required inhaled intranasal corticosteroids for several months to control her symptoms.

Question 9.1.7 What inhaled intranasal corticosteroid would be the safest for her to use chronically?

- A) Fluticasone
- B) Triamcinolone
- C) Mometasone
- D) Beclomethasone

Answer 9.1.7 The correct answer is “D.” One of the major drug interactions with the boosting agents is with intranasal (or inhaled) corticosteroids. Systemic exposure with these is increased significantly when combined with ritonavir or cobicistat to the point where there are well-established reports of Cushing syndrome with use (as little as 7 days) as well as reports of adrenal insufficiency after withdrawal of the intranasal corticosteroid. Concurrent use of these medications leads to >100x increased systemic exposure to the intranasal steroid. Therefore, these are category X drug interactions with these “boosting” agents. The ONE inhaled corticosteroid that seems to be exempt from this interaction is beclomethasone (but good luck with that prior authorization!). Other important interactions to always keep in mind in patients on HIV medications include acid suppressants (which can decrease absorption of some common HIV medications), statins (interactions can either increase or decrease statin levels significantly), and polyvalent cations like calcium and iron (which can decrease absorption of some HAART).

The patient misses her next two appointments and returns to clinic 6 months later. She reports missing several doses of her medications and complains of a 10-lb unintended weight loss. She also notes increased frequency of night sweats but no fevers. A physical examination is unremarkable except for a gaunt appearance and temporal muscle wasting.

Her laboratory results show:

CD4 count: 78 cells/mm³
 Viral load: 6,400 copies/mL
 WBC: 2,400 cells/mm³
 Hgb: 11.3 g/dL
 Platelets: 145,000 cells/mm³

After that visit, she starts taking her HAART faithfully. Repeat CD4 count and viral load 4 weeks later shows:

CD4 count: 32 cells/mm³
 Viral load: 7,100 copies/mL

Question 9.1.8 At this point, what changes, if any, should be made to the patient’s regimen?

- A) The patient has failed HAART treatment and her ARV regimen should be adjusted
- B) The viral load is not over 50,000 copies/mL, so the current regimen should be continued
- C) The patient is doing well and her regimen should be continued
- D) None of the above

Answer 9.1.8 The correct answer is “A.” The patient has failed HAART based on several criteria, including the reemergence of detectable viral RNA after it had been completely suppressed. Her ARV regimen should be changed once the results of the repeat genotype testing are known.

HELPFUL TIP:

When changing drug regimens for virologic failure, it is important to repeat genotype testing while on their current regimen to determine whether the patient’s virus has now developed resistance to their current regimen. This is most helpful if the patient is still taking the medication as it maintains the selective pressure for the resistance mutations.

Based on the genotype results, a new ARV therapy regimen is recommended, along with PCP prophylaxis with TMP/SMX. Because you are starting therapy, MAC prophylaxis with azithromycin can be deferred. Two weeks later, the patient’s CD4 count rises to 210 cells/mm³ and she has more energy. However, she returns to clinic 3 weeks later (5 weeks after starting her new ARV regimen) and is complaining of severe shortness of breath. She says that she had been taking her HIV medications but that she lost her PCP prophylaxis prescription (TMP/SMX) and had forgotten to get a new one. Her current illness began 6 days ago as a fever and mild cough. She developed significant dyspnea with minimal exertion, and now is even short of breath at rest. Her chest hurts bilaterally, worse with inspiration. She has drenching night sweats. She denies hemoptysis, sputum production, nausea, vomiting, or abdominal pain.

Physical examination reveals the following vital signs: T 39°C, BP 90/60 mm Hg, P 135 bpm, RR 38 bpm, and SpO₂ 78% on room air. The patient is in severe respiratory distress and in the tripod position. The lung examination shows diffuse rales and tachypnea. You call the ambulance because she looks like she needs help! You place oxygen to help improve her oxygen saturation and her respiratory rate. She does not respond to oxygen and becomes unresponsive.

Question 9.1.9 Aside from respiratory isolation, what should be done immediately?

- A) Sputum culture to evaluate for any lung organisms that may be causing her respiratory distress
- B) Bronchoalveolar lavage (BAL) for PCP via direct immunofluorescence (DFA)
- C) Bag mask the patient and have your nurse place an IV in order to prepare for rapid sequence intubation and IV fluids
- D) Oxygen, furosemide, and nitroglycerin. She clearly is volume overloaded
- E) Chest x-ray (CXR), blood count, CD4 count, and viral load to assess for underlying infection

Answer 9.1.9 The correct answer is “C.” The patient presented in severe respiratory distress and now has impending respiratory failure. She is also hypotensive and tachycardic and must be stabilized before any further workup is done. Remember those ABCs (Airway, Breathing, Circulation) from all those certification classes you had to take? “D,” oxygen, furosemide, and nitrates are useful treatments of congestive heart failure, but this is unlikely in this young woman. *P. jiroveci* pneumonia (PCP) is the most likely diagnosis that explains her findings; however, community-acquired pneumonia remains on the differential. Further workup including sputum culture, PCP direct immunofluorescence, CXR, and blood count are all indicated but only after the patient is stabilized. Given the timing of the onset of symptoms in the setting of a rapid CD4 response to ARV therapy, this is likely complicated by immune reconstitution inflammatory syndrome (IRIS).

HELPFUL TIP:

Immune reconstitution inflammatory syndrome (IRIS—as opposed to ISIS the terrorist organization) is well named. It is identified by a paradoxical **symptomatic** worsening of a preexisting infectious process as the immune system reconstitutes with ARV therapy. Basically, the body’s immune response wreaks havoc at the sites of infection (e.g., CMV retinitis, tuberculosis, cryptococcal meningitis, and obviously, PCP). The infection may be under treatment or subclinical and becomes symptomatically worse when IRIS develops. Common findings are fever, increased fatigue and malaise, unexplained weight loss, worsening respiratory and neurological status. IRIS usually occurs within the first 4 to 8 weeks after initiation of therapy, but it can be delayed several months in some cases.

After appropriate resuscitation and transportation to a higher level of care at the local emergency room, laboratories and a CXR are obtained. The x-ray is shown in Figure 9-2.

Laboratory results are:

WBC 3,400 cells/mm³

Hgb 11 g/dL

Platelets 180,000 cells/mm³

Creatinine 2.4 mg/dL (high)

LDH 1,280 IU/L (high)

PT 12.4 seconds, PTT 27 seconds

Liver enzymes normal

ABG: pH 7.56, PaCO₂ 23 mm Hg, PaO₂ 68 mm Hg (on 100% FiO₂)

Sputum and blood cultures are pending

Question 9.1.10 What should be the *initial* antibiotic therapy?

- A) Four drug anti-tuberculosis regimen
- B) Doxycycline
- C) IV TMP-SMX
- D) IV corticosteroids followed by IV TMP-SMX
- E) No antibiotics initially—just wait for the culture results

Answer 9.1.10 The correct answer is “D.” The patient is acutely ill, and likely has PCP. Steroids decrease the mortality in patients with severe PCP (PaO₂ <70 on room air or arterial–alveolar O₂ gradient >35 mm Hg). The best antibiotic for PCP is TMP-SMX. IV Pentamidine may be used in cases of sulfa allergy, but it has been associated with hypotension and hypoglycemia. Although the classic CXR appearance for PCP is bilateral interstitial infiltrates, it can present differently (as in this case, showing more centrally located patchy infiltrates). Approximately 10% of people diagnosed with PCP have a normal CXR on presentation. Since the infecting organism is not known with certainty, it would be prudent to secondarily add empiric therapy for bacterial pneumonia with ceftriaxone and azithromycin or

FIGURE 9-2. Chest radiograph.

respiratory fluoroquinolone pending bronchoscopy results. Of note, PCP does not grow in standard cultures, but it can be visualized by silver staining or direct immunofluorescence assays (DFA) on BAL specimens. The yield of the PCP DFA testing is much higher with BAL than sputum. Detection of PCP is not reduced during the first 48 hours after starting therapy, and cysts may be seen for much longer in people responding to therapy, despite effective treatment.

The patient is admitted to the ICU and given antibiotics. Her condition stabilizes until 4 hours into her ICU stay. At that time, her respiratory rate on assisted-control ventilation dramatically increases from 18 to 42. Peak airway pressures according to the ventilator are greater than 60 cm of water, when they were less than 30 cm water previously. Breath sounds are absent on the right side of her chest, and her trachea is deviated to the left. Heart sounds are audible, but tachycardic. Neck veins are distended bilaterally.

Question 9.1.11 What is the next appropriate step, BEFORE a repeat CXR is taken?

- A) Give Versed 2 mg IV for sedation, the patient must be very anxious
- B) Pull the ET tube back 1 to 2 cm, as it is likely in the right main stem bronchus
- C) Perform a blind pericardiocentesis, as the patient is developing tamponade
- D) Insert a large Angiocath into the left second intercostal space to relieve the tension pneumothorax on the left
- E) Insert a large Angiocath into the right second intercostal space to relieve the tension pneumothorax on the right

Answer 9.1.11 The correct answer is “E.” The patient has developed a dreaded complication of PCP, a pneumothorax. The organism, *Pneumocystis*, has a propensity to cause blebs (cysts) in the lung tissue. Since the patient was receiving positive pressure ventilation, a tension pneumothorax developed that requires immediate needle decompression. This should be done without waiting for a portable CXR. When the pneumothorax is later confirmed, a tube thoracostomy may be performed under controlled conditions.

HELPFUL TIP:

Over the past several years, the placement location of an angiocath for relief of tension pneumothorax has changed. The current preferred placement is in the mid-axillary line, fourth or fifth interspace (similar to where you would place a chest tube).

Following a protracted ICU admission, the patient improves and is re-started on HAART based on her drug resistance testing. She is discharged, and in response to this life-threatening complication, she is highly motivated and becomes very adherent with her medications. Two years

later her CD4 is 385 cells/mm³, her HIV RNA concentration is <20 copies/mL (nondetectable), and she recently started a job that she enjoys.

► **Objectives: Did you learn to ...**

- Identify the signs and symptoms of the acute retroviral syndrome?
- Use appropriate tests for the diagnosis of HIV infection?
- Evaluate a patient with HIV and monitor that patient's progress?
- Review the preventative health measures and vaccinations important in patients with HIV infection?
- Define acquired immune deficiency syndrome?
- Understand the guidelines for initiating and changing HAART?
- Recognize some of the more common medications used to treat HIV and their side effects?
- Recognize some of the more common opportunistic infections in patients with HIV and how to prevent them?
- Describe IRIS?

► **CASE 9.2**

A 32-year-old female presents to the office seeking prenatal care. Her last menstrual period was 2-and-1/2 months prior to her visit. She believes that she is pregnant and has tested positive with a home pregnancy test. She has been pregnant twice before, with one living child and one spontaneous abortion (G₃P₁). She is married to the father of her children. She has no health problems but does smoke 1/2 pack of cigarettes per day. She also admits to occasional alcohol use (one drink every 2 weeks). She denies illicit drug use, including IV drug use.

Question 9.2.1 Besides prenatal vitamins with iron and folate, you recommend:

- A) Smoking cessation
- B) Confirming the home pregnancy test with a serum HCG in your laboratory
- C) HIV testing and counseling
- D) A and C
- E) All of the above

Answer 9.2.1 The correct answer is “D.” Smoking during pregnancy is associated with lower birth weight and preeclampsia, and smoking in the house with a young child is associated with respiratory diseases, especially asthma. Although confirming pregnancy by examination (uterine size or fetal heart tones) and/or urine HCG is appropriate, serum HCG is unnecessary and expensive. In addition, when used correctly, home pregnancy tests are highly sensitive and specific. But really, this is the HIV chapter, and we want you to know that HIV screening should be included in the routine panel of prenatal tests for all women seeking prenatal care. Routine testing for HIV in expectant females has dramatically reduced the HIV prevalence in children in developed countries. Vertical transmission

of HIV is still a tremendous problem in Africa and other developing regions of the world.

HELPFUL TIP:

Special consent is not needed prior to testing for HIV. However, the patient **must** be notified and given the opportunity to opt-out.

HELPFUL TIP:

Partners of pregnant women should be encouraged to undergo HIV testing if their HIV status is unknown.

You explain that HIV testing is routine, but that the patient can “opt out,” and the patient agrees to HIV testing. Her pregnancy is confirmed. Her HIV Ab/Ag combination test is positive.

Question 9.2.2 What is the next step in confirming the diagnosis of HIV?

- A) HIV viral load
- B) HIV-1/HIV-2 multispot test
- C) HIV Western blot
- D) HIV genotype
- E) CD4 count

Answer 9.2.2 The correct answer is “B.” The recommended testing algorithm has recently changed. Previously an HIV antibody

ELISA “screening” test was done initially, followed by a “confirmatory” Western blot. However, the current recommendation (based on CDC guidelines) starts with the HIV antigen/antibody combination immunoassay. This combines the p24 antigen test (which is positive before seroconversion) with an antibody test for IgM and IgG. This will diagnose any HIV infection 2 to 3 weeks after infection (including HIV-2). If the antigen–antibody test is positive, it is followed by an HIV-1/HIV-2 antibody differentiation immunoassay. If positive, HIV diagnosis is confirmed. If negative, an HIV RNA viral load should be sent to determine whether the patient truly has HIV (see Figure 9-3).

Your patient is understandably shaken by the news of this test result. Being an empathetic physician, you say something like, “I can see that you are shaken by the news of this test result.” She is most concerned about her unborn child.

Question 9.2.3 What should you tell her?

- A) Her child is almost certainly also infected
- B) A therapeutic abortion at this point is the only humane thing to do
- C) With effective therapy, the risk of transmission to the child can be lowered to less than 2%
- D) With effective therapy, the risk of transmission to the child can be lowered to 15%
- E) Despite effective therapy, the risk of transmission remains at 25%

Answer 9.2.3 The correct answer is “C.” Although it is possible for HIV to infect the fetus in utero, the large majority

Recommended Laboratory HIV Testing Algorithm for Serum or Plasma Specimens

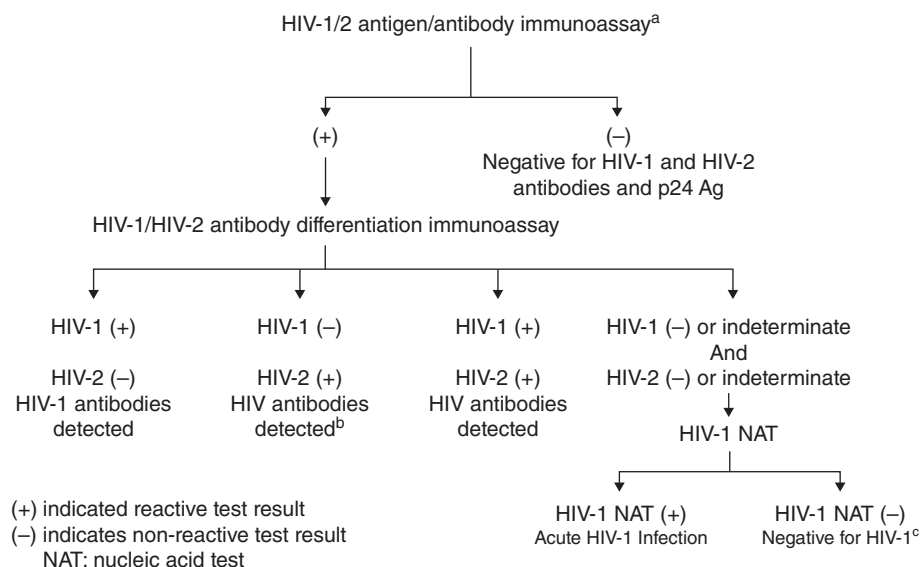

FIGURE 9-3. Algorithm for HIV Testing. Taken from Centers for Disease Control and Prevention and Association of Public Health Laboratories. Laboratory testing for the diagnosis of HIV infection: updated recommendations. Available at: <http://stacks.cdc.gov/view/cdc/23447>. Published June 27, 2014. Accessed August 22, 2018.

of mother-to-child HIV transmission occurs vertically (due to exposure to maternal genital-tract virus during delivery). The most important variable for transmission is the HIV viral load (HIV RNA concentration in plasma) in the mother. ARV drugs reduce perinatal transmission by several mechanisms, including lowering maternal antepartum viral load and providing infant pre- and postexposure prophylaxis. Therefore, combined antepartum, intrapartum, and infant ARV prophylaxis is recommended to prevent perinatal transmission of HIV.

Your patient is somewhat relieved that her baby can be protected and wants to know what can be done to treat her. She feels fine, is now in the second trimester, and would rather not take medications unless she had to.

Some additional laboratory tests are ordered:

CD4 count: 756/mm³
 HIV viral load: 80,000 copies/mL
 Hgb: 11.2 g/dL
 BUN: 11 mg/dL
 Cr: 0.7 mg/dL

Question 9.2.4 What should you tell her about HAART in pregnancy?

- A) To minimize the risk of transmission to her child, she should start HAART as soon as possible
- B) ARV medications are teratogenic and should be avoided at all costs during pregnancy, except just before delivery
- C) Since her CD4 count is normal and she feels well with no sign of opportunistic infections, starting HAART is not indicated
- D) Her renal function makes HAART relatively contraindicated
- E) Her hemoglobin level makes HAART relatively contraindicated

Answer 9.2.4 The correct answer is “A.” ARV therapy is recommended for all pregnant women regardless of their viral load to prevent transmission to the child. Factors that increase risk of transmission of HIV include high maternal viral load, low maternal CD4 count, advanced clinical stage of her HIV, and lack of maternal use of ARV therapy. Vaginal delivery is also a risk factor—but only if the mother did not receive antepartum ARV therapy. Although the patient’s hemoglobin is low, it does not preclude her from taking therapy. Her renal function is normal, so it should not be an issue.

Ideally, the mother should be initiated on ARV as soon as her HIV is diagnosed and have her HIV suppressed (undetectable viral load) on combination antiretroviral therapy (HAART) prior to delivery. If the HIV viral load (HIV RNA concentration in plasma) is nondetectable at 36 weeks, the transmission risk is <2%.

If the mother’s viral load is unknown or >1,000 copies/mL, current guidelines recommend also adding continuous infusion of zidovudine (ZDV) to the mother *during labor* as well as scheduled cesarean delivery. Postpartum prophylactic medications for the newborn should be given for 4 to 6 weeks regardless of maternal viral load. Women who present in labor without HIV testing during pregnancy, should be tested by rapid HIV ELISA. If this is positive, continuous infusion ZDV should be

started. Current guidelines do not recommend additional intrapartum drugs in this setting, **including nevirapine, which has been shown to cause rapid resistance when used in this setting.**

The patient is started on HAART (Truvada plus raltegravir) and tolerates her regimen well. Repeat laboratory results at a return visit 4 weeks later are as follows:

CD4 count: 692/mm³
 HIV viral load: 5,500 copies/mL
 Hgb: 10.9 g/dL

Her HAART seems to be effective. Her viral load has decreased by >10-fold (one log₁₀). You remember from your last patient how sick patients can get with *P. jiroveci* pneumonia.

Question 9.2.5 What do you recommend to this patient regarding PCP prophylaxis?

- A) She should start prophylaxis with TMP–SMX immediately, because PCP in pregnancy can be particularly severe
- B) She should start PCP prophylaxis with inhaled pentamidine, because TMP–SMX is contraindicated in pregnancy
- C) PCP prophylaxis is not indicated since her CD4 count is >200/mm³
- D) PCP prophylaxis is not a major concern for pregnant patients

Answer 9.2.5 The correct answer is “C.” PCP is particularly severe in pregnant patients, but prophylaxis is not generally indicated for CD4 counts >200 cells/mm³. TMP–SMX is associated with hyperbilirubinemia in newborns but is still indicated for PCP prophylaxis. Oral dapsone is another option, as is inhaled pentamidine.

She continues her HAART, but at 36 weeks, her viral load is still detectable (2,500 copies/mL). You recommend changing the ARV, but at the next appointment (37.5 weeks), the patient tells you that she did not fill the new prescriptions, and admits that she has not been adherent with her medications. At this visit, you renew discussions about adherence, and about delivery plans with the patient.

Question 9.2.6 Which of the following is/are true regarding the delivery?

- A) A cesarean section (C-section) is likely to reduce the risk of transmission to her infant
- B) A C-section is indicated because this patient’s viral load remains greater than 1,000 copies/mL despite HAART
- C) A C-section should be performed at 38 weeks gestation, prior to the onset of labor
- D) Postpartum ARV therapy should be given to the mother and infant
- E) All of the above

Answer 9.2.6 The correct answer is “E.” If a patient achieves effective suppression with ARV therapy (undetectable viral load), the risk of transmission is minimal, and the mode of delivery should depend on the preferences of the mother and the other usual obstetric factors. Vaginal delivery is not contraindicated if the mother’s viral load is suppressed. If, as in this patient’s case, the viral load is $>1,000$ copies/mL, current guidelines recommend delivery by C-section at 38 weeks. When performed at 38 weeks, prior to the onset of labor, the relative risk of transmission is reduced by 50%. Intrapartum ZDV, as discussed previously, may also help reduce the risk of transmission. Also, the premature rupture of membranes should be addressed promptly in HIV-infected mothers. Children born to mothers more than 4 hours after rupture are **twice** as likely to acquire HIV. After birth, infants born to any HIV-positive mothers regardless of viral load should receive prophylactic ARV therapy. If the maternal viral load is >1000 copies/mL, the infant should receive combination therapy with two to three drugs, such as zidovudine plus lamivudine plus raltegravir.

The patient delivers a healthy, 3-kg male infant via C-section. The postpartum course is uneventful. Blood is taken from the infant at day 1 and at 2 weeks, and both test positive for HIV antibodies.

Question 9.2.7 What does this mean?

- A) The infant is infected with HIV
- B) The infant’s infection status is unclear from the information given
- C) Maternal HIV antibodies are expected to be circulating in the infant, but it can be assumed that no transmission of infection took place
- D) A positive test at day 1 is expected due to maternal antibodies, but a repeat positive at 2 weeks indicates infant antibody production and is evidence of infection

Answer 9.2.7 The correct answer is “B.” Because the antibodies cross the placenta, children born to HIV-positive mothers will test positive for HIV antibodies for up to 6 months post-partum. Therefore, it requires 2 negative serologic tests at ≥ 6 months OR two or more negative virologic tests at ≥ 1 and 4 months to rule out HIV infection.

Question 9.2.8 How should the HIV status of the infant be determined?

- A) Serial HIV antibody tests: a fourfold drop in titer can be considered negative
- B) p24 antigen testing in the first 48 hours of life
- C) Viral load by PCR in the first 48 hours of life
- D) Viral load by PCR at 14 to 21 days, 1 to 2 months, and 4 to 6 months
- E) p24 antigen and PCR viral load on cord blood samples

Answer 9.2.8 The correct answer is “D.” The best test to assist with diagnosis of HIV infection is viral load by PCR, and a positive test (by DNA PCR or RNA assays) indicates

likely HIV infection. Confirmation of HIV infection is provided by two positive virologic tests obtained from separate blood samples. Overall, the sensitivity of virologic testing increases rapidly by 2 weeks. One can consider obtaining virologic testing within the first 48 hours in newborns who are at high risk for HIV infection, such as infants born to HIV-infected mothers who did not receive prenatal ARV therapy or who had HIV viral loads $>1,000$ copies/mL close to the time of delivery. If this returns positive, this would be indicative of an intrauterine infection rather than intrapartum infection, which is normally acquired during delivery. “A” is incorrect. HIV antibody testing is useless in infants, and quantified titers are not typically generated. “B” is incorrect because the p24 antigen is less sensitive and specific than the viral load in this setting. “E” is incorrect. Tests done on the cord blood may be contaminated with maternal blood and do not give an accurate assessment of the infant’s status.

HELPFUL TIP:

Serial testing of neonates at risk is indicated. Test at age 2 to 3 weeks, 4 to 8 weeks, and 4 to 6 months. If the child is high risk (no prenatal care, known HIV+ mother, known elevated viral load, etc.), consider testing at birth as well.

Question 9.2.9 What should you advise your patient about breastfeeding her son?

- A) HIV is not transmitted by breast milk
- B) HIV is transmitted by breast milk, but the benefits of breastfeeding outweigh the risk of transmission in this setting
- C) HIV is transmitted by breast milk, but her son will be protected from serious infection due to maternal antibodies in the breast milk
- D) HIV is transmitted by breast milk, and breastfeeding should be avoided if possible

Answer 9.2.9 The correct answer is “D.” Postpartum transmission of HIV from mother to child occurs in 10% to 14% of breastfeeding mothers. This is not a major problem in developed nations, where there is reliable access to formula. HIV-positive mothers should be discouraged from breastfeeding in the developed world, including the United States. The recommendations may be different in developing areas of the world, where the mother’s milk may be the only clean source of nutrition available to the infant. In fact, in many developing nations, the benefit of breastfeeding outweighs the risk of HIV transmission; formula feeding can increase mortality due to inadequate access to good nutrition, lack of clean water source with which to mix the formula, and risk of diarrheal illnesses. The World Health Organization (WHO) suggests that “when replacement feeding is an acceptable, feasible, affordable, sustainable and safe, bottle-feeding is the best option.”

Despite the best efforts of your patient and all the physicians and nurses participating in her care, her child tests positive by PCR for HIV at 4 weeks and 4 months. Now, you need to think about how to treat this child with HIV.

Question 9.2.10 Which of the following is true about the use of ARV therapy in children?

- A) Treatment should be initiated immediately for all children as soon as HIV infection is diagnosed
- B) Since they are just little adults with relatively big heads compared to their torsos, treatment indications for children and adults are the same
- C) HAART is highly toxic in children and treatment should be reserved until the child's life is in immediate danger from HIV-related complications
- D) Single-drug ARV therapy is recommended in children rather than HAART

Answer 9.2.10 The correct answer is "A." As of May 2018, the Panel on Antiretroviral Therapy and Medical Management of Children Living with HIV now recommends that **all** children receive antiretroviral therapy, regardless of symptoms or CD4 count, as soon as possible after diagnosis. HAART regimens are more difficult to choose and adjust in children because of a limited number of pediatric (non-pill) formulations and a lack of data about long-term efficacy and safety. However, combination therapy can effectively and safely suppress viral load and stimulate immunologic reconstitution. Monotherapy is NOT recommended.

Question 9.2.11 Which of the following statements regarding the natural history of HIV complications in children is true?

- A) Hepatobiliary complications, such as AIDS cholangiopathy, are more common in children than adults
- B) Kaposi sarcoma is more common in children than adults
- C) Focal brain lesions in children are almost always due to toxoplasmosis
- D) Many children show cognitive and motor deficits, but frank AIDS dementia is uncommon
- E) Lymphocytic interstitial pneumonitis (LIP) is more common in adults than in children

Answer 9.2.11 The correct answer is "D." Twenty-five percent of children with HIV infection demonstrate some cognitive and motor deficits. They face problems with verbal expression, attention deficits, hyperactivity, and hyperreflexia. LIP is characterized by diffuse reticulonodular infiltrates and hilar lymphadenopathy and occurs in up to 40% of children with perinatally acquired HIV. **LIP is very rare in adults.** Kaposi sarcoma is associated with a herpes virus infection and is very rare in children. Toxoplasmosis, usually presenting as focal mass brain lesions, is a reactivation of previous infection, and is therefore also very rare in children. **Hepatobiliary complications are more common in adults** than in children, but the reason for this is unclear.

Question 9.2.12 What should you recommend for this infant regarding PCP prophylaxis?

- A) Prophylaxis is unnecessary because children do not get PCP
- B) Prophylaxis is unnecessary if the child's CD4 count is >200 cells/mm³
- C) Prophylaxis is unnecessary until the child reaches 1 year of age
- D) Prophylaxis with TMP-SMX is contraindicated in infants less than 6 months of age due to the risk of hyperbilirubinemia
- E) Prophylaxis with TMP-SMX as the first-line agent should be initiated at 4 weeks of age because the highest risk for PCP in children is at 3 to 6 months of age

Answer 9.2.12 The correct answer is "E." The highest incidence of PCP occurs in the first year of life with peak onset at 3 to 6 months of age. TMP/SMX is still considered first-line therapy for prophylaxis and should be started at 4 to 6 weeks of age. CD4 counts are naturally higher in children and decrease to adult levels by the age of 6 years. PCP prophylaxis is recommended for all HIV-infected infants <12 months regardless of CD4 count or percentage. It should be continued until the infant is determined to be HIV uninfected or presumptively uninfected. If this drug is not tolerated, dapsone or aerosolized pentamidine are acceptable alternatives. Remember that TMP/SMX can cause kernicterus.

The child tolerates the HAART very well and demonstrates a consistently suppressed viral load. He has further follow-up by a pediatric infectious disease specialist. The mother returns to you for further care. She had been taking the previously prescribed HAART, but quit all her medications 3 months ago because she was having trouble remembering doses causing her to miss several doses per week.

Her latest laboratory results show the following:

CD4 count: 254 cells/mm³

HIV viral load: 50,000 copies/mL

(Previously CD4 count: 692/mm³; HIV viral load: 5,000 copies/mL)

Question 9.2.13 In addition to encouraging her to contact your office immediately when she stops or changes medication, which of the following is the most appropriate advice to provide her now?

- A) She should have continued to take the medications because now the HIV has a "foothold" and it will be much harder to treat
- B) It would not have mattered if she took the medications or not. Her disease is progressing as expected
- C) With the degree of drop seen in her CD4 count, the virus must be resistant, and further HAART is futile
- D) She should have continued the medications, even if she was missing doses. A little of ARV activity is better than nothing

E) She did the right thing by stopping the medications. If a patient is not able to comply fully, it is often better to not take any HAART at all

Answer 9.2.13 The correct answer is “E.” Starting HAART is a very difficult and serious decision and should be made after careful and complete counseling. If taken intermittently, her virus could potentially develop resistance to the medications she is taking, making them ineffective. Patients missing doses of HAART frequently are more likely to have their HIV disease progress. Once multidrug resistance develops, it is more difficult to find an effective regimen to slow disease progression.

After the drug resistance genotype testing did not identify any mutations associated with drug resistance, she agrees to try a new regimen of Truvada (tenofovir/emtricitabine) and dolutegravir. She does not want to have any more children and is using effective contraception, which is important as the dolutegravir is potentially teratogenic.

At her follow-up visit, laboratory results are repeated and show an improvement in her viral load:

CD4 count: 261 cells/mm³

HIV viral load: 7,000 copies/mL.

You explain that if her viral load continues to fall and becomes undetectable, she can expect an improvement in her CD4 count over the next 1 to 2 years. You take this office visit as an opportunity to catch up on preventative medicine. On one prior occasion, 6 years ago, she had an abnormal Pap smear result that returned to normal after a repeat examination and colposcopy. Prior to her diagnosis of HIV, she had never been diagnosed with an STI. A pelvic examination today reveals a normal appearing cervix. A sample for Pap smear is collected and sent to pathology.

Question 9.2.14 How often should this patient get screened for cervical cancer with Pap smear?

- A) Cervical cancer is inevitable, so you should recommend prophylactic radical resection
- B) She must be tested every 6 months, regardless of results of this Pap smear
- C) She may be screened with pap test and HPV co-testing. If both are negative, she may be screened at 3-year intervals
- D) She may be screened per the usual guidelines for HIV-negative women
- E) She has almost no chance of developing cervical cancer and screening may be discontinued

Answer 9.2.14 The correct answer is “C.” Women with HIV are at significant risk of cervical cancer with adolescent women at particularly higher risk due to the higher likelihood of contracting the human papilloma virus (HPV), implicated as the leading cause of cervical cancer. The increased risk of cervical cancer is regardless of how the HIV virus was

acquired (e.g., vertical transmission at birth or horizontal contraction through sexual activity). Prior pap smear screening recommendations for women with HIV were to perform screening at 6 to 12 month intervals pending her CD4 count. However, newer recommendations are more in line with those for women without HIV and do not utilize CD4 counts as part of the screening criteria. For women <30, it is now recommended to START pap smear screening **within 1 year of sexual activity** or age 21, whichever is first. Note, this is a variation from screening recommendations in women without HIV, who should start pap smears at age 21 *regardless* of sexual activity status. For women aged 21 to 29 with new diagnosis of HIV, pap smear should be performed at the time of initial diagnosis. If pap smear is NEGATIVE, a follow-up pap smear should be performed at 12-month intervals until three negative pap smears and then may lengthen out to 3-year intervals.

For those women with HIV infection and > age 30, a pap test can be performed at 12-month intervals until three negative paps and then may lengthen out to 3-year intervals. Another very effective, and preferred, option is to obtain a pap smear with HPV co-testing at baseline and then at every 3-year intervals (*NOTE: this is different than the guidelines for non-HIV-infected women*). Any detection of cervical intraepithelial neoplasia is treated the same as with HIV-negative women. HPV testing alone is NOT recommended for screening or follow-up of an abnormal pap smear in HIV-infected women as there is a high prevalence of oncogenic HPV and results may be suboptimal.

Screening in HIV-infected women should continue even beyond age 65 years due to the higher risk of cervical cancer in this population (**another variation from recommendations for non-HIV-infected women**). However, clinicians should take patient factors such as comorbidities and life expectancy into account and use shared decision-making when determining if continued screening is warranted.

HELPFUL TIP:

Any STI causing genital ulcers (e.g., herpes) increases the risk of transmission of HIV.

Question 9.2.15 Aside from an increased risk of aggressive HPV and a high rate of menstrual disorders, how does the natural history of HIV infection in women differ from that in men?

- A) Women have a lower rate of progressive multifocal leukoencephalopathy (PML) and bacterial pneumonia
- B) Women are more likely to present with oral thrush and recurrent genital candidiasis
- C) Women with the same level of medical care as men have significantly shortened survival
- D) HAART is more effective and better tolerated in women
- E) Most women in the United States acquire HIV from same-sex partners

Answer 9.2.15 The correct answer is “B.” The natural history of HIV infection in women and men is very similar. Women with the same level of access to medical care have similar survival rates to men, and HAART is equally effective in both sexes. Women are more likely to present with recurrent, refractory vaginal candidiasis, oral thrush, PML, and bacterial pneumonias. The majority of women in the United States with HIV have acquired it from heterosexual contact. The second largest route of exposure for US women is IV drug use. Females who have sex with other women are at low risk of contracting HIV; the opposite is true for men who have sex with other men. Worldwide, heterosexual contact is by far the most common means of transmission.

► **Objectives: Did you learn to ...**

- Interpret HIV antibody and viral load tests?
- Evaluate the risk of vertical transmission of HIV?
- Reduce the risk of vertical transmission of HIV?
- Interpret HIV tests in the neonatal period?
- Initiate HAART in children?
- Identify some difference in the clinical manifestations of HIV in women and children?
- Recommend appropriate pap smear screening for HIV-infected women?

► CASE 9.3

A 39-year-old female working as a nursing assistant in your hospital comes into the emergency department looking quite upset. About 30 minutes earlier, she was helping to move a patient with known HIV when his IV was pulled out and he bled. Several drops of blood got on her hands, but she washed them immediately and thoroughly. On examination, she has intact skin on the hands, no signs of trauma, and no residual blood on her.

Question 9.3.1 The most appropriate action to take is:

- A) Reassure her that her risk of contracting HIV for this event is almost zero
- B) Obtain HIV antibody testing
- C) Start her on HAART for prophylaxis
- D) Have her return in 6 weeks for HIV antibody testing
- E) B and D

Answer 9.3.1 The correct answer is “A.” Fortunately, HIV is not the most efficient virus when it comes to spreading itself. Health care workers are at risk of contracting HIV when working with HIV-infected patients, but exposure to infected bodily fluid must occur through a percutaneous route or contact with a mucous membrane or nonintact skin. Even percutaneous exposure (e.g., open bore needle) with HIV-infected blood carries a transmission rate of only about 0.3%, and the mucous membrane exposure to HIV-infected blood carries a 0.09% risk. Therefore, contracting HIV through contact with an infected patient’s blood with intact skin is very low risk.

The patient is reassured that her risk of contracting HIV is negligible. She looks a little sheepish when she tells you, “In all the commotion I knocked over the urinal and spilled the patient’s urine on my leg.” She changed clothes and washed her leg. You inspect her and find some eczema in the area where the urine was spilled.

Question 9.3.2 Now, you recommend that she:

- A) Not worry, as the risk of transmission from this event is also negligible
- B) Start ZDV for 4 weeks for prophylaxis
- C) Be tested for HIV by viral load
- D) Start HAART

Answer 9.3.2 The correct answer is “A.” Your patient now has an area of nonintact skin, which is a concern. However, urine is not considered infectious unless it is grossly bloody. Other bodily fluids **NOT** considered infectious: feces, vomitus, sputum, tears, sweat, nasal secretions, and saliva (things you don’t want contact with anyway). Any visibly bloody fluids, blood, semen, and vaginal secretions are all considered infectious. Other bodily fluids not already mentioned (e.g., CSF and amniotic fluid) should be considered potentially infectious.

HELPFUL TIP:

HIV post-exposure prophylaxis (PEP) should be considered for contact of nonintact skin or oral or genital mucosa (though how this would happen in a health care environment is somewhat sketchy) with potentially infected body fluid (see above) from a source that is HIV positive or has an unknown HIV status. PEP should be started with a three-drug regimen as soon as possible and continued for 4 weeks. There are many options for prophylaxis with various advantages and disadvantages. The Public Health Service currently recommends tenofovir and emtricitabine (Truvada) in addition to raltegravir. A single dose can be given while awaiting rapid HIV testing from the source patient (if known). Note that most institutions have a set of guidelines that may vary from what is discussed here (including “mandatory” baseline testing).

You see the patient back in your clinic 6 months later for routine follow-up.

Question 9.3.3 Given that you did not screen her initially, and she has never been screened, should she be screened for HIV at this time?

- A) No, both of these events were low risk for transmission and there are no recommendations for routine screening
- B) No, both of these events were low risk for transmission, and she does not meet the criteria for risk factor-based testing
- C) Yes, she meets the recommendations for risk factor-based testing
- D) Yes, everyone should be routinely screened for HIV

Answer 9.3.3 The correct answer is “D.” In 2013, the United States Preventive Services Task Force (USPSTF) updated its screening recommendation for HIV, recommending universal HIV testing for all individuals between the age of 15 and 65 who present to any health care setting. The screening interval is not currently well-defined. Repeated screening should be considered in patients known to be at risk for HIV infection, those engaged in risky behaviors, and those who live or receive medical care in high-prevalence settings (i.e., HIV seroprevalence of at least 1%). Depending on their risk, this could be either yearly or every 3 to 5 years. According to the CDC, universal screening may be discontinued if the prevalence of HIV in a population has been documented to be less than 0.1% (1/1,000).

► **Objective: Did you learn to ...**

- Identify when a health care worker is at risk for contracting HIV?
- Apply the USPSTF recommendations for routine HIV screening?

► **CASE 9.4**

A 32-year-old male patient comes in to establish care. He does not have any significant past medical history and is not currently taking any medications. However, his male partner is known to be HIV positive and is currently on HAART. He is not sure what his partner’s viral load is but thinks he is well-controlled. They use protection “most of the time.” He is wondering what he can do to decrease his risk of acquiring HIV.

Question 9.4.1 What should you tell him?

- A) Recommend condom use
- B) Discuss prophylaxis with ARV medications
- C) Discuss sexual risk-reduction counseling
- D) A and C
- E) All of the above

Answer 9.4.1 The answer in this case is “E.” Since he is in a relationship with a known HIV-positive man, it would be reasonable to consider pre-exposure prophylaxis (PrEP). Indications for PrEP go beyond men who have sex with men (MSM) and also encompass high-risk heterosexual adults and IV drug users. To be eligible for PrEP, the patient must be an adult, not have acute or established HIV infection, and not be in a monogamous relationship with a known HIV-negative person. For MSM, it is indicated for anyone with any male sex partner in the past 6 months AND one of the following: any anal sex without condoms in the past 6 months, any sexually transmitted infections in the past 6 months, or in an ongoing sexual relationship with an HIV-positive male partner (current recommendations do not take into account the viral suppression of the HIV-positive partner although studies in IV drug users and heterosexual adults show negligible transmission if the partner’s viral load is undetectable). For heterosexual adults, PrEP is recommended if condoms are infrequently used with a partner who is known to be at substantial risk for HIV infection or if

the patient is in an ongoing relationship with an HIV-positive partner. For IV drug users, PrEP should be considered if the patient has shared injection or drug preparation equipment in the past 6 months.

You decide to start the patient on PrEP based on his risk of acquiring HIV through his infected partner.

Question 9.4.2 What medications should be used?

- A) Tenofovir
- B) Tenofovir/Emtricitabine (Truvada)
- C) Efavirenz (Sustiva)
- D) Tenofovir/Emtricitabine/Efavirenz (Atripla)
- E) None of the above

Answer 9.4.2 The correct answer is “B.” The combination pill of tenofovir and emtricitabine (Truvada) is the only current FDA-approved regimen for PrEP. In trials in IV drug users or heterosexually active adults, tenofovir alone has shown efficacy but is not FDA-approved and has not been adequately studied in MSM. Any PrEP regimen should be taken daily with strict adherence. Coitally timed or other noncontinuous use is not recommended at this point. Pharmacologic PrEP should be done in combination with repeated condom provision, counseling on sexual risk reduction, and evaluation and treatment for other sexually transmitted infections. While the combination pill of Atripla (“D”) would be effective, it would unnecessarily subject the patient to an additional medication (efavirenz) and its associated adverse effects.

When initiating PrEP, discussions regarding an appropriate follow-up plan are imperative.

Question 9.4.3 Which of the following is NOT necessary for monitoring a patient prior to starting and while continuing PrEP?

- A) HIV testing at baseline and again every 3 months
- B) Baseline assessment of creatinine and repeat levels every 6 months
- C) Hepatitis B serologies at baseline
- D) Liver function tests at baseline and at 3 months
- E) Assessment of adherence at each visit

Answer 9.4.3 The correct answer is “D.” LFTs need not be monitored every 3 months. Prior to initiating PrEP, it is important to rule out HIV infection as the two-drug therapy of Truvada would be inadequate in treating HIV and could lead to resistance. In addition, HIV testing should be repeated every 3 months **prior to refilling the prescription**. If signs or symptoms of acute HIV occur, an HIV viral load should be considered. Tenofovir, one of the components of Truvada, has been associated with renal failure and Fanconi’s syndrome. In the trials, only patients whose CrCl was >60 mL/min were included, and therefore the current recommendation is to not prescribe PrEP with Truvada for any patient with a CrCl of <60 mL/min. Once PrEP is initiated, creatinine clearance

should be rechecked every 6 months. In addition, hepatitis B serologies should be checked prior to initiating PrEP with Truvada. Both components of Truvada have activity against hepatitis B and, if stopped in a patient with active hepatitis B, can lead to reactivation and severe hepatic damage.

► **Objective: Did you learn to ...**

- Recognize the effectiveness of PrEP?
- Determine when PrEP is indicated?

Clinical Pearls

- A positive PPD in patients with HIV is considered to be 5 mm of induration.
- All pregnant women should be tested for HIV.
- Daily tenofovir/emtricitabine (Truvada) can be used as pre-exposure HIV prophylaxis in high-risk patients such as IV drug abusers and those who engage in risky sexual behavior.
- Do not treat patients with highly active antiretroviral therapy (HAART) if they are unable to comply with the treatment regimen. Missing doses of HAART can lead to resistant strains of the virus and more difficulty treating the patient later in the disease course.
- HIV does not seem to cause birth defects, and HAART should be continued during pregnancy to reduce vertical transmission risk.
- HIV genotype testing for drug resistance should be done when starting or changing a HAART regimen.
- Neonates suspected of exposure to HIV should be screened with a PCR for viral load.
- Screening for HIV (not in the neonate) should be done using a P24 antigen and with an evaluation of IgM and IgG antibodies. This will detect HIV as soon as 2 weeks after initial infection.
- Start HAART early. In general, the earlier the better.
- The USPSTF suggests that *all* patients age 15 to 65 be screened for HIV.
- Use steroids in patients with pneumocystis pneumonia if the PaO₂ is <70 or the A-A gradient is >35.
- Pap smear screening is important in HIV-infected women due to increased risk of cervical cancer. It is recommended to screen with pap smears more frequently and longer (even past age 65) compared to the general population.

Endocrinology

10

Emad Abou-Arab

► CASE 10.1

A 27-year-old female presents to the office with the chief complaint of fatigue for 4 months. She has gained 17 lb in that same time, despite a decreased appetite. She also complains of depression, increased sleepiness, lack of energy, hair loss, and cold intolerance. Her past medical history is unremarkable, and she takes no medications. She has never had any surgeries. She did a little Internet research, and according to Dr. Oz, she might have a thyroid problem.

Question 10.1.1 Which of the following physical examination findings would be expected?

- A) Tachycardia
- B) Exophthalmos
- C) Fine tremor
- D) Peripheral sensory loss
- E) Delayed relaxation in reflexes

Answer 10.1.1 The correct answer is “E.” The history given is consistent with a hypothyroid state. Symptoms of hypothyroidism include thinning hair, dry skin, a hoarse and deep voice, bradycardia, and a prolonged relaxation in the reflexes. Tachycardia and a fine tremor are more typical of hyperthyroidism, and exophthalmos is characteristic of Graves’ disease (one specific cause of hyperthyroidism). Proximal muscle weakness may occur in hypothyroidism, but sensory loss is not typical (although hypothyroidism, diabetes, gout, rheumatoid arthritis, obesity, and connective tissue disorders can contribute to carpal tunnel syndrome, and carpal tunnel syndrome may be the initial presenting symptom of these diseases).

Question 10.1.2 How can the diagnosis of hypothyroidism best be confirmed?

- A) Elevated thyroid-stimulating hormone (TSH) level
- B) Low TSH level
- C) Thyroid biopsy
- D) Radionuclide scan
- E) Serum thyroglobulin

Answer 10.1.2 The correct answer is “A.” The TSH is the most sensitive test for both hypo- and hyperthyroidism, and changes in the TSH can precede abnormalities in serum thyroxine (best measured as free T4) level. An elevated TSH occurs when the pituitary detects insufficient thyroid hormone production (low free thyroxine), and TSH production is shut off when the pituitary detects an excess of thyroid hormone circulating (elevated free thyroxine). With pituitary dysfunction, there is insufficient TSH production resulting in a low TSH and decreased free thyroxine (T4). Since pituitary disorders are rare, and often suggested by other clues in the history and physical (lack of gonadotropins [amenorrhea, hypogonadism], impaired vision from mass effect), TSH alone is sufficient for initial screening for thyroid disease. “C,” a biopsy, is used to evaluate thyroid masses and nodules as is “D,” a radionuclide scan. A radionuclide scan (“D”) can also be used in the evaluation of thyroid masses. “E,” the serum thyroglobulin measurement, is used to monitor thyroid carcinoma and is not a screening test.

Her laboratory results are normal except for glucose 115 mg/dL, TSH 22.3 μ IU/mL (normal 0.27–4.20), free T4 0.56 ng/dL (normal 0.93–1.70).

Question 10.1.3 Based on prevalence, labs, and presentation, what is the MOST likely cause of this patient’s disease?

- A) Autoimmune hypothyroidism
- B) Iatrogenic hypothyroidism
- C) Tuberculosis infiltration of the thyroid gland
- D) Nonfunctioning pituitary adenoma
- E) Congenital hypothyroidism

Answer 10.1.3 The correct answer is “A.” Autoimmune hypothyroidism (Hashimoto thyroiditis) is the most common cause of hypothyroidism in areas where there is adequate iodine. If this patient had a pituitary adenoma causing hypothyroidism, the TSH (as well as the free T4) would be low. Congenital hypothyroidism causes severe developmental delay and a constellation of other signs termed “cretinism”; screening for hypothyroidism is generally part of neonatal screening.

Tuberculosis is a rare cause of hypothyroidism but is the most common cause of **adrenal** failure worldwide.

HELPFUL TIP:

Outside the United States, iodine deficiency is the most common cause of hypothyroidism, with an estimated 2 billion persons being iodine deficient although not all being hypothyroid.

Question 10.1.4 How should this patient be managed?

- A) I^{131} administration
- B) Surgical excision of thyroid gland
- C) Start synthetic thyroxine hormone at 25 micrograms (μg) PO daily, and re-check symptoms and TSH in 2 months
- D) Start synthetic thyroxine hormone at 200 μg PO daily, and re-check symptoms and TSH in 2 months
- E) Start synthetic thyroxine hormone at 25 μg PO daily, and double every week until the patient experiences weight loss, tremor, and poor sleep (and the desire to find a new doctor)

Answer 10.1.4 The correct answer is “C.” The patient is deficient in thyroid hormone and needs supplementation. Two strategies may be used: (1) start with 25 μg daily and titrate up every 1 to 2 months until the TSH is in the normal range or (2) start with full-dose therapy based on weight (1.6 $\mu\text{g}/\text{kg}$ daily) and adjust based on TSH in 1 to 2 months. Either option is appropriate in young, otherwise healthy adults. **However, older patients (>65 years old) or those with cardiac disease or multiple comorbidities should be started at a low dose (25 μg daily) due to increased cardiac risks associated with being overly replaced (see helpful tip below).** If the patient is titrated up to 200 μg of levothyroxine and does not seem to be responding, the diagnosis needs to be reconsidered or the patient’s adherence needs to be carefully assessed. Iron and food will decrease the absorption of levothyroxine by as much as 40%. Thyroid medication should be taken under similar circumstances each day, and ideally it should be taken on an empty stomach. If it is taken with a meal, it should always be taken with a meal to prevent variable absorption. Peak serum levels occur 2 to 4 hours after an oral dose, but the half-life is 7 days, so day-to-day levels can be misleading. It usually takes 6 to 8 weeks for the body’s endocrine response and TSH to reach a steady state. The goal of therapy is a euthyroid state with the patient experiencing neither hyper- nor hypothyroid symptoms. “A” and “B” are treatments of **hyperthyroidism**. Surgical excision and radioablation with I^{131} are approaches to the treatment of Graves’ disease. Both can result in iatrogenic hypothyroidism that requires lifelong thyroid hormone therapy.

You start the patient on 25 μg levothyroxine (Synthroid) and schedule a return appointment in 2 months. At follow-up, she reports a general improvement in symptoms but is not “back to normal.” She reports continued constipation, a lack of energy, and feeling depressed. Though she initially lost weight in the first month, she has not lost any further

weight and reports a thickening of her hair. Laboratory results are as follows: TSH 11.8 $\mu\text{IU}/\text{mL}$ (0.27–4.20) and free T4 0.75 ng/dL (0.93–1.70).

Question 10.1.5 What adjustments, if any, should be made to her regimen?

- A) None, she will continue to improve at the current dose
- B) Increase the dose to 50 $\mu\text{g}/\text{day}$, and re-check in 2 months
- C) Increase the dose to 200 $\mu\text{g}/\text{day}$, and re-check in 2 months
- D) She is becoming hyperthyroid, so cut the dose to 12.5 $\mu\text{g}/\text{day}$, and re-check in 2 months
- E) Levothyroxine is ineffective in this patient. Change her to desiccated thyroid tissue (e.g., Armour Thyroid) or triiodo-L-thyronine (T3)

Answer 10.1.5 The correct answer is “B.” This patient has improved from her initial presentation, but she is clinically and chemically (elevated TSH) still hypothyroid. Since 2 months have elapsed, she is now at steady state. It is doubtful that her thyroid levels will change much if you wait, so now is a good time to increase her dose. Since you started with a low dose, doubling of the dose is a reasonable increase that is unlikely to make her hyperthyroid. The goals of therapy are amelioration of symptoms and normalization of TSH secretion by maintaining the TSH within the normal reference range—except in the elderly or during pregnancy. There is evidence of better outcomes if the TSH is kept at the *high normal* end in the elderly and the *low normal* end during pregnancy. “E” deserves special mention. Desiccated thyroid is generally avoided due to variability in concentration of thyroid hormone content. T3 has nothing to offer over levothyroxine (T4) despite what the Internet “experts” (and your patients’ grandmothers) say.

HELPFUL TIP:

Poor adherence is the most common reason for failure of medical therapy. Other causes include malabsorption, drug interactions (e.g., rifampin and amiodarone), drug–food interactions, or drugs that reduce absorption (e.g., phosphate binders, PPIs, iron, and sucralfate).

Your patient worries about taking too much thyroid hormone.

Question 10.1.6 Which of the following can result from oversuppression of the TSH (iatrogenic hyperthyroidism)?

- A) Renal failure
- B) Pulmonary fibrosis
- C) Hirsutism
- D) Osteoporosis
- E) Loss of secondary sex characteristics

Answer 10.1.6 The correct answer is “D.” Hyperthyroidism, either iatrogenic or endogenous, causes osteoporosis. For this

reason, it is important to monitor the TSH and assure that the patient is not over-replaced.

The patient has been doing great for a couple of years when she returns to see you for a routine follow-up. Both her TSH and her free T4 are within the normal range. She then informs you that she had no menses for 5 weeks. You check a urine pregnancy test in the clinic and it is positive. The patient is excited about the pregnancy.

Question 10.1.7 What is the most appropriate management for the patient's hypothyroidism?

- A) Continue the current levothyroxine dosage without any change
- B) Increase the levothyroxine dose by 10% now
- C) Increase the levothyroxine dose by 30% now
- D) No change of the levothyroxine dose, but have the thyroid function re-checked in 6 weeks
- E) Refer her to an endocrinologist (wait time is currently 6 months)

Answer 10.1.7 The correct answer is "C." Women with preexisting hypothyroidism who are planning to become pregnant should optimize their thyroid hormone dose preconception if possible. The majority of women with preexisting hypothyroidism require a higher dose of levothyroxine during pregnancy to maintain goal TSH levels. The increase in levothyroxine requirements occurs as early as the fifth week of gestation and plateaus by 16 to 20 weeks. It is generally recommended that the levothyroxine dose be increased by 30% to 50% at the time of the positive pregnancy test through the first trimester. Note that there are trimester-specific goals that differ from the goal in the usual patient. The goal TSH level for the first trimester is 0.1 to 2.5 $\mu\text{IU/mL}$, second trimester 0.2 to 3.0 $\mu\text{IU/mL}$, and third trimester 0.3 to 3.0 $\mu\text{IU/mL}$ (*Am Fam Physician*. 2014;89,4:273–278). Thyroid function should be assessed every 4 weeks. If the TSH values are above goal, the dose of levothyroxine is increased and thyroid function is re-checked in 2 to 4 weeks. "A," "B," and "D" are incorrect because of the reasons mentioned above. Also, "E" is incorrect. If you do not feel comfortable managing the patient's hypothyroidism during her pregnancy, you may still need to increase her levothyroxine first, then refer her to an endocrinologist. Good care transition is critical: assure that the patient's hypothyroidism is managed until she is under the care of the consultant.

HELPFUL TIP:

Hashimoto thyroiditis is associated with primary thyroid lymphoma, which typically presents with an enlarged neck mass and may be associated with local compression symptoms and "B-symptoms" such as fever, weight loss, and night sweats. If lymphoma is suspected, a core needle or excisional biopsy is indicated.

► Objectives: Did you learn to ...

- Recognize the presentation of hypothyroidism and its most common causes?
- Identify common physical examination findings consistent with hypothyroidism?
- Describe the basic medical and laboratory management of patients with hypothyroidism?
- Manage hypothyroidism during pregnancy?

► CASE 10.2

A 32-year-old male presents complaining of severe anxiety. For the last 4 months, he has had difficulty sleeping, progressively worsening anxiety, a 25-lb weight loss, and constantly feels "too warm." He feels "shaky" and has difficulty concentrating. He denies diarrhea, but reports having normally shaped stools four to five times per day—more than usual for him. The patient denies neck or eye discomfort and has not noticed any neck swelling. He has no other significant medical history. His mother, who died 3 years ago from coronary artery disease (CAD), had a "thyroid problem," but he doesn't know any details.

Physical examination reveals an anxious young adult male. He has a noticeable resting tremor. You note mild exophthalmos, conjunctival injection, and lid lag. His thyroid is diffusely, mildly enlarged, is non-tender, and a bruit is audible over the gland. The cardiac examination reveals tachycardia with a flow murmur. The rest of the examination is unremarkable.

Question 10.2.1 What is the most likely diagnosis?

- A) Viral thyroiditis
- B) Graves' disease
- C) Anaplastic thyroid carcinoma
- D) Hyperactive thyroid adenoma
- E) Surreptitious thyroid hormone ingestion

Answer 10.2.1 The correct answer is "B." This is a classic presentation of Graves' disease. The family history, the symptoms and signs of hyperthyroidism (especially the diffusely enlarged goiter with a bruit), and the exophthalmos are typical; conjunctival injection is also frequently noted. "A" is unlikely. Viral thyroiditis can cause hyperthyroidism and a goiter, but the thyroid gland is usually tender. Also, viral thyroiditis will likely not last 4 months, but is usually self-limited to less than 6 weeks. Anaplastic carcinoma ("C") is a devastating disease with a dismal prognosis: the thyroid gets very large very quickly, but the disease does not present with hyperthyroid symptoms. A hyperactive adenoma ("D") and surreptitious ingestion of thyroid hormone ("E") would not cause a goiter or exophthalmos.

HELPFUL TIP:

75% of patients with viral thyroiditis will progress from 2 weeks of self-limited hyperthyroidism to 3 to 6 months

of hypothyroidism that is also self-limited. About 15% of patients go on to a permanent hypothyroid state requiring thyroid replacement. The hyperthyroid phase is best treated with NSAIDs, beta-blockers, and prednisone if needed.

Question 10.2.2 Which of the following tests is most specific for Graves' disease?

- A) Anti-thyrotropin receptor (anti-TSH receptor) antibody
- B) Anti-thyroglobulin antibody
- C) Antithyroid peroxidase antibody
- D) Markedly suppressed TSH

Answer 10.2.2 The correct answer is "A." Graves' disease is an autoimmune process, and lymphocytes in the thyroid gland itself are responsible for a large amount of the thyroid autoantibodies produced. Although several types of antibodies can be assayed, anti-thyrotropin receptor antibody is the most specific. Here is a breakdown of selected thyroid serum assays and where you may see them elevated:

- **Anti-thyrotropin receptor antibody (anti-TSH receptor antibody)** ("A") is found in 80% to 95% of patients with Graves' disease, but also in 10% to 20% of those with other forms of autoimmune thyroiditis.
- **Anti-thyroglobulin antibodies** ("B") are found in Graves' disease, autoimmune thyroiditis, some patients with type 1 diabetes, and in up to 20% of the general population.
- **Antithyroid peroxidase antibody** ("C") is elevated in Graves' disease, autoimmune thyroiditis, type 1 diabetes, and some pregnant patients, etc.
- **Serum thyroglobulin:** A form of T3/T4 produced by follicular cells. Used to monitor thyroid cancer.

You obtain labs and find that the CBC is normal and TSH is undetectable. He is tachycardic at 130 bpm.

Question 10.2.3 How should the patient be treated acutely?

- A) Propranolol and methimazole started immediately
- B) Control the patient's symptoms with propranolol now, then start propylthiouracil (PTU) when the patient feels better
- C) Iodine (Lugol solution)
- D) Radioablation with I^{131}
- E) Thyroidectomy

Answer 10.2.3 The correct answer is "A." There is no need to wait before starting methimazole (Tapazole), which blocks production of thyroid hormone. PTU can also be used, but methimazole is preferred because (1) it affords better control and (2) PTU is associated with more liver toxicity and bone marrow suppression (although these adverse effects can occur with both drugs). PTU is preferred during the **first trimester** of pregnancy due to the risk of birth defects (aplasia cutis and choanal and esophageal atresia) associated

with methimazole. Current guidelines recommend switching from PTU to methimazole for the second and third trimesters because the risk of liver toxicity for the mother (with PTU) is greater than the risk of congenital defects in the fetus; however, some experts still prefer PTU throughout pregnancy.

Propranolol is helpful for controlling the symptoms of hyperthyroidism (tachycardia, tremor, etc.) and prevents the conversion of T4 to active T3. Metoprolol is an alternative. "C" is incorrect, as iodine will provide further substrate for the body in the production of thyroid hormone and should not be given until a thyroid-blocking agent has been started. Iodine is useful during thyroid storm to prevent the release of stored thyroid hormone, but it is given 1 hour after PTU or methimazole. Radioablation is used for patients who prove refractory to medicine or have poor compliance. Thyroidectomy is rarely used for Graves' disease in current medical practice because of the ease and efficacy of radioactive iodine administration (except in the case of pregnancy and few other unusual cases).

Question 10.2.4 Which of the following is/are possible side effects of PTU and methimazole therapy?

- A) Granulocytopenia
- B) Aplastic anemia
- C) Elevated liver transaminases
- D) Inhibition of fetal thyroid gland
- E) All of the above

Answer 10.2.4 The correct answer is "E." All of the above are known side effects of antithyroid drugs (thionamides). Granulocytopenia occurs in about 0.5% of patients and is a sudden, idiosyncratic reaction. **Classically, patients present with a severe sore throat. If you have a patient on PTU or methimazole with a sore throat or fever, check a CBC.** Aplastic anemia may occur but is rare. For these reasons, patients starting these medications should have a baseline CBC. Mild, transient elevation of the liver transaminases is common, and the drug should be discontinued only if the transaminases increase to greater than three times the upper limit of the reference range. Both PTU and methimazole cross the placenta and will inhibit the fetal thyroid, increasing the risk for congenital hypothyroidism. The risk to a fetus posed by the drugs is less than the danger posed by a mother with accelerating hyperthyroidism, so the medications should be used even during pregnancy if indicated. The smallest doses possible should be used. If a pregnant patient is not controlled medically, consider thyroidectomy. Finally, PTU and methimazole can cause an ANCA-positive vasculitis.

HELPFUL TIP:

When treating **hyperthyroidism** in pregnancy, aim for a serum-free T4 level in the upper one-third of the reference range. Avoid radioactive iodine treatment during pregnancy since it will affect the fetus as well.

The patient is interested in treating the ophthalmopathy.

Question 10.2.5 What is the *primary* method for treating Graves' ophthalmopathy?

- A) Orbital radiation
- B) Glucocorticoids
- C) Rituximab
- D) Thyroidectomy
- E) Radioactive iodine therapy

Answer 10.2.5 The correct answer is "B." Approximately 5% to 10% of patients with Graves' disease develop clinically significant ophthalmopathy. Graves' ophthalmopathy manifests as inflamed, red eyes and diplopia/proptosis. The treatment of Graves' ophthalmopathy includes establishing a euthyroid state. PTU and methimazole are preferred since radioactive iodine may worsen Graves' ophthalmopathy. Other measures include reducing eye irritation (e.g., artificial tears/methylcellulose eye drops) followed by a trial of corticosteroids. Glucocorticoids have been shown to be effective in treating Graves' ophthalmopathy. Intravenous (IV) steroids are more effective than oral steroids, but either can be used. Orbital radiation has been used but with little success. Rituximab ("C") is another option that seems to be effective, but it is not first line. Radioactive iodine treatment ("E") has been associated with *worsening* of Graves' ophthalmopathy. Thyroidectomy ("D") is usually reserved for patients who fail antithyroid drugs, have large or obstructive goiters, or who have coexisting hyperparathyroidism requiring parathyroidectomy.

.....

Your patient complies with the recommended regimen and improves. He is not symptomatic at a return visit in 2 months, and his eye pathology has not progressed. After 6 months of good control, the patient elects to have cosmetic eye surgery for his exophthalmos, which has not responded well to glucocorticoids. A preoperative physical is unremarkable. Laboratory studies prior to surgery are normal except TSH 0.21 μ IU/mL (0.27–4.20) and free T4 3.01 ng/dL (0.93–1.70).

After an uneventful surgery, you are called to the postanesthesia room by the oculoplastic surgeon. She reports that the patient has become very anxious and tachycardic. A quick review of the chart reveals no known allergies, no personal or family history of reactions to anesthesia, and the only medication that the patient takes regularly is methimazole (propranolol had been discontinued 2 months earlier due to lack of symptoms).

Physical examination shows T 39.8°C, BP 98/25 mm Hg, RR 34, and P 166 bpm. The patient is agitated but alert and in acute distress. He is tachypneic and tremulous and is unable to carry on a conversation. He seems confused and distracted. The skin is diaphoretic and flushed. His mucous membranes are dry, and his surface veins are flat. There is no JVD and the vena cava looks normally filled on ultrasound. Pulmonary examination reveals diffuse rales. Reflexes are brisk.

Question 10.2.6 What is the likely cause of this patient's symptoms and signs?

- A) The patient became fluid overloaded during the surgery due to excessive hydration
- B) The patient has neuroleptic malignant syndrome (NMS)
- C) The patient has thyroid storm induced by the stress of surgery
- D) The patient has endocarditis and suffered a valve rupture
- E) The patient has euthyroid sick syndrome (AKA nonthyroidal illness syndrome)

Answer 10.2.6 The correct answer is "C." The syndrome of thyroid storm is characterized by fever, tachyarrhythmias, altered mental status, and high-output cardiac failure. It is induced by a major stress (infection, surgery, myocardial infarction, etc.) in a patient with underlying hyperthyroidism (usually undiagnosed). This patient, although **clinically** well-controlled, had a **low TSH and high free T4 prior to surgery**, suggesting he may have suffered a recurrence of disease or had stopped taking his medications. The patient is not fluid overloaded, as evidenced by his clinically dry status (dry mucous membranes, flat neck veins, normal vena caval filling); thus "A" is incorrect. His pulmonary edema (rales) is due to high-output failure rather than fluid overload. NMS presents with altered mental status and hyperthermia (due to increased metabolic activity). But the patient is not currently taking neuroleptics. A ruptured valve due to endocarditis would fit the patient's clinical picture, but he had no fever preceding the surgery or other evidence of endocarditis. Euthyroid sick syndrome (now termed "non-thyroidal illness syndrome") ("E") is used to define a state in critically ill patients with laboratory findings of low free T3, low free T4, and/or low TSH (a central hypothyroidism in response to illness). It is an adaptation which lowers tissue energy requirements in the face of systemic illness. He could have malignant hyperthermia secondary to anesthesia, but this isn't a choice.

**HELPFUL TIP:**

Thyroid storm is a clinical diagnosis consisting of hyperthermia, tachycardia, CNS dysfunction, and signs and symptoms of peripheral hyperthyroidism. While most patients will have an elevated T3 and free T4, there is no laboratory level of these hormones that defines thyroid storm. Thyroid storm may cause right upper quadrant pain due to liver congestion secondary to high-output congestive heart failure.

**HELPFUL TIP:**

A pheochromocytoma can be confused with hyperthyroidism. Both include tachycardia and possible hypertension. Interestingly, serum catecholamines are **normal** (often high normal—but normal) in thyroid storm. But catecholamine sensitivity seems to play a role in thyroid storm. Catecholamines will be elevated in patients with a pheochromocytoma.

Question 10.2.7 How should this patient now be treated?

- A) Administer aggressive fluid hydration, cooling measures, benzodiazepines, and dantrolene
- B) Administer fluid hydration, cooling measures, IV propranolol, IV corticosteroids, methimazole or PTU, then iodine 1 hour later
- C) Administer fluid hydration, dopamine drip for his hypotension, and antibiotics; consult cardiovascular surgery immediately
- D) Hold fluids; administer nitroglycerin drip and furosemide for his heart failure; consider an intra-aortic balloon pump
- E) Administer fluid hydration (even 3 L or more) and antibiotics; consider norepinephrine drip if patient becomes more hypotensive

Answer 10.2.7 The correct answer is “B.” This is the appropriate management for thyroid storm and the correct sequence of therapies. This patient is in distress (hypotensive and tachycardic) and needs fluid hydration, despite his pulmonary edema (but be judicious and use clinical judgment). Cooling measures address his hyperthermia, and beta-blockade (propranolol) will improve his high-output failure (and reduce the pulmonary edema). Corticosteroids help block release of thyroid hormone and decreases peripheral conversion of T4 to T3. In addition, corticosteroids will treat any underlying adrenal insufficiency. Methimazole prevents thyroxine synthesis. This must be given before iodine. The iodine blocks any further release of thyroid hormone. Some experts recommend using PTU instead of methimazole for the patient with life-threatening thyroid storm admitted to an ICU because PTU blocks T4 to T3 conversion and results in lower serum T3 level. “A” is the appropriate management of NMS. “C” is an appropriate approach for valve rupture from endocarditis. “D” describes the management of severe heart failure. “E” describes essential steps in the treatment of sepsis.

**HELPFUL TIP:**

In patients with hyperthyroidism, diarrhea is a sign that can presage thyroid storm.

**HELPFUL TIP:**

Surgery or radioactive iodine can be used to treat Graves' disease. Radioactive iodine can take months to work. Otherwise, hyperthyroid patients are treated for 1 to 2 years followed by a taper of their medications. A taper can be tried earlier in the course (at 6 months) if desired by the patient.

Your patient is treated appropriately and eventually recovers. He continues on methimazole and propranolol and remains in good control. You can try tapering the medications in 6 months to see how he does.

Objectives: Did you learn to ...

- Identify the more common causes of hyperthyroidism?
- Recognize the presentation of Graves' disease?
- Manage hyperthyroidism and describe the indications and risks of each treatment option?
- Recognize and treat thyroid storm?

CASE 10.3

You are seeing a 45-year-old female who is a nursing assistant at a local nursing home. As part of a life insurance mandated blood panel, the patient's TSH is noted to be elevated at 7.2 μ IU/mL (0.27–4.20 μ IU/mL). She has a normal free T4 and is asymptomatic. You repeat the labs, with very similar results.

Question 10.3.1 The best option is to:

- A) Start levothyroxine at a low dose to normalize the TSH
- B) Begin T3 at a low dose
- C) Reassure the patient and have her follow-up for repeat thyroid studies
- D) Begin a workup for central hypothyroidism
- E) Begin methimazole

Answer 10.3.1 The correct answer is “C.” This patient has subclinical hypothyroidism (asymptomatic, TSH between 5 and 10, and normal free T4). There is convincing evidence that **asymptomatic** patients with a mildly elevated TSH (generally $<10 \mu$ IU/mL) and normal free T4 do not benefit from treatment in terms of quality of life, etc. In fact, treated patients tend to have more symptomatic anxiety, atrial fibrillation, etc. Follow-up thyroid studies are indicated, although the interval may differ depending on the clinician's judgment. Of note, many patients will have transient changes in their thyroid hormone levels due to comorbid illness, viral thyroiditis, etc. Generally, the best thing to do is re-check rather than start treatment except in those patients with high risk for progression to overt hypothyroidism (TSH level $>10 \mu$ IU/mL, positive family history, goiter, presence of antithyroid peroxidase antibodies, or desire to become pregnant; see *Clin Endocrinol (Oxf)*. 2015 May 23. doi: 10.1111/cen.12824 for hypothyroidism clinical guidelines).

**HELPFUL TIP:**

Among patients with hyperlipidemia, overt and subclinical hypothyroidism is common. Thus, patients with hypercholesterolemia and hypertriglyceridemia should be screened for hypothyroidism.

**HELPFUL TIP:**

T3 tends to have rapid gastrointestinal (GI) absorption and relatively short half-life leading to erratic T3 serum levels. It is best to avoid T3 in the vast majority of patients with hypothyroidism.

► **Objectives: Did you learn to ...**

- Describe subclinical hypothyroidism?

**QUICK QUIZ: SOMETHING SUBACUTE**

A 32-year-old white female without significant past medical history except an upper respiratory tract infection 4 weeks ago presents to the clinic for a 1-week history of dull anterior neck pain, palpitations, anxiety, poor sleep, and chills. Physical examination is unremarkable except tachycardia (100 bpm), with anterior neck tenderness, but no mass appreciated. Laboratory results: C-reactive protein 5 mg/dL (high), TSH <0.01 μ IU/mL (low), and free T4 5 ng/dL (high). A bedside ultrasound shows an enlarged thyroid gland.

What is the most appropriate next step in management?

- A) Fine needle aspiration for biopsy
- B) Antithyroid medications like methimazole or PTU
- C) 24-hour radioactive iodine uptake test
- D) Neck soft tissue computer tomography (CT)

The correct answer is “C.” Considering her recent viral infection, tender thyroid gland, elevated inflammatory marker, and the low TSH and high T4, this is most likely subacute thyroiditis. The 24-hour radioactive iodine uptake (RAIU) test measures thyroid gland iodine uptake over 24 hours. We need to determine the etiology of this patient’s thyroiditis. In patients with destructive thyroiditis like subacute thyroiditis, the RAIU will be low, usually less than 5% over 24 hours. In contrast, Graves’ disease will have an elevated or normal RAIU. Fine needle aspiration (“A”) is used for evaluation of thyroid nodule but the patient does not have one. Antithyroid agents (“B”) have no role in the treatment of subacute thyroiditis since it is usually a self-limiting disease after transient (2–8 weeks) hyperthyroidism. The primary treatment focus is symptom relief and includes NSAIDs, nonselective beta-blockers, and/or corticosteroids (prednisone) if patient has severe pain or no improvement is seen after 2 to 3 days of more conservative treatment. Ultrasound is an excellent imaging modality to evaluate the thyroid gland, whereas CT scan (“D”) offers little value in this case.

**QUICK QUIZ: THYROID TESTS**

A 52-year-old male is being seen in your clinic for weight loss, tachycardia, and anxiety. You suspect hyperthyroidism and decide to check blood work. The patient has a low TSH suggestive of hyperthyroidism but has a normal free T4.

The most likely explanation of this patient’s symptoms and laboratory findings is:

- A) He has pituitary dysfunction with a pending central hypothyroidism
- B) He has an isolated T3 hyperthyroidism
- C) He has Addison disease
- D) He is taking aspirin that interferes with the assay for free T4
- E) He is taking aspirin that interferes with the assay for TSH

The correct answer is “B.” Five percent of patients with hyperthyroidism have an isolated T3-toxicosis. Thus, if you suspect hyperthyroidism and the patient has a low TSH but a normal free T4, check a T3. Of note, “D” and “E” are incorrect. However, many drugs can interfere with thyroid-binding globulin and cause changes in the measurable amounts of **total** T4 (not free) and T3 in the serum. In most cases, the free T4 and free T3 (unbound thyroid hormones) are not affected by the changes in thyroid-binding globulin levels.

**QUICK QUIZ: HYPERTHYROIDISM****Which of the following cause(s) hyperthyroidism?**

- A) Lithium
- B) Amiodarone
- C) Peginterferon alfa-2 a
- D) Phenytoin
- E) B and C

The correct answer is “E.” Amiodarone (see Helpful Tip) and peginterferon alfa-2 a can cause both hypothyroidism and hyperthyroidism. Amiodarone causes hypothyroidism in approximately 10% of patients who take it chronically and hyperthyroidism in approximately 1%. “A” and “D,” lithium and phenytoin, respectively, cause hypothyroidism. Phenytoin reduces TSH secretion so patients may have a low TSH and a low T4.

► **CASE 10.4**

A 45-year-old female presents to the office complaining of a “ball in my neck.” She noticed a lump in her anterior neck approximately 1 month ago. She is not sure if it has increased in size. She has not noticed any other lumps or masses. She denies dysphagia, odynophagia, neck pain, cough, weight loss, fever, chills, sweats, or a change in bowel habits. She also denies any hyperthyroid or hypothyroid symptoms. In 1993, she immigrated to the United States from Kiev (still in the Ukraine at the time of this writing ... at least until Putin takes it), where she had grown-up and lived—including all of the 80s (you remember—Madonna, leg warmers, Chernobyl). She has no family history of thyroid or other endocrine disorders, but several relatives in Kiev have been diagnosed with various cancers.

Question 10.4.1 Which of the following factors from history INCREASES the likelihood that the nodule is malignant?

- A) Nodule **not** increasing in size
- B) No regional adenopathy
- C) Age >40 years
- D) Male gender
- E) History of radiation exposure

Answer 10.4.1 The correct answer is “E.” This patient lived in Kiev, near the Chernobyl nuclear power plant, during and after

the reactor accident in 1986. She was exposed to radiation and, like her family members, is at significantly increased risk for cancer, especially thyroid malignancies. Other clinical factors that suggest a malignant etiology include (in general, not necessarily in this patient): a nodule >2 cm or increasing in size, dysphagia, hoarseness, regional lymphadenopathy, a fixation to the surrounding tissues, female gender, age <40, and family history.

HELPFUL TIP:

There are a lot of cancer survivors walking around who received radiation to the neck (e.g., mantle radiation for Hodgkin lymphoma). These patients are at increased risk of developing thyroid cancers.

Physical examination reveals an obese female in no acute distress. Her head, eye, nose, and oral examinations are normal. She has a 2-cm firm nodule on the right pole of the thyroid. The nodule moves along with the other subcutaneous structures upon swallowing. She has no lymphadenopathy. The rest of the examination is normal.

Question 10.4.2 Which of the following next steps would be most likely to yield a *definitive* diagnosis?

- A) Thyroid ultrasound
- B) Fine needle aspiration (FNA)
- C) Thyroid scan (Tc^{99})
- D) Serum thyroglobulin level
- E) Serum calcitonin level and CEA level

Answer 10.4.2 The correct answer is “B.” FNA can conclusively prove or disprove the presence of neoplasm and should be considered for all thyroid nodules and cysts. That is the bottom line; the rest are interesting—but do the FNA.

Ultrasound can be used if there is low malignant potential in order to look for worrisome sonographic features, but it cannot definitively differentiate a benign nodule from a malignant one. Besides, *any thyroid nodule with diameter greater than 1 cm should be evaluated with FNA*. Thus, no ultrasound is needed in this case except to guide the FNA.

A thyroid scan (“C”) will identify if a nodule is actively processing thyroid hormone (“functional” or “hot”) or is not metabolically active (“nonfunctional” or “cold”). A “hot” nodule may cause hyperthyroidism, is usually benign (“hot is not” malignancy), and can be treated with I^{131} . A cold nodule is either an adenoma or a malignancy, and a biopsy is mandated.

A serum thyroglobulin (“D”) is the tumor marker for thyroid carcinoma and should be drawn before thyroidectomy. It has no value as a diagnostic test in the initial evaluation before malignancy is diagnosed but can be followed as a marker. Anti-thyroglobulin antibodies may interfere with the assay, however.

Serum calcitonin and CEA levels (“E”) are elevated in the case of medullary carcinoma, but would have low yield in the

initial evaluation. Refer to the American Thyroid Association guidelines for management of thyroid nodules (*Thyroid* 2016;26(1):1–132) for additional details on the evaluation of thyroid nodules.

Fine needle aspiration is consistent with papillary carcinoma. A serum thyroglobulin level, TSH, basic chemistries, a blood count, and a blood type are ordered.

Question 10.4.3 What should be done next?

- A) Observe the nodule for 1 month
- B) Computerized tomography (CT) of the head and neck with contrast
- C) Radiation therapy with I^{131}
- D) Radiation therapy with external beam radiation
- E) Suppression of TSH levels with levothyroxine

Answer 10.4.3 The correct answer is “B.” Surgery for removal of the tumor is the most appropriate next step, but a CT scan is indicated to delineate the extent of the neoplasm. Radiotherapy with I^{131} is used after surgery for metastatic disease, but external beam radiation is not used for thyroid cancers except for palliative therapy of anaplastic carcinoma. Because these tumors are TSH responsive, suppression of TSH level **following surgery** for papillary carcinoma is achieved with levothyroxine (usually 2.2–2.5 $\mu\text{g}/\text{kg}$ —fairly high dose to completely suppress TSH production).

HELPFUL TIP:

The most common thyroid cancer is papillary carcinoma. Medullary carcinoma may be associated with an elevated calcitonin and other endocrine malignancies (e.g., multiple endocrine neoplasia II [MEN II]).

HELPFUL TIP:

There’s a caveat to the emphatic endorsement of FNA (which has a deservedly good reputation for diagnosis). Here it is: thyroid follicular lesions. When an FNA returns material from a thyroid follicular neoplasm, 15% to 25% of these may be harboring cancer. Follicular thyroid cancer cannot be ruled out on the basis of an FNA due to inability to differentiate a malignancy from a benign adenoma. Usually, a thyroid lobectomy or total thyroidectomy is recommended to further evaluate a follicular neoplasm so that a pathologic examination can be completed.

► Objectives: Did you learn to ...

- Recognize the major risk factors influencing the development and prognosis of thyroid carcinomas?
- Evaluate a thyroid nodule?
- Describe the management of papillary carcinoma, the most common of the thyroid cancers?

► CASE 10.5

A 78-year-old female is brought to the emergency department (ED) for strange behavior. According to her family, she has been more sleepy and weak throughout the last week. She is acting more withdrawn and depressed and seems to respond to nonexistent external stimuli. When asked about her depression, she reports she is sad because a man in a clown suit who trains poodles keeps telling her she is going to die (or maybe she just has bad flashbacks to the circus when she was younger). She complains of abdominal cramps and blames it on “being plugged up,” and her family reports no bowel movement for 2 days. She also notes chronic bone pain in her hips and back. That’s about all you can get before the bad news clown returns.

A physical examination is notable only for a 3 cm irregular mass in her right breast (we’re very impressed that you did a breast examination in the ED). The family thinks that the mass is new. Her neurological examination is normal, except for her apparent confusion.

Question 10.5.1 What finding would you expect from an ECG?

- A) Peaked T-waves
- B) Long QT interval
- C) Short QT interval
- D) Torsades de pointes

Answer 10.5.1 The correct answer is “C.” This patient is likely to have hypercalcemia, probably from an undiagnosed metastatic breast cancer. The ECG in a patient with significant hypercalcemia will show a short QT interval with possibly J-waves (aka Osborne waves, more frequently seen in hypothermia); rarely there is diffuse ST elevation (which is more commonly seen in pericarditis). **Hypocalcemia** is associated with a long QT interval, which can occasionally lead to arrhythmias due to an R on T phenomenon (an R-wave of a PVC fuses with the previous T-wave predisposing to torsades de pointes). **Hypercalcemia** produces symptoms in the CNS (confusion, psychosis, depression), GI system (abdominal pain, cramps, constipation), kidneys (nephrolithiasis, polyuria, renal insufficiency), and musculoskeletal system (weakness, myopathy, osteoporosis). To help you remember the symptoms of hypercalcemia, use the phrase “stones, bones, moans, groans, and psychiatric overtones.” “A,” peaked T-waves, are associated with hyperkalemia.

Your patient’s total serum calcium level is reported as 15.3 mg/dL (upper limit 10.4 mg/dL).

Question 10.5.2 What is the NEXT step in her treatment?

- A) Moderately aggressive normal saline hydration
- B) IV chlorthalidone administration
- C) IV calcitonin administration
- D) PO bisphosphonate
- E) IV glucocorticoids

Answer 10.5.2 The correct answer is “A.” Although “C” and “D” may be indicated, adequate hydration and establishing urine output is critical to the treatment of hypercalcemia and should be the next step. A normal saline infusion will increase urinary calcium excretion by inhibiting proximal tubular sodium and calcium reabsorption. **Note that IV furosemide (and diuretics in general) are falling out of favor and should not be used. Hydration is the most important goal.** An IV bisphosphonate infusion (not PO, “D”), such as zoledronic acid, should be started concurrently and will lower the calcium level over 2 to 4 days. Calcitonin has a limited duration of action and can be used in emergencies where saline is ineffective. Glucocorticoids are generally useful in hypercalcemia secondary to granulomatous diseases and some lymphomas neither of which our patient has. “B” is of special note. Chlorthalidone and other thiazide diuretics **increase** calcium levels and are contraindicated. In addition to the above, dialysis can be used in a hypercalcemic emergency (generally in patients with unresponsive severe hypercalcemia [e.g., those with renal failure]).

The patient is treated appropriately for her hypercalcemia and her mental status improves. A biopsy of her breast mass is done and reveals an infiltrating ductal carcinoma. A bone scan reveals diffuse metastatic disease.

Question 10.5.3 Which of the following statements about the mechanism for malignancy-associated hypercalcemia is/are TRUE?

- A) Decreased bone reabsorption increases the serum calcium
- B) Secretion of osteoclast-inhibiting factors increases the serum calcium
- C) Secretion of parathyroid hormone (PTH)-like substances increases the serum calcium
- D) Direct erosion of bone by tumor cells does not cause hypercalcemia
- E) All of the above

Answer 10.5.3 The correct answer is “C.” This is a case of humoral hypercalcemia of malignancy (HHM). Secretion of PTH-like substances causes retention of calcium by the kidneys, which elevates the serum calcium. Tumors can also produce osteoclast-**activating** (not inhibiting as in answer “B”) factors leading to increased bone resorption and elevation of the serum calcium (remember that osteoblasts deposit bone and osteoclasts reabsorb bone). Finally, direct erosion of bone by tumor cells also contributes to the release of calcium from the bones (and predisposes the patient to fractures). The neoplasms most commonly associated with hypercalcemia are cancers of the breast, lung, prostate, and kidney as well as multiple myeloma and a few other hematologic cancers.

Question 10.5.4 Your patient’s cancer cannot be cured. How can her chronically elevated calcium level be managed?

- A) Oral glucocorticoids
- B) Oral phosphates
- C) Oral bisphosphonates
- D) All of the above

Answer 10.5.4 The correct answer is “D.” Glucocorticoids (e.g., prednisone 20–40 mg/day) *decrease intestinal calcium absorption*, but in and of themselves can lead to bone density loss and an increased risk for fractures. Oral phosphates can decrease intestinal calcium absorption and bone reabsorption of calcium. Bisphosphonates, as previously discussed, decrease the serum calcium and increase bone density.

HELPFUL TIP:

Granulomatous diseases like tuberculosis, sarcoidosis, Crohn disease, and leprosy are associated with hypercalcemia because of increased levels of active vitamin D.

► Objectives: Did you learn to ...

- Recognize neoplastic causes of hypercalcemia?
- Identify presenting symptoms of hypercalcemia?
- Understand the mechanisms underlying hypercalcemia in malignancy?
- Initiate emergency treatment for symptomatic hypercalcemia?

► CASE 10.6

A 42-year-old male presents to the office for routine follow-up of his hypertension. He denies any complaints. He has primary hypertension, for which he takes benazepril 20 mg PO daily and hydrochlorothiazide 25 mg PO daily. The patient takes no other medications. His vital signs are as follows: BP 135/70 mm Hg, P 72 bpm, R 18, and T 98.6°F. The physical examination is completely normal. His calcium is elevated at 12.8 mg/dL (upper limit normal 10.4 mg/dL). The rest of his electrolytes, BUN, and creatinine are normal as is a CBC and ECG. “Hmm ...” you think. “This calcium level could be falsely elevated.”

Question 10.6.1 Which of the following is/are responsible for spuriously elevated serum calcium?

- High phosphate diet
- Fever and active metabolic state
- Use of alendronate or risedronate
- Prolonged application of the tourniquet while drawing blood
- All of the above

Answer 10.6.1 The correct answer is “D.” Prolonged application of the tourniquet or a high calcium meal before a blood draw can cause a spuriously elevated serum calcium. In fact, up to 50% of patients with hypercalcemia have a normal calcium when it is checked a second time. So, the next step after finding elevated calcium is to repeat the test. “A” and “C” will cause a low calcium level.

Question 10.6.2 Assuming you repeat the laboratory value and the calcium remains elevated, your next step is:

- A bone scan for occult cancer
- Immediate dialysis

- Nothing, since the patient is asymptomatic
- Discontinue the hydrochlorothiazide and re-check calcium in 2 weeks
- Discontinue the benazepril and re-check potassium in 2 weeks

Answer 10.6.2 The correct answer is “D.” This patient has hypercalcemia. Asymptomatic hypercalcemia is not uncommon on routine screening examinations. It should be addressed because it is always abnormal and can be treated early before any symptoms develop. In this patient, the most likely cause is hydrochlorothiazide. Thiazide drugs increase the renal reabsorption of calcium. Angiotensin-converting enzyme (ACE) inhibitors may cause hyperkalemia but are usually not associated with hypercalcemia. An investigation for occult cancer may be in this patient’s future, but it is reasonable to address the potential adverse drug effect first. Dialysis is not indicated.

Being the smart practitioner that you are, you think that the hypercalcemia could be related to his hydrochlorothiazide use, so you ask him to stop it. He returns for a laboratory draw 2 weeks later. The calcium level is now 12.9 mg/dL. “Rats,” you say. “Where’s my thinking cap—I mean iPad?”

Question 10.6.3 What should you do next?

- Wait another month and re-check before taking any other action
- Order a 24-hour bisphosphonate infusion
- Perform prostate and testicular examination for masses, chest x-ray, and serum assay for intact PTH (iPTH)
- Perform prostate and testicular examination for masses, chest/abdomen/pelvis CT, and bone scan
- Perform prostate and testicular examination for masses, chest x-ray, then reassure patient if normal

Answer 10.6.3 The correct answer is “C.” In this patient, it is reasonable to rule out primary hyperparathyroidism while also checking for other potential causes. A chest x-ray will rule out significant lung masses and sarcoidosis. A testicular and prostate examination for masses is important so that **large** tumors in these organs do not go unnoticed (remembering that a digital rectal examination is neither sensitive nor specific as a screening test for prostate cancer, but it may be useful in conjunction with prostate-specific antigen testing if prostate cancer is on your differential). An elevated or high normal iPTH in the presence of hypercalcemia confirms the diagnosis of hyperparathyroidism after ruling out familial hypocalciuric hypercalcemia. *The test for iPTH will not significantly cross-react with the PTH-like hormone produced by neoplasms.* Unless the history or physical is suspicious for lymphoma, or some other occult neoplasm, a pan-body scan is a waste of money and exposes the patient to unnecessary radiation. At this point, it is not necessary to acutely lower the calcium level because the cause has not been identified and the patient is asymptomatic. See Table 10-1 for more causes of hypercalcemia.

TABLE 10-1 CAUSES OF HYPERCALCEMIA

Pseudohypercalcemia (from elevated albumin or rarely in multiple myeloma....an ionized calcium will be normal).

Excessive calcium intake

Hypervitaminosis D

Hyperparathyroidism (primary and secondary)

Hyperthyroidism

Malignancy

Hypervitaminosis A

Adrenal insufficiency

Pheochromocytoma

Rhabdomyolysis

Familial hypocalciuria

Immobilization

Medications

- Lithium
- Megestrol
- Methyltestosterone
- Mycophenolate
- Tacrolimus
- Tamoxifen
- Theophylline (toxicity)
- Thiazides

The patient's complete examination is normal as is the chest x-ray. The iPTH level is twice the upper limit of normal and his urinary calcium scores, which should be done as part of the workup of hypercalcemia (24-hour urinary calcium excretion and his calcium-to-creatinine clearance rate) are *not* suggestive of familial hypocalciuric hypercalcemia (a discussion of which is outside the scope of this book).

Question 10.6.4 How should this patient be treated?

- A) Immediate CT of the chest, abdomen, and pelvis
- B) IV bisphosphonate infusion
- C) Daily dialysis until the calcium level is normal
- D) Referral for parathyroidectomy
- E) Referral for thyroidectomy

Answer 10.6.4 The correct answer is "D." This patient has primary hyperparathyroidism. Patients with symptomatic primary hyperparathyroidism (e.g., nephrolithiasis, symptomatic hypercalcemia) should have parathyroid surgery, which is the only definitive therapy. In asymptomatic patients, surgical indications also include a serum calcium level greater than 1.0 mg/dL over the upper limit of the reference range, a creatinine clearance less than 60 mL/min, a 24-hour urinary calcium >400 mg/day, nephrolithiasis or nephrocalcinosis by imaging, bone density T-scores less than -2.5 in any area, a previous osteoporotic fracture, and age less than 50 years. In elderly patients with mild hyperparathyroidism and asymptomatic hypercalcemia, medical management is an option. If the iPTH is low, then measuring the parathyroid hormone-related peptide (PTHrp, which is made by malignancies) and vitamin D metabolites is needed to further work up the cause. If PTHrp is elevated, a bone scan or body CT may be warranted. Although bisphosphonates will lower the serum calcium and may be used in an emergency, a parathyroidectomy is curative. Dialysis is not indicated in this patient.

Your patient undergoes a parathyroidectomy and is discharged from the hospital. The pathology report on the removed tissue confirms the presence of a parathyroid adenoma and no malignancy. He returns for his first postoperative appointment 1 week later, and he is complaining of weakness. He says that the day after the surgery he felt fine but has progressively gotten weaker since that time. Last night, he was kept awake by recurrent muscle spasms in his legs and arms. He denies fever, chills, nausea, or vomiting. He says he is eating, drinking, and passing urine normally. He has had no hematuria or dysuria. His vital signs are normal.

On physical examination, he appears anxious. Just after taking the patient's vital signs, his left arm develops a muscle spasm and an involuntary flexion of the wrist that lasts for about 20 to 30 seconds. Tapping the cheek just anterior to the tragus causes the ipsilateral face to twitch (to your great delight ... it is just like in the books!). The rest of cranial nerve examination is normal. His neck wound is healing well, with minimal erythema and no tenderness. The rest of the physical examination is unremarkable.

Question 10.6.5 What is causing this patient's symptoms?

- A) He suffers from vitamin D deficiency
- B) This patient has MEN II and also has a pheochromocytoma
- C) Too much parathyroid tissue was removed during the surgery
- D) The stress of the surgery precipitated thyrotoxicosis
- E) The stress of the surgery precipitated the onset of multiple sclerosis

Answer 10.6.5 The correct answer is "C." This patient likely has hypocalcemia due to excessive removal of parathyroid gland tissue—a rare and unfortunate complication of parathyroidectomy. It is usually detected in the immediate postoperative course. The patient's physical examination demonstrates Chvostek sign (tapping over the facial nerve elicits a twitch) and Trousseau signs (carpopedal spasm after placement of a blood pressure cuff). Vitamin D deficiency, although a cause of hypocalcemia, is unlikely to develop so quickly. The usual causes of vitamin D deficiency are malabsorption or inadequate intake. There is nothing to suggest MEN II (hyperparathyroidism, medullary thyroid carcinoma, and pheochromocytoma). There is also nothing here to suggest pheochromocytoma (episodic diaphoresis, labile blood pressure, recurrent palpitations, and near-syncope). There is no clinical evidence of thyrotoxicosis (tachycardia, tremor, etc.).

HELPFUL TIP:

Another consideration for a patient who had a recent parathyroidectomy for primary hyperparathyroidism: "hungry bone syndrome" (great name, right?), in which the unmineralized bone matrix produced during the period of hyperparathyroidism begins to mineralize after the PTH has normalized. This results in hypocalcemia and hypophosphatemia.

**HELPFUL TIP:**

It is always difficult to remember the MEN types. Here is a tip for you by Dr. Mark Yoffe (who wanted to see his name in print ... and a shout-out to his mom!).

MEN 1: the number “1” in MEN1 should remind you of primary or prime number. MEN1 involves things that start with the letter P:

- Pituitary adenoma
- Parathyroid hyperplasia
- Pancreatic islet cell tumors (gastrinoma, insulinoma, glucagonoma)

MEN 2A: happens to involve the letter C (This is MEN 2A, so there are two C's in each item!):

- Calcitonin (medullary carcinoma of the thyroid with elevated calcitonin level)
- Calcium (parathyroid hyperplasia, which causes elevated calcium levels)
- Catecholamines which are made in the chromocytes (as in pheochromocytoma)

MEN 2B: B is for big (marfanoid habitus) and for belly problems (mucosal neuromas)

A calcium and albumin level is sent, as well as a CBC and routine chemistry panel including magnesium. Everything is normal except: calcium 5.1 mg/dL (8.8–10.4 mg/dL) and albumin 3.0 g/dL (3.4–5.0 g/dL). His phosphate level is 4.2 mg/dL (2.5–4.5 mg/dL).

Question 10.6.6 Does this patient have hypocalcemia?

- No, the serum calcium level is normal
- No, the serum calcium level when corrected for the albumin is normal
- Yes, because the serum calcium-phosphate product is >20
- Yes, because the serum calcium level is still low when corrected for albumin
- Not enough information given to determine

Answer 10.6.6 The correct answer is “D.” The patient’s calcium level is low, even after correcting for hypoalbuminemia. To correct for albumin, add 0.8 mg/dL to the serum calcium level for each 1 g/dL the albumin is <4 g/dL. In other words, corrected serum calcium = $[(4 - \text{albumin}) \times 0.8] + \text{measured serum calcium}$. In this case the equation is $[(4 - 3) \times 0.8] + 5.1 = 5.9$ mg/dL. When evaluating hypocalcemia, it is prudent to check a BUN and creatinine to rule out renal failure as a cause (from renal osteodystrophy ... see Chapter 5 for more information).

**HELPFUL TIP:**

If you want to take the easy route and avoid the math, check an ionized calcium. The ionized calcium need not be corrected for albumin. An ionized calcium will also be useful in patients with monoclonal gammopathy or multiple myeloma. Occasionally, these proteins can also bind calcium.

Question 10.6.7 How should this patient now be treated?

- Calcium gluconate 1 g by rapid IV push
- Correct his hypomagnesemia with IV MgSO_4
- Administer IV normal saline 1 L bolus
- Initiate calcium carbonate 1 to 4 g with vitamin D orally divided in two to three doses daily
- No therapy, as the calcium level will correct itself

Answer 10.6.7 The correct answer is “D.” The patient now requires oral calcium supplementation, usually given with vitamin D to stimulate absorption. He will likely require vitamin D and calcium supplementation for the rest of his life. This patient has neither hypomagnesemia nor hyperphosphatemia, nor any other electrolyte abnormalities. If he had, correcting either would also raise the serum calcium. “A” deserves special mention. IV calcium gluconate or calcium chloride is usually indicated for severe hypocalcemia with signs and symptoms (e.g., tetany, seizures, or prolonged QT), but they should not be given by rapid IV push but rather by slow push over a couple of minutes.

► Objectives: Did you learn to ...

- Describe the evaluation and treatment of primary hyperparathyroidism?
- Recognize the signs and symptoms of hypocalcemia and hypercalcemia?
- Recognize the causes of hypercalcemia and hypocalcemia?
- Evaluate and treat hypocalcemia?

► CASE 10.7

A 36-year-old female presents to the office complaining of difficulty losing weight for 2 years. She seeks a prescription drug to aid in these efforts. She has tried every fad diet she comes across (grapefruit, banana, alkaline diet, blood-type diet, etc.), but nothing seems to help. She tries to exercise regularly but manages only walking a couple of miles each week. A nutritional history reveals that she is eating a sensible low-fat diet (how often do you see that!). Her past medical history includes hypertension treated with medications for the last 3 years and type 2 diabetes mellitus (DM2) treated for 1 year. She also has been seeing a psychiatrist over the last 6 months for emotional lability, which she blames on anxiety over her inability to get pregnant. The patient takes glyburide 5 mg PO daily and chlorthalidone 25 mg PO daily. A review of systems reveals thinning hair, irregular menses, delayed wound healing, and infertility (she’s been trying to get pregnant for over 1 year).

Question 10.7.1 What advice do you offer this patient now?

- She is eating right; she just needs to exercise more
- Low-fat diets are ineffective; she needs to reduce her carbohydrate intake
- She has failed lifestyle modifications, and appetite suppressant medications are indicated

- D) She is likely depressed and needs to continue psychiatric therapy and probably should start treatment with a selective serotonin-reuptake inhibitor (SSRI)
- E) Reserve any dietary advice at this time, as she first needs a medical workup

Answer 10.7.1 The correct answer is “E.” The patient’s symptoms of weight gain and associated findings on review of systems (emotionally labile, thinning hair, infertility, irregular menses, and delayed wound healing) suggest a secondary cause, most likely an endocrine abnormality. (What else would you expect? This is the endocrine chapter after all)

Her vitals in the office: P 88 bpm, BP 155/94 mm Hg, R 20, and T 37.7°C. **On physical examination, you note an obese female with truncal obesity and thin extremities. She has thinning hair, round facies, hirsutism, and a buffalo hump at her upper back. Her skin is hyperpigmented with abdominal striae. The rest of the examination is unremarkable.**

Question 10.7.2 Based on this patient’s history and physical examination, what diagnosis is most likely?

- A) Hypothyroidism
- B) Hyperthyroidism
- C) Cortisol excess secondary to chronic steroid therapy
- D) Cortisol excess secondary to an endogenous process
- E) Cortisol deficiency secondary to autoimmune adrenal insufficiency

Answer 10.7.2 The correct answer is “D.” This patient has the classic symptoms and signs of Cushing syndrome, or cortisol excess. This may be due to corticosteroid therapy (the most common cause), ectopic ACTH production from neoplasms (lung, pancreas, kidney, etc.), adrenal neoplasms producing cortisol, or ACTH-production from a pituitary neoplasm (termed Cushing disease). Her condition is unlikely due to steroid therapy, as this should have been revealed in her medical history. At this point in the evaluation, it is not clear what the source of the ACTH is, just that there is excess ACTH being produced. Note that the hyperpigmentation of this patient’s skin indicates an ACTH excess. ACTH stimulates melanocytes causing the hyperpigmentation. Hyperpigmentation will not be seen with exogenous steroid use. The same mechanism is in play in Addison’s secondary to adrenal destruction; the pituitary is pumping out ACTH in an attempt to flog the adrenals into producing cortisol. Other skin findings may include easy bruisability, purplish striae, and skin atrophy.

Labs are sent, most of which are normal except for an elevated glucose of 210 mg/dL and an elevated 24-hour urinary free cortisol of 115 µg (normal <100 µg). Based on these findings, a dexamethasone suppression test is ordered. The patient is given huge (gargantuan, way big), supratherapeutic dexamethasone doses for 2 days, and then serum ACTH is drawn, and another 24-hour urine collection is done. The

repeat serum ACTH is still *slightly* elevated and 24-hour urinary free cortisol is 78 µg (normal).

Question 10.7.3 What is the source of this patient’s cortisol excess?

- A) An ACTH-producing tumor
- B) A cortisol-producing adrenal tumor
- C) Surreptitious use of oral steroids
- D) Not enough information to determine

Answer 10.7.3 The correct answer is “A.” When the patient was given exogenous steroids during the test, there was a partial suppression of cortisol production (a decrease in 24-hour urinary free cortisol). But more importantly, the serum ACTH level remained above normal despite the high steroid load. The ACTH level should have been low in the presence of dexamethasone, or any exogenous steroid, which would act to shut off ACTH production in the normal patient. If ACTH is still being produced despite a high steroid load, then there must be an ACTH-producing neoplasm somewhere in the body (either ectopic production from a lung, renal, or pancreatic cancer, or an ACTH-producing pituitary tumor that has escaped normal regulatory feedback mechanisms).

On physical examination, the patient has a visual field cut.

Question 10.7.4 What is the best next step in this patient’s evaluation?

- A) Ultrasound of kidneys to assess for masses and adrenal flow
- B) CT scan of the brain to rule out metastatic lesions and assess pituitary size
- C) CT scan of the adrenals to evaluate for adrenal neoplasms
- D) MRI of the pancreas to evaluate for neoplasms
- E) MRI of the pituitary gland to evaluate for a neoplasm

Answer 10.7.4 The correct answer is “E.” The previous studies strongly suggest Cushing syndrome and the visual field cut suggests a pituitary source of excess ACTH (e.g., ACTH-producing tumor of the pituitary gland). An MRI of the pituitary is the best means to confirm this. CT scan may suggest enlargement of the sella turcica (where the pituitary gland sits), but it is insensitive for detecting abnormalities in the pituitary, especially microadenomas.

HELPFUL TIP:

If the MRI is negative, then the rarer case of ectopic ACTH production from occult cancer must be considered, and a body CT scan is indicated.

► **Objectives: Did you learn to ...**

- Recognize the common presenting signs and symptoms of Cushing syndrome?
- Differentiate Cushing syndrome from Cushing disease?
- Identify the causes of cortisol excess and how they are best evaluated?

► CASE 10.8

JFK is a 38-year-old male presenting to the office with the chief complaint of weakness. He reports that he lacks the energy to complete his previously busy work schedule (such as invading Cuba) and has cut his hours back the last 2 to 3 weeks, which has recently become a financial hardship. He also reports poor appetite and a 20-lb weight loss over the last month. He has had alternating periods of diarrhea and constipation. He is often feeling faint and has come near to passing out after standing up quickly a few times; this is different for him from baseline. He used to rescue sailors at sea. He has no previous medical or surgical history. He denies medications or allergies. He reports that several of his relatives on his mother's side have had thyroid problems. "I can't go on like this," he complains in an accent that betrays his Boston roots.

On physical examination, his vitals reveal BP 85/38 mm Hg, P 85 bpm, R 20, and T 37°C. The examination shows hyperpigmentation of buccal mucosa and weakness in the proximal musculature (4+/5 strength in both upper and lower extremities) but with normal reflexes and sensation in all extremities. His skin is hyperpigmented at the elbows, knuckles, knees, and the palmar creases. There is no edema.

Question 10.8.1 What is the most likely cause of this patient's symptoms?

- A) Hyperthyroidism
- B) Hypothyroidism
- C) Adrenal gland hyperactivity
- D) Adrenal insufficiency
- E) Depression

Answer 10.8.1 The correct answer is "D." Several clues point you in this direction, aside from the patient's name. First, the hyperpigmentation found at stress/crease points on the skin suggests the diagnosis of adrenal insufficiency. The low blood pressure and orthostasis is also more likely to be seen in adrenal insufficiency.

This patient has a number of symptoms consistent with both depression and hypothyroidism ("B" and "E"), but his physical examination suggests another diagnosis. A patient with depression and no underlying medical cause would have a normal physical examination. A patient with hypothyroidism may have a slightly low blood pressure, but not markedly low as in this patient. The heart rate in symptomatic hypothyroidism is usually low. Hypothyroidism may also cause changes in the hair, skin, and thyroid gland that are not seen here. Finally, the patient's reflexes are normal, rather than delayed. There is nothing in this case to suggest hyperthyroidism or cortisol excess ("A" or "C").

Laboratory results show a low sodium (129 mg/dL), low glucose (69 mg/dL), and high potassium (5.4 mg/dL) along with a normal TSH and a mildly low hemoglobin.

Question 10.8.2 Based on the information provided thus far, what is the best test to diagnose this patient's condition?

- A) Cosyntropin stimulation test
- B) Random serum cortisol
- C) Bone marrow biopsy
- D) Plasma renin
- E) Ultrasound of kidneys to measure their size

Answer 10.8.2 The correct answer is "A." The laboratory chemistry results (hyperkalemia, hyponatremia, and hypoglycemia), combined with the history and physical examination, strongly suggest a mineralocorticoid deficiency. A cosyntropin stimulation test uses synthetic ACTH to try to induce a burst of cortisol secretion. No adequate increase in the serum cortisol in response to the cosyntropin suggests that the adrenal glands are unable to respond to the body's mineralocorticoid and glucocorticoid needs. A positive cosyntropin test makes the diagnosis of adrenal insufficiency. A random serum cortisol is definitely second best, as cortisol levels normally fluctuate widely throughout the diurnal cycle. Plasma renin is used in the evaluation of mineralocorticoid excess (hyperaldosteronism) and should be low in adrenal insufficiency secondary to adrenal dysfunction (aldosterone causes sodium reabsorption and potassium excretion, the exact opposite seen in this patient whose adrenals don't make aldosterone). "E" is not likely to be helpful. Even in the case of adrenal insufficiency, the kidneys are unlikely to change in size. Although an ultrasound may show small, shrunk adrenals that have been destroyed by tuberculosis, a CT scan is a better tool for assessing the adrenals. "C" is way off base. This patient has no indication for a bone marrow biopsy.

HELPFUL TIP:

An early morning serum cortisol level is often low in patients with adrenal insufficiency. However, this test alone is insufficient for screening, as it has a high false-negative rate. But a low (<5 µg/dL) early morning serum cortisol is likely to be due to adrenal insufficiency.

HELPFUL TIP:

Interpreting the cosyntropin stimulation test is not always straightforward. The current criteria used to indicate normal adrenal function are a minimum serum cortisol concentration ≥ 18 to 20 mcg/dL (500–550 nmol/L) BEFORE OR AFTER corticotropin injection. An algorithm is available at <http://www.arupconsult.com/Algorithms/AdrenalInsufficiency.pdf>

Further laboratory results are as follows:

Random serum cortisol: 4 µg/dL (normal ≥ 20 µg/dL)
 Serum cortisol 1 hour after 0.25 mg cosyntropin IV:
 4.5 µg/dL (low)

Question 10.8.3 Based on the prevalence in the United States, what is the most likely underlying cause of this patient's condition?

- A) Autoimmune disease
- B) Invasive carcinoma
- C) Meningococcal septicemia
- D) Sarcoidosis
- E) Tuberculosis

Answer 10.8.3 The correct answer is "A." All the conditions listed are known causes of *primary* adrenal insufficiency, and all cause this disorder by destruction of the adrenal glands. However, in the United States the most common cause is autoimmune destruction of the adrenal glands; tuberculosis is the most common cause worldwide. Adrenal destruction will result in a lack of adrenal hormone secretion and a blunted response of the adrenals to ACTH—hence, the minimal rise of cortisol despite administration of synthetic ACTH (cosyntropin). Cortisol level after cosyntropin stimulation test should be higher than 18 to 20 mcg/dL (500 to 550 nmol/L) in patients with normal adrenal function.

Without measuring the serum ACTH or 24-hour urine ACTH level, it is still possible to tell the difference between primary (lack of adrenal response to ACTH) and secondary (pituitary lack of ACTH) adrenal insufficiency.

Question 10.8.4 Which of the following suggests primary adrenal insufficiency (e.g., adrenal destruction) rather than secondary?

- A) Baseline serum cortisol level >7 $\mu\text{g/dL}$
- B) Presence of hyperpigmentation on physical examination
- C) Presence of neuropathy on physical examination
- D) Predominant symptoms of depression

Answer 10.8.4 The correct answer is "B." Hyperpigmentation at skin creases occurs in primary adrenal insufficiency (but not secondary adrenal insufficiency). This is because in primary adrenal insufficiency, the **pituitary** is intact. As a result, the ACTH level is high, as is the level of melanocyte-stimulating hormone. It is this melanocyte-stimulating hormone that causes hyperpigmentation. An early morning baseline serum cortisol level of 5 mcg/dL or above ("A") would suggest primary adrenal insufficiency **unlikely** (the adrenals are still making cortisol). Hypoglycemia and depression ("D") are symptoms common to all causes of adrenal insufficiency so don't differentiate between primary adrenal failure and secondary causes of adrenal insufficiency. Neuropathy ("C") is not a common finding in adrenal insufficiency.

HELPFUL TIP:

Patients with primary adrenal insufficiency **may** present with low serum sodium and high serum potassium (although many will have normal electrolytes). This is primarily because of loss of the aldosterone

system. Patients with secondary adrenal insufficiency (e.g., pituitary cause) have intact adrenal glands and therefore intact aldosterone production. Thus, they will generally have normal electrolytes and less dehydration, hypotension, etc.

Question 10.8.5 How should this patient now be treated?

- A) Prednisone 60 mg PO for 5 days, then slowly tapered over 2 weeks
- B) Cosyntropin 0.5 mg SC daily indefinitely
- C) Corticosteroids (prednisone 5 mg or hydrocortisone 15 mg) daily indefinitely
- D) Corticosteroids (prednisone 5 mg or hydrocortisone 15 mg) daily plus mineralocorticoid (fludrocortisone 0.1 mg) daily indefinitely
- E) Adrenal transplant

Answer 10.8.5 The correct answer is "D." This patient requires chronic corticosteroid supplementation, and because he has primary adrenal insufficiency, he also requires mineralocorticoid supplementation. Usually, mineralocorticoid administration is not necessary in the acute setting, like adrenal crisis, but the vast majority of patients with primary adrenal insufficiency eventually require mineralocorticoid replacement with fludrocortisone. Cosyntropin treatment ("B") would have no effect since the adrenals are not functioning. A short burst of prednisone ("A") is important if this patient experiences a sudden stressor, such as an infection, but it is not the primary therapy. Medical therapy is fairly effective, so adrenal (or renal) transplant ("E") is not a usual treatment option.

JFK is treated appropriately and, after 4 weeks, is feeling much better, has regained most of his lost weight, and feels well enough to take on both Castro and Khrushchev (local competitors to his dry-cleaning business). He no longer suffers spells of lightheadedness or depression. To celebrate his new good health, he and a blond starlet go out for a lavish seafood dinner, including fresh oysters. Within 8 hours of the meal, JFK develops severe cramping abdominal pain and profuse watery diarrhea (so much for the date ...). He tries to treat himself at home with Pepto-Bismol and oral fluids but becomes progressively weaker. After 12 hours of intestinal symptoms, he calls for an ambulance because he is too weak to stand.

Upon presentation in the ED, his vital signs are: P 130 bpm, BP 70/20 mm Hg, R 30, and T 38°C. He is diaphoretic, ill-appearing, and in severe distress.

Question 10.8.6 After establishing adequate IV access, what should be done next?

- A) Order a chest x-ray
- B) Start "renal-dose" dopamine through a peripheral line
- C) Give 2 L normal saline by bolus
- D) Start normal saline at 125 cc/hr
- E) Give levofloxacin 500 mg IV

Answer 10.8.6 The correct answer is “C.” This patient is severely volume depleted and needs crystalloid immediately. All other treatment concerns, although they may eventually be done, are secondary.

Despite fluid boluses, he remains hypotensive. You scratch your head and ponder what you may have forgotten.

Question 10.8.7 What should have been done simultaneously for this patient when the fluids were started?

- A) Intubation by rapid sequence and mechanical ventilation
- B) Administration of a phenylephrine drip
- C) Administration of 4 mg dexamethasone IV
- D) Administration of 100 mg hydrocortisone IV
- E) C or D.

Answer 10.8.7 The correct answer is “E.” This patient has adrenal insufficiency and requires additional “stress doses” of steroids in times of severe physical stress (e.g., infection, trauma, myocardial ischemia). The steroids he regularly takes for his disease may not be sufficient during these periods, precipitating addisonian crisis. Without this additional treatment, the patient may experience intractable hypotension and possibly death. In a less acute situation in which the patient has a minor illness, two to three times the usual maintenance glucocorticoid dose for 3 days (known as the “3 × 3 rule”) may benefit the patient.

HELPFUL TIP:

If you suspect adrenal insufficiency crisis (addisonian crisis), start steroids immediately even if you do not have laboratory confirmation. Dexamethasone is an option for treatment, and it will not interfere with the cortisol assay when doing a cosyntropin stimulation test. But note that dexamethasone does not have mineralocorticoid activity and should be replaced by hydrocortisone succinate just as soon as the cosyntropin stimulation test is done.

The next day when you are doing your inpatient rounding, you meet your patient’s cousin Kenneth, who is a 59-year-old white male with a past medical history of hypertension, COPD, alcohol abuse, and osteoarthritis in his shoulders and knees; he is an enthusiastic, if not clumsy, tennis player. A particularly enthusiastic colleague injected 80 mg of triamcinolone in both of the patient’s knees and shoulders several months ago (total dose of 320 mg). He had just gone to a joint injection workshop and figured, what the heck, let’s practice! The patient notes weakness, lightheadedness, nausea, and decreased appetite recently. His home medications are lisinopril and inhaled albuterol. Vitals are BP 70/44 mm Hg, HR 60 bpm, T 35.6°C, oxygen saturation 98%. Physical examination shows a mildly distressed patient with mild expiratory wheezing on auscultation and unsteady gait when he tries to stand up.

Lab results: sodium 123 mEq/L (low), K 3.8 mEq/L (normal), BUN 30 mg/dL (normal range <20 mg/dL), creatinine 2.1 mg/dL (patient’s baseline is 0.6 mg/dL), Cl 84 mEq/L (low), and CO₂ 26 mEq/L. CBC, LFTs, total protein, and albumin are normal. A troponin, TSH, urine drug screen, alcohol level, and urinalysis are also normal.

He receives a couple of liters of normal saline, and his blood pressure normalizes. A repeat lab shows sodium 130 mEq/dL and creatinine 1.1 mg/dL. One of your resident physicians decides to further workup the hyponatremia and checks the cortisol level, which returns 1.5 µg/dL (low) with ACTH at 18 pg/mL (normal 7–63 pg/mL). A cosyntropin stimulation test is done and the serum cortisol level goes up to 14.9 µg/dL.

Question 10.8.8 What is the most likely cause of the patient’s hyponatremia?

- A) Secondary adrenal insufficiency due to panhypopituitarism
- B) Secondary adrenal insufficiency due to exogenous steroid use
- C) COPD exacerbation
- D) Hypothyroidism

Answer 10.8.8 The correct answer is “B.” The patient received ridiculous doses of intra-articular triamcinolone several months ago causing adrenal suppression. “A” is incorrect because the initial ACTH is normal, which is not the typical finding for central causes of adrenal insufficiency. “C,” COPD exacerbation, is not consistent with the adrenal function tests. “D,” hypothyroidism, can cause fatigue and hyponatremia, but the patient’s TSH is within the normal limits.

► Objectives: Did you learn to ...

- Recognize the presentation of adrenal insufficiency?
- Evaluate a patient with adrenal insufficiency?
- Treat a patient chronically for adrenal insufficiency and when in adrenal crisis?
- Understand secondary adrenal insufficiency due to exogenous steroid use?

QUICK QUIZ: DIABETES DIAGNOSIS

Which of the following can be used to diagnose diabetes mellitus (DM)?

- A) Fasting blood glucose on one occasion
- B) Glycosylated hemoglobin (HbA1C) on one occasion
- C) A random blood sugar of >160 mg/dL
- D) None of the above

The correct answer is “D.” Here is why: The diagnosis of DM requires two elevated fasting blood sugars of ≥126 mg/dL or two HbA1c levels of ≥6.5%. It can also be diagnosed if the patient has a single random blood sugar of >200 mg/dL with typical signs and symptoms of DM (polyuria, polydipsia, weight loss, and blurred vision). To be complete, a 2-hour postprandial

glucose tolerance test result of >200 after 1.75 g/kg of glucose (max dose 75 g) is diagnostic of DM. However, this is rarely used in the United States.

QUICK QUIZ: A1c IN SPECIAL CONDITIONS

Which of the following conditions artificially raises the value of hemoglobin A1c (HbA1c)?

- A) Iron deficiency anemia
- B) Sickle cell disease
- C) Chronic liver disease
- D) Acute blood loss anemia
- E) All of the above

The correct answer is “A.” Iron deficiency may falsely elevate the HbA1c. Several other conditions can cause a falsely low HbA1c including sickle cell disease, malaria, acute blood loss, and hemolysis (see a pattern developing here?). This makes sense: in all these conditions the bone marrow is pumping out new cells that have not been exposed to the elevated glucose levels. Conversely, iron deficiency and vitamin B12 and folate deficiencies may be associated with falsely high HbA1c levels, which is due to the proportion of older red cells (and therefore more glycosylated cells) in the blood being high compared to the normal individual. Chronic kidney disease may cause either a falsely elevated or falsely low HbA1c.

► CASE 10.9

You are called to the ED to see a 17-year-old man brought in by his parents who found him in his room at home. He is lethargic, but not unconscious or comatose. He is unable to give a coherent history. His parents state that they have been concerned because the patient has been losing weight in the last 2 months and acting more tired than usual. They are worried that he might be abusing drugs, but have not found any drugs or drug paraphernalia in the home. They have observed no other signs of illness. The family history is positive for hypertension in multiple family members, and the patient’s mother has hyperlipidemia. There is no family history of kidney or liver disease, heart attacks, strokes, diabetes, or cancer. His vitals are: T 36.9°C, P 125 bpm, BP 98/54 mm Hg, respirations are deep with a rate of 28, SpO₂ 95% on room air. He is lethargic and nonverbal but arouses to pain. His mucous membranes are dry with a fissured tongue. You smell a fruity aroma on his breath that reminds you of that bowl of fruity cereal you left at home. His breathing is fast and he is tachycardic. His abdominal examination reveals a soft abdomen with mild, generalized tenderness. No rebound or guarding.

EKG shows sinus tachycardia. CBC shows an Hgb 17.9 g/dL, WBC 16,200 cells/mm³ with neutrophil predominance, and platelets 650,000 cells/mm³. Electrolytes show sodium 131 mEq/L (slightly low), potassium 5.7 mEq/L (high), chloride 97 mEq/L, bicarbonate 10 mEq/L (low), BUN 63 mg/dL

(high), creatinine 1.8 mg/dL (baseline 0.7 mg/dL), and glucose 635 mg/dL (high). Serum ketones are positive. You are concerned about his respiratory status so you obtain a venous blood gas (just as good as an ABG in almost every circumstance and it hurts less ... and you can get the oxygen saturation off a monitor) on room air with pH 7.20, PaCO₂ 27 mm Hg, PaO₂ 101 mm Hg, and bicarbonate 10 mEq/L.

You diagnose diabetic ketoacidosis (DKA) with dehydration >10% and admit the patient to the intensive care unit. As the first stage of therapy you wish to replace the lost fluid volume.

Question 10.9.1 Which of the following regimens is the most appropriate initial intervention?

- A) 5% dextrose in 0.45% (half-normal) saline to run at 150 cc/hr
- B) 0.45% (half-normal) saline with 20 mEq potassium/L, to run at 150 cc/hr
- C) 0.9% (normal) saline 1 L to infuse as quickly as possible
- D) 0.9% (normal) saline with 20 mEq potassium/L to run at 1,000 cc/hr
- E) 5% dextrose in 0.225% (quarter-normal) saline with 20 mEq potassium/L to run at 1,000 cc/hr

Answer 10.9.1 The correct answer is “C.” Initial volume replacement should be with isotonic saline infused at a rapid rate until the volume deficit is corrected. “D” is of special note. In general, potassium should be added to the fluid later (often the second bag) unless the patient is already hypokalemic on the initial blood work (getting a potassium, glucose, and sodium on the first blood gas is good policy). Potassium replacement may be essential even in the hyperkalemic patient, as correction of the ketoacidosis leads to a rapid shift of potassium into the intracellular compartment. Remember that an acidosis artificially increases the serum potassium by shifting potassium extracellularly. The potassium increases by approximately 1 mEq/L for every pH point of 0.1 below 7.4 (so, a pH of 7.3 will increase the potassium from 4 to 5 mEq/L). See Chapter 5 for more on acidosis, alkalosis, and the effects on potassium. “D” is incorrect because you would like the first liter to infuse as quickly as possible in DKA and not over an hour. Besides, 20 mEq of potassium IV in 1 hour should not be routine and only given if the patient has continuous cardiac monitoring.

HELPFUL TIP:

Patients with severe hyperglycemia (like this guy) will have hyponatremia secondary to the osmotic effect of glucose pulling water into the intravascular space, increasing the plasma water content. What is the corrected sodium for this patient? It is approximately 140 mEq/dL based on the formula: **corrected sodium = measured sodium + [1.6 (glucose – 100)/100]**. This is very approximate. If the glucose is >400 mg/dL, use “2” rather than 1.6 for the correction. As an aside, the bowl of fruity cereal the provider left at home? All of the colors of Fruit Loops taste exactly the same. Another bubble broken ...

**HELPFUL TIP:**

Urine ketones are >99% sensitive for DKA in the right circumstance. Thus, checking serum ketones is superfluous in most cases.

**HELPFUL TIP:**

When should you start insulin? When should you start potassium? The American Diabetes Association gives us guidance. (1) DO NOT start insulin if the potassium is LESS THAN 3.3 mEq/L. Give fluid and potassium replacement first. The risk of hypokalemia and arrhythmias is too great. (2) Start potassium in the patient with DKA if their potassium is <5.3 mEq/L; give 20 to 40 mEq/hr IV (cardiac monitored). Once you correct the acidosis the potassium will drop, of course.

Question 10.9.2 What is the most appropriate initial insulin regimen for this patient?

- A) Subcutaneous NPH insulin, 1 unit/kg; repeat as necessary
- B) IV regular insulin, 5 unit IV bolus, followed by constant infusion at 0.05 to 0.1 unit/kg/hr; adjusted as needed
- C) Subcutaneous regular insulin, 0.5 to 1 unit/kg; adjust dose by fingerstick blood glucose results
- D) Intramuscular regular insulin, 5 to 10 units hourly; adjust dose by fingerstick blood glucose results
- E) Insulin glargine 10 units daily adjusted based on fasting glucose levels

Answer 10.9.2 The correct answer is “B.” A bolus of IV regular insulin, followed by a constant infusion, adjusted to reduce the blood glucose level by 50 to 75 mg/dL/hr, is the appropriate therapy. This may frequently require >0.1 unit/kg/hr, but 0.05 to 0.1 unit/kg/hr is a good place to start. Intramuscular insulin administration is an alternative, but absorption is unreliable, especially in hypotensive patients. Long-acting insulins and subcutaneous insulin administration have no place in the initial management of DKA.

**HELPFUL TIP:**

Although tradition, the bolus of regular insulin is unnecessary and does not change outcomes. Starting a drip of regular insulin is the critical step here.

Question 10.9.3 Which of the following types of insulin can be administered IV?

- A) NPH insulin
- B) Glargine insulin (e.g., Lantus)
- C) Lente insulin
- D) Ultralente insulin
- E) None of the above

Answer 10.9.3 The correct answer is “E.” The only insulin that can be administered IV is regular insulin. As an aside, some insulins are incompatible when mixed together in the same syringe. For example, insulin glargine should not be mixed with any other forms of insulin due to the low pH of its diluent. Further, phosphate-buffered insulins (e.g., NPH) should not be mixed with Lente insulins.

The patient’s status improves, and you re-check his blood sugar. His glucose is now 200 mg/dL and his insulin drip is running at 5 units per hour. His pH is 7.30 with a bicarbonate level of 14 mEq/L.

Question 10.9.4 Given that his glucose has almost normalized, your reaction at this point is to:

- A) Administer bicarbonate in order to finish correcting the pH
- B) Decrease the rate of the insulin infusion to 2 units per hour
- C) Add 5% to 10% dextrose to his IV fluids
- D) Consider the addition of an oral hypoglycemic agent
- E) Discontinue IV fluids and switch to oral rehydration

Answer 10.9.4 The correct answer is “C.” This patient is still acidotic and will need continued insulin to reverse his catabolic state. Thus, the appropriate treatment is to increase the amount of sugar he is getting—add some dextrose to his IV fluids. Remember, DKA is not primarily a result of too much sugar but rather of too little insulin. “A” is incorrect. **Bicarbonate plays no role in the treatment of DKA no matter what the pH.** In fact, the administration of bicarbonate actually prolongs acidosis and ketosis and produces a paradoxical CNS acidosis. In addition, it shifts the oxygen dissociation curve to reduce oxygen delivery to the tissue. Finally, **the only predictor of cerebral edema in children treated for DKA is the administration of bicarbonate.** So, there is no need to restrict fluids in children being treated for DKA (although this does NOT mean you should over-hydrate them).

**HELPFUL TIP:**

The common causes of DKA: “the 5 I’s” mnemonic.

Insulin or medication noncompliance; Infection; myocardial Infarction; Incision (surgery); Incidental (new diagnosis of DM presenting with DKA). (Not by Dr. Mark Yofee ... but still a shout out to his mom.)

Question 10.9.5 Which of the following statements is FALSE?

- A) The Somogyi phenomenon occurs when a patient’s blood sugar becomes elevated and there is a reactive hypoglycemia
- B) Patients who are being treated appropriately for DKA may have an increase in serum ketones during treatment
- C) An elevated WBC count is not a strong predictor of infection in patients with DKA
- D) Glucagon is an inappropriate treatment of patients with alcoholic hypoglycemia

Answer 10.9.5 The correct answer (and false statement) is “A.” Consensus is that the **Somogyi phenomenon does not exist regardless of what we were taught** (*N Engl J Med.* 1987;317(25):1552). But just for the record, it was thought to occur when a patient becomes **hypoglycemic** (often in the middle of the night) and experiences a reactive hyperglycemia from adrenergic outpouring. Actually, quite a different phenomenon appears to occur: nocturnal **hyperglycemia** is strongly associated with elevated morning glucose levels. All of the rest are true statements. “B” is correct because beta-hydroxybutyrate is metabolized to acetoacetic acid that will increase serum ketone measurements. “C” is true since DKA is a pro-inflammatory state and the WBC count is often elevated due to DKA and not infection. “D” is a true statement. Patients with alcoholic hypoglycemia have exhausted their glycogen stores and are also generally NAD deficient and thus have impaired gluconeogenesis. Thus, glucagon will not work. Another group on which glucagon will not work is the infant or child who becomes hypoglycemic overnight and has a seizure in the morning. They have already depleted their stores of glycogen.

**HELPFUL TIP:**

Consider the possibility of a silent myocardial infarction in a diabetic patient who is generally well-controlled but suddenly has elevated blood sugars.

**HELPFUL TIP:**

Twenty percent of patients with DKA have relatively “normoglycemic” DKA and present with a blood sugar under 300 mg/dL.

It is time to transition this patient to a home-going insulin regimen.

Question 10.9.6 Which of the following statements is FALSE regarding the use of insulin in this patient?

- A) Insulin detemir and insulin glargine are both long-acting, essentially equivalent, and can (almost always) be used once a day as basal insulin
- B) If you use NPH, start with 0.1 to 0.2 units/kg/day and give 2/3 in the AM and 1/3 HS
- C) Regular insulin should be given with meals to cover blood sugars and generally requires 0.1 to 0.2 units/kg/day as a start
- D) Metformin can markedly reduce the need for insulin in this patient
- E) This patient’s insulin need may markedly diminish over the next 2 weeks

Answer 10.9.6 The correct answer (which is false) is “D.” Metformin is used only in DM2. By virtue of the fact that he’s presenting with DKA, our patient almost assuredly has type 1 diabetes mellitus (DM1). The rest are true statements. Insulin detemir and glargine can both be used once a day in most

patients (although not always). The starting dose of both regular and NPH insulin is about 0.1 to 0.2 units/kg/day for a total initial insulin dose of 0.2 to 0.4 units/kg/day to start. “E” refers to the “honeymoon period.” Patients usually present with DM in relation to some metabolic stress. Once this stress resolves, the need for insulin may decrease markedly. Thus, close monitoring is required. (Editor’s note: Yes, metformin has been studied in DM1 but seems to not lead to changes in the HbA1c [although it can reduce the insulin dose needed]).

**HELPFUL TIP:**

There is no outcome advantage to brand name insulins versus generic insulins (*JAMA* 2018 Jul 3; 320:53). Cost and convenience should be the main considerations in choosing one versus the other. Lantus, Novolog, and Humalog cost up to \$250/bottle with generic NPH costing as little as \$25/bottle.

**HELPFUL TIP:**

DKA often presents as an acute abdomen with abdominal pain, nausea and vomiting and can be mistaken for appendicitis, etc.

► **Objectives: Did you learn to ...**

- Diagnose a patient with DKA?
- Initiate therapy in DKA?
- Identify causes of DKA?
- Realize that the Somogyi phenomenon is scary but not real (like Godzilla)?

**QUICK QUIZ: DIABETES PREVENTION**

Which intervention has been shown to have the *greatest effect* in preventing or delaying the onset of DM2 in patients with impaired fasting glucose or impaired glucose tolerance?

- A) Dietary modifications and increased activity
- B) Early glipizide treatment
- C) Early metformin treatment
- D) Intensive fitness training
- E) Weight loss >25% of baseline

The correct answer is “A.” Metformin has been shown to have some benefit in delaying progression to diabetes but is less effective than diet and activity modifications. The studies showing benefit from lifestyle modifications used much less aggressive targets for weight loss and activity level than the 25% listed in answer “E.” Thus, “E” is incorrect. Other medications that have been used (successfully) to reduce progression to diabetes include the thiazolidinediones (“glitazones”) and acarbose. However, exercise and diet are superior to drugs. The benefit of drugs is marginal. In addition, the thiazolidinediones have significant downsides including edema and possibly increased cardiac events.

**HELPFUL TIP:**

Nonpharmacologic therapies that can reduce insulin resistance include engaging in 30 minutes of modest aerobic exercise 5 days per week (tell patients to aim for 150 minutes of exercise per week—how it's divided is not important), having high fiber in the diet, decreasing caloric intake (small portions), and losing weight. Magic pill? We're still waiting ... However, weight loss surgery has been shown to "cure" diabetes in those with Type 2 DM and reverse hypertension and dyslipidemia in substantial minorities—up to 30% for diabetes, 50% for hypertension (*JAMA* 2018 Jan 16; 319:291 and *JAMA* 2018 Jan 16; 319:266).

**QUICK QUIZ: DIABETIC RETINOPATHY**

Which of the following interventions has NOT been shown to prevent loss of vision in patients with retinopathy due to type 2 diabetes?

- A) Laser photocoagulation therapy
- B) Aspirin
- C) Tight glycemic control
- D) Tight blood pressure control

The correct answer is "B." Aspirin has not been shown to be of any benefit in the Early Treatment Diabetic Retinopathy Study. All the other options have been shown to be useful in delaying the development of diabetic retinopathy or preventing its progression to visual loss.

▶ CASE 10.10

You are seeing a new patient in your office. He is a 47-year-old man with a presenting complaint of fatigue for several months. He denies fever, rigors, cough, nausea, or diarrhea. He has lost about 10 lb. Upon questioning him you discover that he is also having nocturia and is thirsty all the time. He has asthma, for which he uses an albuterol-metered dose inhaler occasionally. He has no other chronic medical problems and takes no other medications on a regular basis. He has a family history of diabetes, hypertension, and heart disease. He smokes about one pack per day, and he works as a teacher at the local high school. He is aware of no occupational exposure to toxins.

Physical examination reveals the following: T 37°C, BP 135/83 mm Hg, P 72 bpm, BMI 38 kg/m². Aside from obesity, the remainder of the examination is normal.

Laboratory test results reveal the following: normal CBC, BUN/creatinine, and electrolytes. You ask him to return to the office the next day for fasting laboratory tests, which reveal a fasting glucose of 123 mg/dL and an HbA1c of 7.5%.

Question 10.10.1 Does this patient have diabetes?

- A) Yes; he has an elevated fasting glucose
- B) Probably; he needs a second fasting glucose to confirm the diagnosis
- C) Probably; he needs a second HbA1c to confirm the diagnosis
- D) Yes; he has the classic symptoms of diabetes: fatigue, weight loss, and thirst, associated with an elevated glucose
- E) Probably not; his HbA1c is not >8%

Answer 10.10.1 The correct answer is "C." If results of two different diagnostic tests for DM are discordant, the test that is diagnostic of diabetes should be repeated. "A" and "B" are incorrect because the fasting glucose is <126 mg/dL (the threshold for diabetes). "D" is incorrect because we do not have his random glucose value that is ≥200 mg/dL. "E" is incorrect because the A1c cutoff for diabetes diagnosis is ≥6.5%.

**HELPFUL TIP:**

The 2018 ADA guidelines recommend screening *all* asymptomatic adults every 3 years starting at age 45; earlier screening is recommended for adults at high risk of type 2 diabetes (BMI ≥25 kg/m²; first-degree relative with DM; history of CVD; habitual physical inactivity; high-risk race/ethnicity [African Americans, Asian Americans, Mexican Americans, Native Americans, Pacific Islanders, and Native Hawaiians]; previously identified impaired glucose tolerance; hypertension; dyslipidemia [HDL <35 or triglycerides >250]; history of gestational diabetes or delivery of a baby weighing >9 lb; and polycystic ovary syndrome). Pre-diabetics should be tested yearly. Of note, the USPSTF recommendations on *who* to screen for diabetes are similar, but include the age ranges of 40 to 70 years and do not specify a screening frequency.

Question 10.10.2 Assuming another A1c is above 6.5%, what further study must be done to complete the diagnosis of diabetes and determine whether the patient has type 1 or type 2 diabetes?

- A) C-peptide level
- B) Anti-islet cell antibodies
- C) Anti-insulin antibodies
- D) None of the above

Answer 10.10.2 The correct answer is "D." This patient's age, history, examination (BMI 38), and laboratory findings are consistent with the diagnosis of DM2. None of the other studies listed needs to be performed. However, if questions remain regarding the type of diabetes (which will then affect therapy, prognosis, follow-up, etc.), you may choose to perform further studies. In DM1, the C-peptide level (a marker of endogenous insulin production) is low. If it is equivocal, give a glucose load (e.g., large meal) and see if it goes up. If it goes up, the diagnosis is likely DM2. Anti-islet cell antibodies are present in 80% of type

1 diabetics and, if found in the patient with criteria for diabetes, are essentially diagnostic of type 1 diabetes. “C” is incorrect because anti-insulin antibodies have a low sensitivity for DM1 and may be elevated secondary to the use of exogenous insulin.

HELPFUL TIP:

To be complete, anti-glutamic acid decarboxylase (anti-GAD) antibodies are present in 70% of patients with DM1 at the time of diagnosis.

Question 10.10.3 The pathologic factors involved in type 2 diabetes in adults include:

- A) Pancreatic beta-cell destruction through a yet undetermined infectious process
- B) The production of anti-insulin antibodies that cause precipitation of insulin/antibody complexes
- C) Resistance to the effects of insulin at peripheral tissues and a relative insulin deficiency that is progressive over time
- D) An autosomal-dominant process, with the diabetes gene located on the long arm of chromosome 18
- E) Too much exercise and a complete lack of a “beer gut”

Answer 10.10.3 The correct answer is “C.” DM2 is the result of the development of insulin resistance at the peripheral tissues (e.g., fat and muscle cells) and a relative lack of insulin compared to the increasing amount that the body requires. “A” is incorrect. Autoimmune destruction of beta-cells in the pancreas is responsible for causing DM1. “B” is incorrect, although there are anti-insulin antibodies found in DM1. “D” is incorrect as well, but there is a strong genetic component to DM2. The exact genetic factors that cause DM2 in adults have not been completely elucidated, but no single responsible gene is transmitted in an autosomal dominant fashion. “E” is incorrect because lack of exercise, weight gain, dietary factors, and truncal obesity (the “beer gut”) predispose persons to the development of DM2.

You meet with the patient and his husband to go over the test results and explain the diagnosis of diabetes. Given his age, body habitus, and lack of exercise, you feel certain that this patient has type 2 diabetes. You provide some basic education on the nature of diabetes, its natural history, and what can be done to manage it.

Question 10.10.4 What is the *most* important next step for this patient?

- A) Initiation of insulin therapy
- B) Initiation of an ACE inhibitor
- C) Referral to an endocrinologist
- D) Diabetic education classes
- E) Initiation of glyburide or other sulfonylurea

Answer 10.10.4 The correct answer is “D.” A general education program that includes information on diet, disease management, and the family’s role in successful diabetes care is the

most important intervention listed. While specialist consultation may be useful in complex diabetic patients or in those who are not responding to treatment, primary care physicians provide care to the majority of patients with diabetes. Insulin therapy is not indicated at this point, and an ACE inhibitor may or may not be helpful depending on the patient’s blood pressure and urine protein. “E” is also incorrect (keep reading to learn why).

Upon his return, you find that the patient’s blood pressure is elevated. On three separate occasions, he has systolic pressure ≥ 140 and diastolic pressure ≥ 90 mm Hg.

Question 10.10.5 Which class of medications is the best choice for initial therapy of hypertension in diabetics?

- A) ACE inhibitors
- B) Calcium-channel blockers
- C) Loop diuretics
- D) Vasodilators
- E) Beta-blockers

Answer 10.10.5 The correct answer is “A.” ACE inhibitors have been shown to provide renal protection in patients with diabetes (types 1 and 2). Patients with albuminuria and hypertension will certainly benefit from an ACE inhibitor. Loop diuretics (e.g., furosemide) are not indicated for the **primary** treatment of hypertension in diabetics (or, really, anyone else). Angiotensin receptor blockers (ARBs) are a reasonable alternative in the hypertensive patient with albuminuria if an ACE inhibitor is not tolerated. Vasodilators and calcium-channel blockers are not optimal choices in this patient although *non-dihydropyridine* calcium channel blockers (verapamil, diltiazem) are an option for renal protection in patients with worsening albuminuria especially in those who cannot tolerate an ACE inhibitor or ARB. “E,” beta-blockers, should not be used first line for treating hypertension in patients without cardiac disease.

Question 10.10.6 Which of the following is NOT a side effect of ACE inhibitors?

- A) Acute renal failure
- B) Hyperkalemia
- C) Dry cough
- D) Angioedema
- E) Cooties

Answer 10.10.6 The correct answer is “E.” All of those listed—except cooties—are side effects of ACE inhibitors. Cooties are airborne parasites for which obnoxious fourth-grade boys serve the main host. Hope you got your “cooties shot” when you were younger. If so, you should be fine.

Adverse effects of ACE inhibitors are due to either reduced angiotensin II formation or to increased kinin formation. Those related to reduced angiotensin II formation include hypotension, acute renal failure, hyperkalemia, and problems during pregnancy. Side effects thought to be related, at least in part,

to increased kinins include cough, angioedema, and anaphylactoid reactions. Termination of the ACE inhibitor should be considered if hyperkalemia cannot be controlled or the serum creatinine concentration increases more than 30% above the baseline value within the first 6 to 8 weeks when blood pressure is reduced. Also, both ACE inhibitors and ARBs are contraindicated in pregnancy.

HELPFUL TIP:

Guidelines published by JNC8 (2014) and the ADA (2018) endorse higher blood pressure goals for hypertensive diabetics than was the case in prior guidelines. The blood pressure target for most diabetic patients is now <140/90 mm Hg. A lower target (e.g., 130/80) may be appropriate for certain individuals, such as younger patients, if it can be achieved without undue treatment burden.

After 3 months of dietary therapy and lifestyle modifications, the patient returns to see you with his husband. While he has been adherent to the recommendations given by you and the diabetes education staff, his HbA1c remains elevated at 7.9%. You decide to begin pharmacologic therapy.

Question 10.10.7 Which medication is the most appropriate first-line therapy for an obese patient with type 2 diabetes?

- A) A thiazolidinedione (“glitazone” [e.g., Actos])
- B) A sulfonylurea (e.g., glipizide)
- C) Insulin
- D) Metformin
- E) A dipeptidyl peptidase-4 inhibitor (DPP-4 or “gliptin” [e.g., Januvia])

Answer 10.10.7 The correct answer is “D.” Too easy? Well, every once in a while, you deserve a break, right? Metformin does not cause weight gain (unlike many other treatments for diabetes), has evidence for reducing the complications of diabetes, and is generally well-tolerated and inexpensive. Thus, it is the drug of choice in most DM2 patients. In addition, it carries very little risk of hypoglycemia. GI side effects are common, however (nausea, diarrhea). Some patients will lose weight from use of metformin. Thiazolidinediones known as “glitazones” (“A”) are not first-line for several reasons, chief among these being the possibility of increased cardiovascular events (rosiglitazone and pioglitazone can exacerbate CHF). The track record of rosiglitazone is somewhat spotty: it was removed from the market due to an increase in cardiovascular events and then was reintroduced even though there was no additional safety data; avoid it if you can. Sulfonylureas (“B”) are also effective and well-tolerated, but have a significant risk for hypoglycemia and are associated with weight gain. Studies comparing effects on end-organ disease show better outcomes with metformin than with sulfonylureas. All other oral drugs are best considered

second-line agents. “E” is of special note. DPP-4 inhibitors, also known as “gliptins,” block the degradation of the body’s endogenous incretin, which helps to lower blood sugar. DPP-4 acts as a “glucagon-like peptide-1” (GLP-1). DPP-4 inhibitors (sitagliptin [Januvia], saxagliptin [Onglyza], alogliptin [Nesina] ... see below for a caution) can be used as an “add-on” therapy if traditional hypoglycemic agents are not effective and have the benefit of some weight loss. In a patient with very poor control (e.g., A1c >9%) at diagnosis, insulin (“C”) would be a potential first-line agent, but not in this patient whose is partially controlled.

HELPFUL TIP:

New data suggests an association (or maybe causality) of congestive heart failure with saxagliptin (Onglyza) and alogliptin (Nesina). This does not seem to be a problem with sitagliptin (Januvia). These drugs only reduce HbA1c by about 0.5% and have no data demonstrating cardiovascular benefit. Other reported side effects include headache, nasopharyngitis, and upper respiratory tract infections. Also, acute pancreatitis has been reported in association with DPP-4 inhibitors, but currently there is insufficient evidence to determine a causal relationship.

HELPFUL TIP:

Another class of “glucagon-like peptide-1” (GLP-1) drugs act as receptor agonists (e.g., exenatide [Byetta or Bydureon], liraglutide [Victoza], albiglutide [Tanzeum], etc.) which bind to the GLP-1 receptor. They are resistant to breakdown by the body and thus provide sustained glucose control. These are given by subcutaneous injection and are fairly costly, but have the advantage of being more potent than the gliptins and may even cause weight loss in type 2 diabetics.

HELPFUL TIP:

Good glucose control can cost an arm and a leg (or at least a leg). Can’t they leave well enough alone? Just what we need, more abbreviations. The last new(ish) class of drugs for DM2 are the “flozins” properly known as “SGLT2 inhibitors” (sodium-glucose cotransporter-2). Examples are canagliflozin (Invokana), empagliflozin (Jardiance), etc. They promote the renal excretion of glucose (literally peeing out the sugar) and thereby lowering A1c levels by 0.5% to 0.7%. The overall benefits of SGLT2 inhibitors include a decrease in blood pressure and weight and a low incidence of hypoglycemia. There is some evidence that they improve cardiac and renal outcomes (although marginally). Invokana (one of Trump’s daughters?) and the other flozins are associated with an increased risk of amputations (BMJ 2018;363:k4365). The other side

effects are exactly what you would think, given that the mechanism of action increases sugar content of urine: vulvovaginal candidiasis, urinary frequency, hypovolemia/dehydration, and (serious) urinary tract infection. LDL goes **up** 4% to 8%. Also, the FDA has issued a warning regarding Fournier's gangrene, keto-acidosis, and fractures. There is also some concern about an association with bladder cancer that requires further post-market monitoring.

Question 10.10.8 Which of the following is NOT a side effect of GLP-1 receptor agonists (exenatide, liraglutide, albiglutide)?

- A) Weight gain
- B) Pancreatitis
- C) Hypoglycemia
- D) GI upset
- E) Thyroid tumor

Answer 10.10.8 The correct answer is "A." Actually, GLP-1 agonists may cause weight loss of 1.5 to 2.5 kg over 30 weeks. These drugs are associated with pancreatitis although rarely, and the association is tenuous. Due to an association with thyroid cancer, their use is contraindicated in patients with a personal or family history of medullary thyroid carcinoma or MEN 2A or 2B. The risk of hypoglycemia is small—but not zero—with GLP-1 agonists. Somewhere between 10% and 50% of patients may develop GI symptoms.

Question 10.10.9 Metformin should NOT be used in which class of patients?

- A) Patients with COPD
- B) Patients with a GFR < 30 mL/min
- C) Patients with leukemias or lymphomas
- D) Postmyocardial infarction patients with normal systolic function
- E) Patients with insufficient fat stores

Answer 10.10.9 The correct answer is "B." Patients with renal disease are at a higher risk of lactic acidosis, the most severe complication of metformin therapy, although it is exceedingly rare (3 cases per 100,000 vs. 2 cases per 100,000 with other hypoglycemic agents). Current manufacturer recommendations state that metformin should be avoided if the serum creatinine ≥ 1.5 mg/dL in males and ≥ 1.4 mg/dL in females. However, metformin is safe to start as long as the GFR is > 45 mL/min and can be used until the GFR is 30 mL/min (max dose 1,000 mg/day for those with a GFR between 30 and 60 mL/min, per FDA Package Labeling 2016). Outcomes in patients with mild CHF and renal failure (GFR > 30 mL/min) are **actually better** with metformin than without (*Ann Intern Med.* 2017;166(3):191–200). Patients with pulmonary or neoplastic diseases may take metformin unless they also have severe hepatic or renal failure. **Metformin should be held for 48 hours after contrast studies.** Please refer to the general

recommendations regarding anti-hyperglycemic therapy in type 2 diabetes by the ADA (Figure 10-1).

HELPFUL TIP:

Metformin is associated with vitamin B12 deficiency, and periodic testing of vitamin B12 should be considered in metformin-treated patients, especially in those with anemia or peripheral neuropathy.

Question 10.10.10 Which one of the following is NOT a risk factor or prognostic marker for lower-extremity amputation in patients with diabetes?

- A) Diabetic retinopathy
- B) Bony deformity of the feet or ankles
- C) C-reactive protein (CRP) level
- D) Abnormal monofilament testing for sensory function
- E) Severe nail pathology

Answer 10.10.10 The correct answer is "C." The risk of ulcers or amputations is increased in patients who have had diabetes for 10 years or more, are male, have a history of poor glucose control, have evidence of microvascular complications of diabetes (e.g., retinopathy), or are on Invokana. Bony deformities, loss of protective sensation, and severely dystrophic toenails are also risk factors for amputation. The Semmes-Weinstein 10-gram monofilament sensory examination is the most sensitive neurologic test for predicting the future occurrence of a diabetic foot ulcer. An elevated CRP in and of itself is not a known risk factor for amputation, but CRP may be elevated if there is lower extremity infection present.

At the next visit, you review the patient's medical record and try to assure that he is up to date on his preventive health care.

Question 10.10.11 Which of the following is NOT true regarding preventive services in diabetics?

- A) Patients diagnosed with type 2 diabetes should have a dilated eye examination at the time of diagnosis
- B) Patients with type 1 diabetes should have a dilated eye examination at the time of diagnosis if they are over age 12
- C) Check TSH annually in type 1 diabetes, in patients with dyslipidemia, or diabetic women over age 50 years
- D) A urine microalbumin should be checked at least yearly in all type 2 diabetics
- E) A foot examination using a 10-g nylon microfilament should be done annually for all diabetics

Answer 10.10.11 The correct answer is "B." Patients with diabetes type 1 should have an eye examination **3 to 5 years** after the diagnosis and then yearly. Age at the time of diagnosis is not a factor in determining when an eye examination should be done. See Table 10-2 for components of recommended diabetes follow-up.

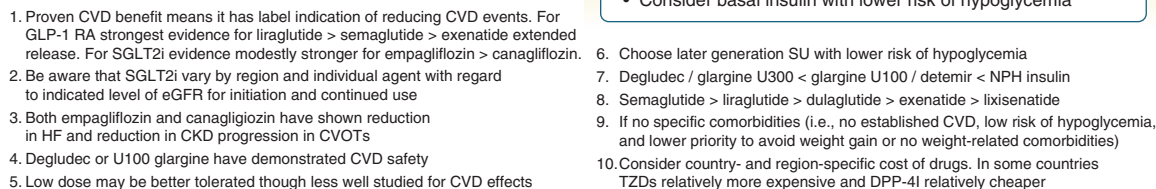

FIGURE 10-1. Recommendations for medical treatment of diabetes mellitus type 2.
From American Diabetes Association. Standards of Medical Care in Diabetes 2019. *Diabetes Care*. 2019;42:S90-S102.

TABLE 10-2 SUMMARY OF SCREENING RECOMMENDATIONS**Diabetes mellitus type 1:**

- Urine microalbumin starting at age 12 and then every 6 to 12 months
- Dilated eye examination within 5 years of diagnosis and then annually
- HbA1c every 6 months for stable patients achieving glycemic goals, every 3 months for patients changing therapy or not meeting glycemic goals
- Blood pressure screening at every visit
- Foot examination and screening for polyneuropathy at diagnosis and annually
- If not performed/available within past year
- Fasting lipid profile, including total, LDL, and HDL cholesterol and triglycerides, as needed
- Serum creatinine and calculated glomerular filtration rate
- TSH in type 1 diabetes, dyslipidemia, or women over age 50 years

Diabetes mellitus type 2:

Same as DM1 above, except:

- Eye examination at time of diagnosis and then yearly
- Urine microalbumin at the time of diagnosis and then every 6–12 months

American Diabetes Association. Comprehensive medical evaluation and assessment of comorbidities. *Diabetes Care*. 2019;42(S1):S34–S45.

Question 10.10.12 Speaking of prevention, your patient, now 48 years old with his diabetes controlled, asks if he should be taking an aspirin daily to protect his heart. You respond:

- A) “Take aspirin 325 mg daily because it will lower your risk of myocardial infarction”
- B) “Diabetes does not automatically qualify you for aspirin therapy. Let’s check your atherosclerotic cardiovascular disease (ASCVD) score”
- C) “The risks and benefits of aspirin in your case are unknown”
- D) “Take it by the truckload. I’ve got a lot of stock in Bayer”

Answer 10.10.12 The correct answer is “B.” The ADA recommends considering aspirin therapy (75–162 mg/day) as a primary prevention strategy in those with type 1 or type 2 diabetes at increased cardiovascular risk (10-year risk $\geq 10\%$). Who would be in this category of risk? Diabetic men AND women aged ≥ 50 years who have at least one additional major risk factor (family history of cardiovascular disease, hypertension, smoking, dyslipidemia, or microalbuminuria). ADA recommends AGAINST aspirin use for CVD prevention for adults with diabetes at low ASCVD risk, since the potential adverse effects from bleeding likely offset the potential benefits. If you decide to prescribe aspirin for primary CVD prevention in a diabetic, use 81 mg daily.

**HELPFUL TIP:**

As diabetes itself confers increased risk of ASCVD, a moderate to high intensity statin is recommended as primary prevention for those patients 40 years or older.

Moderate intensity is recommended for patients without known ASCVD and high intensity for those patients with known ASCVD. See Chapter 2 (Cardiology) for more information.

Unfortunately, this patient follows the “rule” of type 2 diabetes and ends up on multiple medications. When he returns to your clinic a few months later, he is complaining of shortness of breath and lower extremity edema. You decide to follow the “rule” of blaming drugs first ...

Question 10.10.13 Which of the following drugs (by itself—not in combination with other drugs) is the most likely cause of this patient’s edema, shortness of breath, and possible heart failure?

- A) Metformin
- B) Glyburide
- C) Pioglitazone
- D) Lisinopril
- E) Insulin

Answer 10.10.13 The correct answer is “C.” The thiazolidinediones (“glitazones”) tend to cause fluid retention as one of their major side effects. Thus, they are contraindicated in patients with a history of heart failure. Some drug combinations can cause edema, including the combination of glimepiride and metformin.

Because of the problem with edema, you decide to change this patient to a sulfonylurea, and you choose to start glyburide. The patient does well on this for several weeks but is then found unconscious in his home with a blood sugar of 20 mg/dL. Strike two, doc! He is rapidly revived by the paramedics with an amp of D50. You are called to see the patient in the ED. He is currently awake, conversant, and eating (“a great excuse for a couple of cookies!”). He would like to go home since he is back to his baseline.

Question 10.10.14 Which of the following is the best next step in the management of this patient’s hypoglycemic episode?

- A) Discharge the patient from the ED and have him continue his regimen, including glyburide
- B) Discharge the patient from the ED and have him stop his glyburide and start insulin
- C) Admit the patient and start him on IV dextrose 5% infusion
- D) Admit the patient and observe him for 24 hours
- E) Give him a gift card to local casino buffet, and tell him, “Pretend it’s your birthday!”

Answer 10.10.14 The correct answer is “D.” Patients on an oral hypoglycemic agent—especially longer-acting agents like glyburide—should be admitted for observation. It would be reasonable to let him eat, check his glucose periodically, and hold his diabetic medications. He is currently stable and does not

appear to need IV dextrose (“C”), but the patient should have IV access, and a half- or full-ampule of D50 can be given if necessary. The absorption of oral hypoglycemic agents is somewhat erratic, and their effect can be prolonged. The patient may have an additional episode of hypoglycemia for up to 36 to 48 hours after the initial episode. This is not true of patients on insulins (NPH or short-acting insulin [e.g., regular, lispro]), who may be discharged from the ED after a few hours. But for this patient, discharge from the ED (“A,” “B,” and “E”) would be unwise.

**HELPFUL TIP:**

Fifteen to 20 g of fast-acting carbohydrates such as glucose tablets, honey, corn syrup, nonfat or 1% milk, jellybeans, gumdrops, gel tube, raisins, hard candy, regular soda, and sweetened fruit juice can be used to treat symptomatic hypoglycemia. For severe hypoglycemia, glucagon injection may be needed. Glucagon, 1 mg IM or IV, is another option.

**HELPFUL TIP:**

The following medications generally do not cause hypoglycemia: metformin, acarbose, dipeptidyl peptidase (DPP-4) inhibitors, and glucagon-like peptide-1 (GLP-1) receptor agonists. Hypoglycemia is rare with the SGLT2 inhibitors.

It turns out that one of your partners has started this patient on a beta-blocker for its cardioprotective and antihypertensive effects while you were on vacation. The patient wants to know if this may have prevented him from noticing the signs and symptoms of hypoglycemia.

Question 10.10.15 Your response is:

- A) “Beta-blockers reduce your ability to recognize hypoglycemia and the drug should be stopped”
- B) “Beta-blockers reduce your ability to recognize hypoglycemia but the benefits are worth it”
- C) “Beta-blockers do not decrease your ability to recognize hypoglycemia to any great degree. Don’t worry about it”
- D) “ACE inhibitors are better drugs because they do not contribute to hypoglycemia in diabetics”

Answer 10.10.15 The correct answer is “C.” Beta-blockers do not significantly interfere with patient ability to recognize hypoglycemia, but they have been associated with hypoglycemia (mechanism is purported to be impairment in gluconeogenesis). The main thing that contributes to unawareness of hypoglycemia in diabetics is the rate of glucose drop (a slow drop is less likely to be noticed) and autonomic insufficiency (patients cannot respond with tachycardia, sweating, etc., to the outpouring of adrenergics). “D” is incorrect. ACE inhibitors, like beta-blockers, have been associated with hypoglycemia in diabetics. Other nondiabetic drugs that have been associated with hypoglycemia include quinolones, salicylates, and pentamidine.

**HELPFUL TIP:**

The ADA recommends the target A1c in nonpregnant adults with diabetes be <7%. However, it also advises more or less stringent glycemic goals may be appropriate for individual patients and goals should be individualized on the basis of duration of diabetes, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness, and individual patient considerations. For patients with multiple comorbidities and higher risks for hypoglycemia and other drug adverse effects, a higher A1c, even up to 8.5%, may be acceptable (but try telling that to the insurance companies). **It is recommended to perform A1c twice yearly in those patients who are meeting treatment goals, and quarterly in patients with poor glycemic control.**

You admit the patient and advise him to carry a source of glucose with him at all times and everybody has a happy outcome until ...

The patient has developed persistent hyperglycemia despite being on maximal doses of metformin and glyburide. He is willing to begin insulin therapy but wants to give himself as few injections as possible.

Question 10.10.16 Which of the following regimens would be best for him?

- A) A single injection of insulin glargine (Lantus™) or NPH insulin at bedtime
- B) A single injection of 70/30 NPH/regular insulin at bedtime
- C) A baseline bedtime injection of insulin glargine and up to three injections of short-acting insulin with meals
- D) Regular insulin with meals to control postprandial blood sugars.

Answer 10.10.16 The correct answer is “A.” Because of its slow release, insulin glargine provides a steady-state insulin level throughout 24 hours; insulin detemir and NPH are alternatives. In fact, NPH likely causes *less* hypoglycemia than do insulin glargine and insulin detemir, and the outcomes are the same (and glargine and detemir cost 10× as much as NPH; see JAMA 2018;320:53). Regular insulin (as found in 70/30) is generally not the place to start with type 2 diabetics (“B”). Multiple daily insulin injections may be necessary for type 1 diabetics, but this is not true for type 2 patients. For type 2 diabetes, long-acting insulin is usually started first and bolus mealtime insulin added later, so “C” would not be the first choice. As noted above, regular insulin (“D”) isn’t the place to start in DM2. If you are trying to start with the simplest possible regimen, choose something like “A.”

**HELPFUL TIP:**

Sulfonylureas and insulin work in the same manner: they both increase circulating insulin levels. For this reason, some choose not to use these two drugs together and will taper the sulfonylurea after the patient is on a stable dose of insulin.

Your patient is hospitalized for acute diverticulitis and requires urgent partial colectomy.

Question 10.10.17 Which of the following statements regarding the management of diabetes in hospitalized patients is TRUE?

- A) Hyperglycemia in the hospital has minimal, if any, effect on outcomes of myocardial infarction.
- B) A standardized sliding-scale insulin regimen is adequate to control hyperglycemia in all hospitalized diabetic patients.
- C) Insulin requirements will be lower for acutely ill, hospitalized diabetic patients.
- D) Metformin should be discontinued in seriously ill, hospitalized patients.

Answer 10.10.17 The correct answer is “D.” In general, one should consider discontinuation of metformin in severely ill, hospitalized patients due to the possible need for contrast studies, changes in fluid balance, changes in glomerular filtration rate, uncertainty about oral intake (e.g., NPO status), etc. “A” is incorrect. Hyperglycemia is associated with worse outcomes in hospitalized patients with cardiac disease and those who are in an intensive care unit for most reasons. But this may be because elevated blood sugars suggest they are under greater metabolic stress and sicker to begin with. “B” is also incorrect. Sliding-scale regimens, if used at all, should be individualized to each patient, rather than prescribed as a standardized regimen. It has become clear that a sliding scale is not the best way to control blood sugars in hospitalized patients. Continuing some type of basal insulin (or basal-bolus) regimen is best, using correctional insulin as needed. In hospitalized patients, it is generally recommended to discontinue oral antidiabetic agents and control the glucose using insulin only, provided in a combination form including basal long-acting insulin plus pre-meal short-acting insulin if on diet and correctional insulin (aka basal/bolus insulin). The stress of acute illness and surgery will likely increase insulin requirements in most diabetics, not decrease them.

HELPFUL TIP:

Chasing the glucose in an attempt to maintain tight control in the hospital is counterproductive and does not improve outcomes! *Even though patients with hyperglycemia may do worse, it is clear that the elevated glucose is a marker for metabolic stress which is why outcomes might be worse ... they are sicker to begin with.* Thus, for sicker patients, aim for a blood sugar of between 120 and 180 mg/dL. This has been found to be superior to more intensive glycemic control. Some studies suggest a goal of as high as 250 mg/dL (*Crit Care Med* 2018;46:935). For now, 180 mg/dL seems reasonable.

He does well and is ready for discharge. He asks about self-monitoring of blood glucose.

Question 10.10.18 How often should a type 2 diabetic on oral hypoglycemic agents measure his or her blood glucose?

- A) Once or twice a week, at varying times during the day
- B) Four times daily—before meals and at bedtime
- C) Twice daily—fasting and 2 hours after a meal
- D) Once or twice daily—fasting and before a meal
- E) Routine blood sugars are not indicated on a daily basis for type 2 diabetics

Answer 10.10.18 The correct answer is “E.” Daily measurements of finger stick sugars in patients on oral hypoglycemic agents do nothing to improve glycemic control (*BMJ*. 2012;344:e486). In these patients, we are not reacting to daily fluctuations in glucose control but rather making changes in response to long-term trends, and typically HbA1c is used. Occasional random sugars are not unreasonable to get a general idea about glycemic control. Type 2 diabetics on insulin (and all type 1 diabetics) should measure their blood glucose at least daily, and ideally two or three times per day, regardless of the presence or absence of symptoms.

The patient has come back to your clinic several times for follow-up, and his current medications are adjusted to their maximum doses. The patient is not interested in injectable medication—he changed his tune from earlier after reading online how he might get addicted to insulin. You discuss adding a third oral agent (to his metformin and glyburide), and muster an expression that you hope conveys enthusiasm. However, the patient’s diabetes is not optimally controlled, and he develops diabetic neuropathy years later.

Question 10.10.19 Which of the following agents is LEAST effective in treatment of diabetic neuropathic pain?

- A) Tricyclic antidepressants
- B) SSRIs
- C) Duloxetine (Cymbalta)
- D) Pregabalin (Lyrica) or gabapentin
- E) Venlafaxine (Effexor XR)

Answer 10.10.19 The correct answer is “B.” SSRIs are generally ineffective in treating neuropathic pain. Several drugs have been approved specifically for relief of diabetic peripheral neuropathic pain in the United States (pregabalin, duloxetine, and tapentadol), but none affords complete relief, even when used in combination. **Low-dose tricyclic antidepressants are the most effective of this group (e.g., nortriptyline or amitriptyline 25 mg qhs), but also have anticholinergic side effects** (*Lancet Neurol*. 2015 Feb; 14:162). Pregabalin, gabapentin, amitriptyline (except in older adults), or duloxetine should be used as first-line treatment for painful diabetic neuropathy. Venlafaxine and opioid-like medications (tramadol, tapentadol) may be considered second- or third-line. Remember that gabapentin is ONLY FDA approved for post-herpetic neuralgia. It is overused and causes weight gain, mental slowing, sleepiness, and is abusable.

**HELPFUL TIP:**

Well, LA-DI-DA (well, LADA, anyway). LADA stands for latent autoimmune diabetes in adults. This is a patient who clinically starts out with DM2 but also has circulating anti-islet cell and/or anti-GAD antibodies. At some point in their disease, these adult patients lose enough pancreas to convert to a type 1 diabetic. These are patients who initially respond to noninsulin hypoglycemic agents (metformin, sulfonylureas, etc.), but eventually no longer respond to these drugs and become insulin dependent. They may represent up to 10% of the DM 2 population.

► **Objectives: Did you learn to ...**

- Recognize diagnostic criteria for diabetes?
- Differentiate diabetes type 1 from type 2?
- Evaluate a patient with new-onset type 2 diabetes?
- Identify risk factors for complications of diabetes?
- Initiate and manage oral therapy in type 2 diabetes?
- Start a type 2 diabetic patient on insulin?
- Manage diabetes in the hospital setting?
- Treat painful diabetic peripheral neuropathy?

► **CASE 10.11**

A 32-year-old female presents to your office complaining of “hypoglycemia.” She notices that about 2 to 3 hours after a meal she gets nauseated, shaky, and irritable. When she wakes up in the morning, she generally feels well even though she eats dinner at about 5:00 PM and does not eat any snacks afterward and generally does not have breakfast until 8:00 AM.

Question 10.11.1 You can tell her that:

- A) She likely has an insulinoma
- B) She likely will have normal blood sugars when she feels shaky
- C) Hypoglycemia does not exist as an entity in this form and she likely has anxiety
- D) She likely has “fasting” hypoglycemia
- E) Hypoglycemia is an uncommon problem in nondiabetics but it could explain her symptoms

Answer 10.11.1 The correct answer is “E.” “A” is incorrect because a patient with an insulinoma should be hypoglycemic after a 15-hour fast (when she’s not eating between 5:00 PM and 8:00 AM). “B” is incorrect. This patient may have postprandial hypoglycemia that occurs 2 to 4 hours after eating. The process leading to postprandial hypoglycemia is as follows: the patient has a large meal with simple carbohydrates, the serum insulin level increases in response but overshoots, and the patient becomes transiently hypoglycemic for 15 to 20 minutes usually 2 to 4 hours after eating. This is associated with adrenergic outpouring in an attempt to correct the problem. It is the adrenergic outpouring

that causes the symptoms of tremor, nausea, etc. “C” is incorrect because hypoglycemia does exist. “D” is incorrect. The patient does not have symptoms of fasting hypoglycemia, which occur 4 to 6 hours (or longer) after the last meal.

Question 10.11.2 All of the following are associated with postprandial hypoglycemia EXCEPT:

- A) Diuretics
- B) Alcohol intake
- C) Postgastrectomy syndrome
- D) Beta-blockers

Answer 10.11.2 The correct answer is “A.” Diuretics tend to **increase** the blood sugar a bit. Aspirin, indomethacin, ACE inhibitors, pentamidine, and renal failure may be associated with postprandial **hypoglycemia**. Other medications that are associated with **hyperglycemia** include quinolones, atypical antipsychotics, corticosteroids, calcineurin inhibitors, protease inhibitors, and some lipid-lowering agents like niacin and atorvastatin. It is worth noting that carvedilol and nebivolol are not associated with the development of **hyperglycemia**, and that quinolones (especially gatifloxacin) are associated with both hyper- and hypoglycemia. It turns out that the kidneys are responsible for about 50% of gluconeogenesis. If the kidneys aren’t working, the ability to respond to hypoglycemia is blunted.

**HELPFUL TIP:**

Hypoglycemia should be suspected in any patient with diabetes who has focal neurologic signs (such as might be seen in a stroke).

Question 10.11.3 You advise this patient to do all of the following EXCEPT:

- A) Increase the amount of simple carbohydrates with her meals
- B) Increase the amount of complex carbohydrates with her meals
- C) Increase the amount of protein with her meals
- D) Increase the amount of fat with her meals
- E) Eat smaller, more frequent meals

Answer 10.11.3 The correct answer (and what you would not want to do) is “A.” Her problem is caused at least in part by a high intake of simple carbohydrates, leading to a rapid and high peak in her blood sugar followed by an excessive release of insulin. Thus, one would want to decrease the amount of simple carbohydrates in the diet and add protein, fat, and complex carbohydrates. There is little data suggesting that any of these is particularly effective, however. Delaying gastric emptying (using an agent like propantheline, an anticholinergic/antispasmodic) does **not** seem to make a difference (but might make the patient sleepy enough that she doesn’t notice the symptoms!). Reducing the spike in carbohydrate absorption using alpha-glucosidase inhibitors (e.g., acarbose) makes sense but also does not have any good supporting data for this indication.

**INTERESTING (BUT MAYBE NOT SO HELPFUL) TIP:**

Gin and tonic and ackee fruit (from Caribbean islands) are known causes of hypoglycemia. In “gin and tonic hypoglycemia” (the actual name of the syndrome), alcohol prevents effective counter-regulatory measures to the hypoglycemia produced by the quinine. Ackee fruit, common in the Jamaican diet, contains “hypoglycin” that prevents gluconeogenesis. And, no, you cannot use gin and tonic to control your diabetes!

**HELPFUL TIP:**

For insulinoma, watch the patient during a **controlled** fast during which the patient is observed and can be treated for hypoglycemia if necessary. If you are considering self-induced hypoglycemia with insulin (e.g., factitious hypoglycemia), measure the c-peptide. This will be **low** if the patient is being administered exogenous insulin because pancreatic insulin production will be shut off in response to hypoglycemia (remember, however, that it will also be low in type 1 diabetes).

► Objectives: Did you learn to ...

- Evaluate a patient with possible hypoglycemia?
- Treat a patient with postprandial hypoglycemia?
- Identify causes of hypoglycemia?

**QUICK QUIZ: CARBOHYDRATES AND CALORIES****Which of the following statements is FALSE?**

- A) The use of the glycemic index (GI) and load may help diabetic patients improve their carbohydrate-containing food selection
- B) Diabetics should avoid sucrose-containing foods because they worsen glycemic control more than a comparable amount of starch
- C) For weight loss, either low-carbohydrate or low-fat calorie-restricted diets may be effective in the short term (up to 1 year)
- D) Moderate alcohol intake may reduce the risk of developing diabetes
- E) Carbohydrates have fewer calories per gram than alcohol

The correct (and false) answer is “B.” Several studies demonstrate that dietary sucrose does not increase glycemia more than isocaloric amounts of starch. For example, the glycemic index (GI) of sucrose is 84 while that of a banana is 88 (higher GI being worse). GI represents how much the serum glucose will increase after the ingestion of 50 g of the carbohydrate in the food when compared to a standard (often oral glucose). It typically ranges between 50 and 100, where 100 represents the standard blood sugar response to an equivalent amount of pure glucose. GI < 55 is considered low, 56 to 69 medium, and 70 or over high.

A related measure, the glycemic load (GL), uses white bread as the standard of comparison. It takes into account not only the carbohydrates in a food but also the fiber and other nutrients and *how much* carbohydrate is in the food. For example, the carbohydrate in whole grains may be absorbed more slowly so the glucose will not rise as much for a given amount of carbohydrate in the food (when compared to white bread).

Both GI and GL are helpful in medical nutritional therapy for diabetes. For “C,” although low-fat diets have traditionally been promoted for weight loss, studies found that subjects on low-carbohydrate diets lost more weight. Nonetheless, either low-carbohydrate or low-fat calorie-restricted diets are effective for weight loss. Regarding “D,” observational studies report that moderate alcohol intake may reduce the risk for diabetes, but the data do not support recommending alcohol consumption to individuals at risk of diabetes. Did you know that 1 g of alcohol has 7 calories while 1 g of carbohydrates has only 4? Now you do!

► CASE 10.12

A 24-year-old female presents to the office complaining of amenorrhea. Six months ago, her menses became irregular and light. For the last 4 months, she has not had a period at all. This is causing her great distress, as she constantly worries about being pregnant. She does desire to have children “some day,” but not now. She has run multiple home pregnancy tests, all of which have been negative. Last week, she developed clear leakage from her nipples, and the patient is now convinced she is pregnant and that the home pregnancy tests must be faulty. She requests that you perform “a real pregnancy test.”

Question 10.12.1 Which of the following may cause her amenorrhea?

- A) Emotional stress
- B) Pregnancy, despite multiple negative tests
- C) Thyroid dysfunction
- D) Pituitary tumor
- E) All of the above

Answer 10.12.1 The correct answer is “E.” The differential diagnosis for amenorrhea is rather broad but includes all of the above diagnoses and more. The most common cause in a woman of childbearing age is, of course, pregnancy. Although urine-based pregnancy tests have become very sensitive (able to detect as little as 20 IU/mL of β -hCG), the patient may have been using the tests incorrectly and thus was getting false-negative results. Other causes of amenorrhea include hypothyroidism, strenuous exercise or anorexia, emotional stress, pituitary tumor, certain medications (e.g., phenothiazines, dopaminergic agents, chemotherapy, and estrogens), and ovarian failure or agenesis. See Chapter 15 for a more thorough discussion of amenorrhea.

Further history from the patient reveals menarche at age 12, no pregnancies, and no previous history of menstrual irregularities. She participates in low-impact exercise regularly and

does not engage in long-distance running or other demanding endurance sports. Review of systems reveals frequent mild headaches, but no visual disturbances or symptoms of hypothyroidism.

Physical examination demonstrates a well-developed, well-nourished (neither obese nor excessively thin) adult female. She has appropriate secondary sex characteristics, no hirsutism, and a normal thyroid gland to palpation. Galactorrhea is noted on breast examination. The pelvic examination is normal, with appropriately developed external genitalia, vagina, and cervix. The uterus is palpable and small, and the ovaries are neither palpable nor tender.

Question 10.12.2 In addition to a serum β -hCG and a TSH, what other test(s) should be ordered?

- A) Karyotype, to evaluate for testicular feminization (now called “complete androgen insensitivity syndrome”) and Turner syndrome
- B) Adrenal MRI, to evaluate for adrenal hyperplasia
- C) Prolactin level
- D) All of the above
- E) None of the above

Answer 10.12.2 The correct answer is “C.” A prolactin level is an essential component of this evaluation. A prolactinoma is the most common form of pituitary adenoma, and it can cause secondary amenorrhea, galactorrhea (as in this patient), and infertility (or erectile dysfunction and hypogonadism in men). Expansion of the mass in the sella turcica may cause headaches or visual field defects (bitemporal hemianopsia), but the tumors are more often too small to have any local effects. Adrenal hyperplasia is unlikely in the patient because of a lack of virilizing characteristics from androgen excess (such as hirsutism). Also, adrenal imaging is not usually the first step in the diagnosis of this disorder (24-hour urine collection for cortisol and 17-OHS is indicated if adrenal hyperplasia is suspected). A karyotype is not indicated in this patient because she has secondary amenorrhea, or amenorrhea that has developed after a period of time of normal menses. Patients who complain of never having a menstrual cycle are considered to have primary amenorrhea, which may be evidence of either Turner syndrome (XO genotype) or complete androgen insensitivity (aka testicular feminization, which has an XY genotype with end-organ resistance to testosterone, resulting in a female phenotype). Both cases result in ovarian agenesis and, therefore, no menstrual cycles.

You obtain laboratory tests, and the results are as follows: TSH 3.1 IU/mL (0.27–4.20), β -hCG undetectable, prolactin 150 ng/mL (3.4–24.1).

Question 10.12.3 What is the best next step in this patient’s evaluation?

- A) Reassure patient that stress is causing her amenorrhea and she will improve when she learns to deal with her life
- B) No additional tests at this time but return in 2 weeks for a repeat prolactin level

- C) Admit the patient to the hospital and start bromocriptine therapy STAT
- D) MRI brain to evaluate for pituitary mass
- E) Refer patient for neurosurgical intervention

Answer 10.12.3 The correct answer is “D.” This patient has a high prolactin level and symptoms of prolactin excess. In the absence of medications causing an elevated prolactin (phenothiazines, narcotics, estrogens, etc.) and a normal TSH, this prolactin result is virtually diagnostic for a prolactinoma. Imaging is indicated regardless of visual symptoms. A visual field examination by confrontation is insensitive for a minor visual field loss. If she had a mild elevation in prolactin (up to two times the upper limit of normal), and no other symptoms/signs, then repeating the level over several visits may be appropriate. If the level remains elevated, imaging and medical therapy should then be considered. Neurosurgical intervention is not immediately indicated, since a trial of medical therapy is usually the first step in treatment.

This patient undergoes a brain MRI, which shows a 1.3-cm pituitary mass.

Question 10.12.4 How should this finding be interpreted and managed?

- A) This is a microadenoma, and the result can be ignored
- B) This is a microadenoma, and medical therapy with a dopamine agonist is indicated
- C) This is a macroadenoma, so medical therapy is futile, and the patient should be referred for surgery
- D) This is a macroadenoma, but medical therapy with a dopamine agonist should still be attempted
- E) This is a macroadenoma, which tends to be self-limited, so therapy can be held for 6 months when a repeat scan will be done

Answer 10.12.4 The correct answer is “D.” A pituitary tumor <1 cm in size is considered a microadenoma, and tumors 1 cm or greater in size are considered macroadenomas. The treatment implications are slightly different. In both cases, medical therapy with a dopamine agonist (e.g., bromocriptine, cabergoline) is indicated. Successful shrinkage of even macroadenomas is possible with this therapy. Remember that the secretion of prolactin is under a negative feedback loop. As CNS dopamine levels go up, prolactin levels go down. When dopamine levels go down, prolactin levels go up.

HELPFUL TIP:

Many psychoactive medications inhibit dopamine and can result in hyperprolactinemia. Resist the knee-jerk reaction of stopping a psychoactive medication in a patient found to have hyperprolactinemia. High prolactin levels do not kill patients, but untreated mental illness does. Risks, benefits, and likelihood that the drug is to blame must all be considered.

The patient is started on bromocriptine and is scheduled for follow-up in 3 weeks. She returns earlier than scheduled due to severe nausea and lightheadedness. No other new symptoms have occurred. The patient's vital signs are normal, but the systolic blood pressure decreases by 20 mm Hg and the pulse increases by 20 beats/minute upon standing.

Question 10.12.5 Aside from a bolus of IV fluids, how should you address this problem?

- A) This is a common side effect from bromocriptine. Decrease or stop the bromocriptine, and consider another type of dopamine agonist, such as cabergoline
- B) Admit her to the hospital and arrange for a STAT head CT scan to rule out bleeding from the pituitary adenoma
- C) Repeat the pregnancy test
- D) She is having an anaphylactic allergic reaction. Administer epinephrine and diphenhydramine immediately
- E) She has failed medical therapy and must be referred for neurosurgical intervention

Answer 10.12.5 The correct answer is "A." The most common side effects of dopamine agonists are nausea, postural hypotension, and difficulty concentrating. These symptoms tend to be lessened when lower doses are used, and the dose is increased very slowly. Cabergoline tends to be better tolerated than bromocriptine.

The patient is able to tolerate cabergoline and continues the medication for 6 months. During this time, the prolactin level decreases slowly. She has had resumption of her menses. A repeat MRI is done after 6 months and shows a marked decrease in size of the adenoma. The patient has reached that magical inflection point in life where she recognizes that her own mortality is inevitable, and she desires to get pregnant "as soon as possible." She wants to know if she should have surgery to remove the adenoma.

Question 10.12.6 What is/are the indication(s) for transsphenoidal pituitary surgery?

- A) Failure to respond to dopamine agonists
- B) Failure to tolerate dopamine agonists
- C) Treatment of giant adenoma (>3 cm) in a patient who desires pregnancy, despite efficacy of medical therapy
- D) A and B
- E) All of the above

Answer 10.12.6 The correct answer is "E." Surgery should be reserved for those patients who fail to respond to or cannot tolerate medical therapy. Note that visual field defects are not a specific indication for surgery, since medical therapy can be effective in decreasing the size and related local effects of the tumor. If a patient desires pregnancy and has a large mass (>3 cm), surgery may be considered as an adjunct to medical therapy. During pregnancy, there is a physiological increase in the size of the prolactinoma. If such a patient becomes pregnant

(without a prior reduction in tumor size) and discontinues the dopamine agonist for the duration of pregnancy, the adenoma may increase to a clinically important size before delivery.

HELPFUL TIP:

Bromocriptine and cabergoline are classified as category B for pregnancy risk (in other words, they are generally considered safe). These medications can be continued during pregnancy, but a careful risk-benefit analysis and discussion between patient and physician must occur before making treatment decisions.

The patient wants to know how long she should be on cabergoline or bromocriptine and when a trial off of the medication is indicated.

Question 10.12.7 You tell her which of the following?

- A) Patients with a pituitary adenoma have to be on medication "forever" to suppress the tumor
- B) A trial off of a dopamine agonist should be done at 6 months
- C) Prolactin levels can be allowed to rise after menopause without problem unless visual symptoms or other local symptoms develop. So, she should continue the medication until menopause
- D) None of the above

Answer 10.12.7 The correct answer is "C." Dopamine agonists can be stopped at menopause. Follow-up can be done using blood levels of prolactin. If prolactin levels rise, an MRI can be done to see if the adenoma is becoming larger. If not, there is no reason to treat the adenoma in postmenopausal patients. "A" is incorrect because "C" is correct—a simple test taking skill! If you see "forever" on a test it is probably wrong. (Also, never answer "never" and never answer "always.") "B" is incorrect. **If there is no adenoma noted on MRI at baseline**, and the prolactin is normal, a trial off of dopamine agonists can be tried at 1 year. Taper the drug and follow the prolactin. **In those with an adenoma on MRI at baseline**, a trial off of medications at 2 years is *reasonable*, provided the prolactin level has fallen to normal and there is no evidence of adenoma by MRI in the past 2 years. If prolactin levels remain under control, there is no need to continue medication.

► **Objectives: Did you learn to ...**

- Generate a list of potential causes of secondary amenorrhea?
- Evaluate a patient with secondary amenorrhea?
- Diagnose and treat hyperprolactinemia secondary to a pituitary prolactinoma?

► **CASE 10.13**

A 39-year-old female presents to the office complaining of amenorrhea. She has had normal menses until 8 months ago, when they became infrequent and then stopped. She insists she cannot be pregnant, because she has not been sexually active "in years." She believes she is going through

“the change” but wants to know why she is reaching menopause at a much earlier age than other women she knows. On review of systems, she complains of headaches “for years” and recent onset of weakness and fatigue. She also complains of arthritis in the hip and knees, something she attributes to “getting old.” She reports that her hands are swollen, and her rings do not fit any more. She denies other complaints.

On physical examination, vitals are normal. The patient is an adult female of average height, with a noticeably large jaw and hands. Her hair is thick and coarse, and hirsutism is present. Her thyroid gland is slightly enlarged, but regular in shape. No bruit or tenderness is present. The point of maximal impulse is displaced laterally, but the heart rhythm is regular and without murmur. The rest of the examination is normal.

Question 10.13.1 What is the most appropriate next step?

- A) Reassure the patient that menopause is a normal process and offer estrogen replacement therapy for symptomatic relief (but warn the patient about risks of long-term use)
- B) Tell the patient you suspect depression and offer a regimen of counseling combined with SSRI therapy
- C) Tell the patient she may suffer from growth hormone (GH) excess and recommend sending a serum insulin-like growth factor-I (IGF-I) level
- D) Tell the patient to quit being a hypochondriac and that her Internet search is not equivalent to your medical degree

Answer 10.13.1 The correct answer is “C.” This patient represents a classic presentation of acromegaly due to GH excess, and the best single test for this is the IGF-I level. Although GH levels will often be elevated, the IGF-I does not vary from hour to hour and is not dependent on food intake, as is the case with GH. An elevated GH after a glucose load is also very suggestive of GH excess. Acromegaly of adult onset (after fusion of the long bones) does NOT result in increased height, but does cause coarsening of facial features, prognathism, and thickening of the feet and hands. These changes can be very subtle, and there is generally a lag of **12 years** before diagnosis. Comparing older photographs of the patient to their current appearance may be a clue (a driver’s license photograph may be a convenient source ... although nobody looks good in their driver’s license photo). Patients with acromegaly also develop hypertrophy of certain organs (such as the thyroid and heart) and may present with heart failure due to cardiomyopathy. Eighty-five percent of females with acromegaly have at least some menstrual dysfunction and 60% are amenorrheic. Finally, arthropathy is common in acromegaly and may be the overriding symptom that prompts a patient to be evaluated.

HELPFUL TIP:

Premature ovarian failure is defined as menopause at age 40 or younger (two standard deviations below the mean).

The patient’s IGF-I is elevated, and her TSH is normal. An MRI is performed that reveals a pituitary mass slightly <1 cm in diameter.

Question 10.13.2 What is the most effective therapy for this condition?

- A) Weekly anti-IGF-I antibody infusions
- B) Bromocriptine therapy
- C) Transsphenoidal pituitary resection
- D) Somatostatin analogs (such as octreotide)
- E) Pegvisomant (GH receptor antagonist)

Answer 10.13.2 The correct answer is “C.” Acromegaly is caused by a GH-secreting pituitary tumor. Surgery is the treatment of choice for patients with a microadenoma (1 cm or less in diameter) or for patients with a macroadenoma that appears to be fully resectable. Somatostatin analogs and pegvisomant (Somavert®) may be useful adjuncts to surgery and are an option for patients who are not surgical candidates. Bromocriptine is not very effective, and only about 10% of acromegaly patients will achieve normal IGF-I levels with bromocriptine; however, cabergoline seems to work in about half of patients. Cabergoline has an advantage over somatostatin analogs, in that it can be taken orally. Radiation is also an option for therapy, especially for those patients who are not surgical candidates and do not tolerate or do not respond to medical therapy. “A,” anti-IGF-I antibody (if it existed as a medication), would not have an effect on a GH-secreting tumor. But it does not exist. It’s a made-up answer, so it’s wrong. By the way, there’s no made-up stuff on the real examination ... we think.

► **Objectives: Did you learn to ...**

- Recognize signs and symptoms of GH excess?
- Evaluate and manage a patient with GH excess?

QUICK QUIZ: GROWTH HORMONE

A 6-year-old boy is brought into the office by his concerned mother due to “growing too slowly.” She has noticed that he is significantly shorter than his classmates at school, and she wants something done about it. She heard a report on the nightly news about a medication that makes children grow taller and insists on getting it for her son. Both parents are deluded and expect their son to play in the NBA or NFL and believe he will not make it unless he “gets a lot taller really soon.” She informs you in no uncertain terms that if you don’t prescribe this “growing pill,” she will just find someone that will.

You believe this mother is in need of some education about GH deficiency.

What are the *approved* indications in children and adolescents for GH replacement therapy?

- A) Growth hormone deficiency
- B) Growth failure due to chronic renal insufficiency, intrauterine growth retardation with lack of “catch-up” growth by age 2, Turner syndrome, and Prader–Willi syndrome

- C) An adolescent male who wishes to play college or pro basketball but is only 5 feet 9 inches on a good day
- D) A and B
- E) All of the above

The correct answer is “D.” GH replacement is specifically approved for GH deficiency and growth failure due to chronic renal insufficiency, intrauterine growth retardation and no “catch-up” growth by age 2, Turner syndrome, and Prader-Willi syndrome. It has been approved for use in “idiopathic short stature” (more than two standard deviations below the mean height for age). Not all patients with GH deficiency require GH replacement, because not all will suffer the negative end-organ effects, such as marked short stature, growth failure, hypoglycemia in infancy, and central distribution of body fat.

HELPFUL TIP:

As with acromegaly, IGF-I should be checked when considering short stature secondary to pituitary failure. It is also important to check IGF-binding protein-3 levels. Low levels of IGF-binding protein-3 may cause problems with binding of IGF to the proper receptors.

HELPFUL TIP:

Even when used appropriately, GH only leads to a couple of inches increase in adult height. Poof ... there go the NBA dreams.

Clinical Pearls

- Do not order a thyroid ultrasound to routinely evaluate abnormal thyroid function tests.
- Do not prescribe/recommend multiple daily blood glucose monitoring in patients on oral hypoglycemic regimens.
- Do not use bicarbonate to help correct the acidosis of DKA. The main intent is to provide IV fluid hydration and insulin to help bring down the sugars and correct the acidosis.
- Do not use diuretics to treat acute hypercalcemia. The important point is to aggressively hydrate the patient.
- Do not use T3 for hypothyroidism as its rapid gastrointestinal absorption and relatively short half-life lead to erratic T3 serum levels.
- Initiate thyroid replacement at a low dose (e.g., 25 mcg levothyroxine) in the elderly (>65 years old) or those with cardiac disease, and slowly titrate upward every 4 to 8 weeks.
- Rely primarily on the TSH to screen for thyroid disease in symptomatic individuals and as part of monitoring thyroid function in thyroid disease.
- Screen all obese adults from ages 40 to 70 for diabetes.

- Start steroids immediately if you suspect an adrenal insufficiency (Addisonian) crisis.
- Start with an ACE inhibitor (or an ARB if ACEI is contraindicated or has side effects) in the treatment of proteinuria and hypertension in patients with diabetes.

Rheumatology

11

Priyanka Iyer, Sanjeev Patil, and Bharat Kumar

A few words on “rheumatology panels.” Doing a “rheumatology panel” will never be the right answer. *The diagnosis of rheumatologic disease is clinical with specific clinical criteria for each illness.* While antinuclear antibody (ANA), rheumatoid factor (RF), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and other tests may be useful in supporting a clinical diagnosis and assessing disease activity, these tests have **poor specificity** and may be positive in a variety of disease states. A positive ANA without a clinical diagnosis is meaningless. Likewise, RF helps to gauge prognosis (seropositive vs. seronegative) in rheumatoid arthritis (RA) but has limited value as a diagnostic test. RF may also be positive in sarcoidosis, viral infections (especially hepatitis C), and autoimmune diseases such as granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), as well as a variety of primary lung and liver diseases. ESR and CRP may support the clinical impression of inflammatory disease but are again nonspecific.

► CASE 11.1

A 43-year-old female presents with body aches and stiffness, which are worse in the morning. She further describes a low-grade fever and pain in her hands, feet, and left knee. She feels that her grip strength is diminished. These symptoms started rather abruptly 2 weeks ago and have not responded to acetaminophen.

She frequently camps with her family. She remembers that 1 week they could not go because her 8-year-old daughter had a fever, mild diarrhea, abdominal pain, and a skin rash (“legs, arms, and especially face were red and warm, and she seemed ‘flushed’ all the time”). Her daughter’s symptoms resolved in a few days, she did not see a doctor, and no one else was sick. She has no other illnesses, and review of systems is otherwise negative.

On physical examination, her vitals are normal. She is unable to close her hands completely. Although the physical examination is somewhat limited by pain, there appears to be swelling of all metacarpophalangeal (MCP) and

proximal interphalangeal (PIP) joints, as well as mild erythema over the MCP joints bilaterally. In addition, upon examination of the left knee, the bulge sign (indicating effusion) is detected.

Question 11.1.1 If found on physical examination, which of the following would be **LEAST** useful in helping you in narrowing your diagnosis?

- A) Bilateral metatarsophalangeal (MTP) joint swelling and tenderness
- B) Painless oral ulcerations, with clean edges
- C) Firm, slightly tender subcutaneous nodules at the olecranon bursae
- D) A “bull’s eye” rash in the right axilla
- E) Icterus and tender hepatomegaly

Answer 11.1.1 The correct answer is “A.” This patient presents with polyarticular inflammatory arthritis of unclear etiology. While important to note, MTP joint swelling would not add much to the picture of subacute, symmetrical, small joint polyarthritis that you have already found on examination. The differential diagnosis includes acute viral arthritis, specifically parvovirus B19 (due to the daughter’s history of acute illness resembling erythema infectiosum), coxsackievirus, hepatitis B (hinted at in “E”), and HIV. Also on the differential will be Lyme disease (“D,” although small joint symmetrical arthritis would be atypical), RA (“C,” the presence of rheumatoid nodules would be helpful although these would be unlikely in early disease), and other inflammatory disorders. “B,” *painless* ulcerations, are classically associated with SLE (systemic lupus erythematosus), but it ought to be noted that lupus aphthae (ulcers) may be painful as well.

After you sneak off to do a little reading, you examine her again. She has no rash. You detect bilateral pain and swelling of the third and fourth MTP joints. There are no oral ulcerations and no lymphadenopathy. She is not icteric, and her abdomen is diffusely, mildly tender. There is no hepatomegaly. You decide to order some blood tests.

Question 11.1.2 If positive, which of the following tests would be MOST helpful in ruling in a specific diagnosis?

- A) Positive ANA
- B) Elevated white count
- C) Positive parvovirus B19 IgM
- D) Positive urinalysis for white blood cells (WBCs)
- E) Elevated ESR and CRP

Answer 11.1.2 The correct answer is “C.” The presence of IgM antibodies to parvovirus B19—or rising titers of IgG antibodies—indicates acute viral infection, which may present with symptoms and signs seen in this patient. “A,” positive ANA, will not help you rule in a diagnosis at this point. While the ANA is a highly sensitive test, it is not specific and has a low positive predictive value in the absence of the appropriate clinical symptoms and signs (just hammering this home). “B,” “D,” and “E” are all important findings, but would not lead you toward a specific diagnosis. “D,” WBC in the urine could be from interstitial nephritis, a UTI, a nephritic urine from other causes, etc. Table 11-1 presents a framework for who should be tested for and diagnosed with RA.

HELPFUL TIP:

Note that the diagnosis of RA no longer requires 6 weeks of symptoms, although a longer duration of polyarthritis makes RA more likely. Similarly, it would be unusual for parvovirus B19 to cause symptoms for 6 weeks. However, the virus can cause prolonged joint pain in 10% of affected adults.

Her laboratory results return as follows:

- Hepatitis B: Surface antibody positive, surface antigen negative
- CMV: IgG positive, IgM negative
- Parvovirus: IgG positive, IgM negative
- RF: 200 (normal: <14 units)
- Anti-citrullinated peptide antibodies (ACPA) 64 units (strong positive >60 units)
- ANA: Negative
- ESR: 58 mm/hr

Note that based on results so far and according to Table 11-1, she has 7 points (4–10 joints involved, high titers of RF and ACPA, and elevated ESR).

Question 11.1.3 Which of the following is the most appropriate next step?

- A) Bilateral hand x-rays
- B) CT of the chest
- C) Smith antibody, double-stranded DNA (dsDNA), complement levels

TABLE 11-1 AMERICAN COLLEGE OF RHEUMATOLOGY 2010 CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS

Patients:

1. Who have at least 1 joint with definite clinical synovitis with the synovitis not better explained by another disease. 6 points makes the diagnosis of RA:	
A. Joint involvement	
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints)	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)	5
B. Serology (at least 1 test result is needed for classification)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-phase reactants (at least 1 test result is needed for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of symptoms	
<6 weeks	0
>6 weeks	1

ACPA, anti-citrullinated peptide antibodies; RF, rheumatoid factor; CRP, c-reactive protein; ESR, erythrocyte sedimentation rate.

Diagnose rheumatoid arthritis if: Score of categories A–D is at least 6/10.

Used with permission from Aletaha D. Rheumatoid arthritis classification criteria: An American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum.* 2010;62:2569–2581.

- D) Start methotrexate 15 mg weekly by mouth and daily folic acid, with or without low-dose prednisone and follow-up in 4 to 5 weeks
- E) Start prednisone 60 mg daily by mouth and follow up in 4 to 5 weeks

Answer 11.1.3 The correct answer is “D.” This patient most likely has seropositive RA (see criteria in Table 11-1). The patient should be started on a disease-modifying anti-rheumatic drug (DMARD), such as weekly methotrexate at a moderate dose, along with folic acid 1 mg daily and prednisone 10 to 20 mg daily. Evidence suggests that there is a “window of opportunity” when treating early RA and that an early remission may lead to sustained remission.

Note that investigating for any evidence of other systemic involvement should be included as part of the initial evaluation. It is appropriate to obtain CBC, liver function tests, electrolytes, BUN, creatinine, and urinalysis (to rule out glomerulonephritis). “A” is incorrect. She is presenting fairly early after the onset of symptoms, so it is unlikely that hand x-rays will provide any significant findings. “B” is also incorrect. Without

further symptoms or signs of lung involvement (e.g., pulmonary osteoarthritis and respiratory symptoms), a CT scan would be inappropriate. As to “C,” she has no other symptoms of lupus and also had a negative ANA, so further testing for lupus (Smith antibody, dsDNA [also known as anti-native DNA antibodies], complement levels) is not appropriate. “E” is incorrect. Although steroids are indicated, *low doses* are fine; higher doses are rarely necessary and are associated with greater side effects. Therefore, early institution of a DMARD would be preferable.

HELPFUL TIP:

Anti-citrullinated protein antibodies (ACPA), also known as anti-CCP (anti-cyclic citrullinated peptides), are very specific for RA; however, their sensitivity is 67% and therefore may be negative in RA.

HELPFUL (IF LONG) TIP:

In all cases of RA, and especially in those with a poorer prognosis, DMARDs should be instituted promptly, and escalated fairly rapidly, with goal being disease remission. Methotrexate (MTX) is the most commonly used DMARD in the United States, but combination therapy (methotrexate plus hydroxychloroquine or sulfasalazine) or triple therapy (methotrexate, hydroxychloroquine, and sulfasalazine) improves outcomes over methotrexate alone. *Low-dose* prednisone is indicated for immediate symptomatic relief. Recent data suggests that *low-dose* prednisone in the first 6 months up to 2 years after diagnosis is associated with better prognosis and more sustained remission. Occupational therapy referral is helpful in identifying and treating functional impairment due to RA. Vitamin D 800 IU/day and calcium 600 to 800 mg BID should be initiated with prednisone therapy to help prevent corticosteroid-induced osteoporosis. Evaluation of bone density (DEXA scan) and a bisphosphonate (e.g., alendronate) should be considered if >5 mg of prednisone is to be used for >3 months.

HELPFUL TIP:

RA typically has an insidious onset with a fluctuating course; however, a significant minority of patients (perhaps one-third) will experience rapid onset, over days to weeks.

She returns in 4 weeks and is now about 7 weeks into her illness. She reports a moderate response to your intervention (you started methotrexate 15 mg weekly with 1 mg folic acid daily and prednisone 20 mg daily), but now she has 1 to 2 hours of morning stiffness. She continues to complain of pain in her hands and feet, with poor grip. In fact, she had to take time off from work during the last week. On examination, she has persistent swelling of MCPs 2 to 5 bilaterally and

MTPs 3 and 4 bilaterally. You also note swelling in the left wrist and both knees, but tenderness is reduced and there is no erythema. You are now reconsidering your diagnosis. Did you miss something?

Question 11.1.4 What examination finding is so general that it would NOT help you support/reconsider your diagnosis?

- A) Pleural rub auscultated on lung examination
- B) Firm, slightly tender subcutaneous nodules at the olecranon bursa
- C) Faint pink rash over chest, which is not visible 15 minutes later
- D) Reduced passive flexion in left knee
- E) Left foot drop

Answer 11.1.4 The correct answer is “D.” While important to note, limitation of passive movements of the knees is indicative only of knee effusion (or pain), which you have already observed, and is not specific for any particular etiology. She responded modestly to methotrexate and prednisone but clearly still has active arthritis. What can you use to expand or limit your differential diagnosis? Pleural friction rub (“A”) is indicative of possible lupus. Diagnostic criteria for lupus include serositis, which may be detectable as a pleural rub on auscultation of the lungs (also, look for malar rash, discoid lesions, alopecia, and oral ulcerations). Although not part of the diagnostic criteria for the disease, RA may also present with pleuritis or pericarditis. Rheumatoid nodules (“B”) are found in RA. A salmon-colored, evanescent macular rash (“C”) would lead you to consider adult-onset Still disease. Still disease, also known as juvenile idiopathic arthritis (JIA, discussed in Chapter 13), presents with an evanescent rash, intermittent fever, and arthritis. “Adult onset” Still disease is Still disease with onset after age 16. In addition, RF and CCP antibodies are typically negative in adult-onset Still disease. A finding of isolated foot drop (“E”) may be the result of mononeuritis multiplex, a feature of vasculitides, and paraneoplastic syndromes. In fact, foot drop is the most common weakness with mononeuritis multiplex followed by wrist drop. Mononeuritis multiplex is defined as injury of two or more *named* nerves secondary to a vasculitis (e.g., ANCA-associated vasculitis, polyarteritis nodosum, cryoglobulin-associated vasculitis, lupus, RA, Sjogren syndrome, etc.).

Question 11.1.5 Since your patient is taking methotrexate, you caution her to avoid which of the following?

- A) Aspirin
- B) Sulfonamide antibiotics
- C) Ibuprofen
- D) Folate
- E) Penicillin antibiotics

Answer 11.1.5 The correct answer is “B.” Methotrexate is a folate antagonist. Antifolate medications, such as sulfonamide antibiotics, must be avoided in patients taking methotrexate because the combination may result in pancytopenia. Supplemental folate, 1 mg daily, reduces the adverse effects of methotrexate. Patients with RA are often treated with aspirin

or NSAIDs in combination with methotrexate. Penicillin antibiotics can be administered safely with methotrexate, although methotrexate levels may increase by 8% or so.

HELPFUL TIP:

Drug interaction programs often warn about concomitant use of NSAIDs and methotrexate, as well as aspirin and methotrexate. These warnings are most relevant to high-dose methotrexate used to treat cancer, not the lower doses used for inflammatory arthritis.

At her first return visit, she had only mild improvement so you (rightly) added hydroxychloroquine (good job!). Initial hand x-rays demonstrate mild periarticular osteopenia. Liver function tests, urinalysis, CBC, BUN, and creatinine are normal. She returns 6 weeks after starting the hydroxychloroquine and is much improved, having returned to work full-time. She tells you that she still has problems with opening jars and about 45 minutes of morning stiffness, “But nothing like it was.”

Question 11.1.6 What is the BEST course of action to follow now?

- A) Continue her current therapy and follow up in 6 to 12 months with transaminases, RF, and hand x-rays
- B) Continue her current therapy and follow up in 3 to 4 months with transaminases, RF, and hand x-rays
- C) Continue current therapy and follow up in 3 to 4 months; arrange for monthly BUN, creatinine and CBC; and schedule for an annual ophthalmology examination
- D) Begin prednisone taper, continue other medications, and arrange for monthly transaminases and CBC; schedule for baseline ophthalmology exam; and schedule follow-up in another 2 to 3 months
- E) Instruct her to discontinue methotrexate, taper the prednisone dose, and continue hydroxychloroquine; arrange for follow-up in 1 year

Answer 11.1.6 The correct answer is “D.” She seems to be responding to therapy, and a 3-month trial on her current medications (during which the methotrexate dose may be increased) is indicated. A slow prednisone taper should be initiated to minimize the cumulative dose of corticosteroids. Close follow-up is critical; she should contact you, should symptoms return during the steroid taper. Guidelines for monitoring her DMARD regimen recommend measurement of transaminases and CBC every 8 to 12 weeks for methotrexate and routine eye examination to assess for hydroxychloroquine-related retinal toxicity. A baseline eye examination is necessary when starting hydroxychloroquine; annual screening should begin after 5 years, unless the patient is at high risk for complications. Hand x-rays are recommended at 2-year intervals. “E” is incorrect: DMARD therapy reduces her risk of joint destruction and disease progression and should not be discontinued.

At her next visit 3 months later, she feels better. Although she still has difficulty opening jars, she now has <30 minutes of morning stiffness and almost no pain. On examination, she has no rash, nodules, or evidence of serositis. She now has swelling over MCPs 2 to 4 on the right and 2 to 3 on the left. Her grip is still somewhat weak but improved. Laboratory data shows an ESR of 28 mm/hr, CRP 0.7 mg/dL, and normal transaminases and CBC. Her symptoms increased when she tapered prednisone to less than 10 mg/day, so she is taking 20 mg/day once again.

Question 11.1.7 Which of the following is the most appropriate next step?

- A) Increase methotrexate to 25 mg weekly, continue hydroxychloroquine, and refer to rheumatology
- B) Stop methotrexate and switch to leflunomide 20 mg/day
- C) Increase prednisone to 60 mg daily
- D) Discontinue all medications except methotrexate
- E) Discontinue methotrexate, taper prednisone, and continue hydroxychloroquine

Answer 11.1.7 The correct answer is “A.” Despite her initial response, she has evidence of ongoing inflammatory activity by history and examination. Discontinuing or reducing medication is inappropriate. According to published guidelines, consultation with a rheumatologist is now indicated—if it had not been sought sooner. She has had a fair initial response to methotrexate, prednisone, and hydroxychloroquine. Further benefit may be gained with increasing the methotrexate dose. Addition of sulfasalazine would also be appropriate. If “triple therapy” with methotrexate, hydroxychloroquine, and sulfasalazine fails, she will need a biological agent. “B” is incorrect: since she had an initial response to methotrexate, and may show further efficacy at a higher dose, it would be wise to further increase the methotrexate dose, rather than substituting another agent, such as leflunomide. Leflunomide is a nonbiologic immunosuppressant that can cause liver injury. Its place in therapy is in patients who cannot tolerate or have a contraindication to a biologic agent (see below). “C” is incorrect: doses of prednisone this high are not indicated for RA.

Question 11.1.8 This patient wants to become pregnant. You can tell her that:

- A) Symptoms remit in 70% of women during pregnancy
- B) She should avoid pregnancy while taking methotrexate
- C) RA is a contraindication to pregnancy
- D) Prednisone cannot be taken during pregnancy
- E) A and B

Answer 11.1.8 The correct answer is “E,” both “A” and “B” are correct. RA is an autoimmune disease, and it tends to remit during pregnancy when a woman is relatively immunosuppressed. Methotrexate is class X for pregnancy and is actually used in ectopic pregnancy to arrest fetal growth. Women taking methotrexate should use an effective form of contraception

and continue contraception for 3 months after stopping methotrexate. “D” is incorrect since prednisone is often used to control RA during pregnancy, when methotrexate is contraindicated. Prednisone does not cross the placenta, but use during pregnancy is associated with higher risk for gestational diabetes.

The patient is an avid runner and, prior to her diagnosis, participated in numerous outdoor activities. She is concerned about whether she will eventually become disabled.

Question 11.1.9 You can let her know that:

- A) RA tends to progress without any remissions to involve almost all joints in all patients
- B) Prednisone-free disease remission has become the goal of treatment
- C) Patients with RA have the same life expectancy as the general public
- D) Renal involvement is common with RA and is a major source of morbidity and mortality
- E) She won’t need to worry about having a life after she gets pregnant and has a child. All her energy will be absorbed by that little parasite ... er, child.

Answer 11.1.9 The correct answer is “B.” With the advent of new potent disease-modifying agents, it is now possible for RA patients to achieve remission, defined as the absence or near absence of joint pain and swelling. “A” is incorrect. Untreated RA may progress to involve further joints, but not all joints are affected by RA. Classically, the distal interphalangeal joints are spared and, if there is DIP involvement, should prompt reassessment of the diagnosis. Moreover, treatment with DMARDs can, and frequently does, induce remission. “C” is incorrect. RA reduces the life expectancy by up to 10 years (due to earlier cardiac disease, infections, lymphoma). “D” is incorrect. Renal disease is a rare complication of RA; however, it can be a result of some of the medications used to treat RA. Finally, “E.” If she wants a life after becoming a parent, she can borrow a life from us—we’re chained to this book. Or, she can buy one at Costco wholesale.

She has an exacerbation of her disease despite triple therapy. You refer to a rheumatologist who recommends the use of a biologic agent for RA.

Question 11.1.10 Which of the following screenings are required before beginning a biological agent to treat rheumatoid arthritis?

- A) CMV
- B) TB
- C) Heart failure
- D) Mucosal candidiasis
- E) B and C

Answer 11.1.10 The correct answer is “E.” There are a number of biologics for treating rheumatoid arthritis that are TNF inhibitors. Etanercept (Enbrel) is a soluble TNF receptor antagonist. Infliximab (Remicade) and adalimumab (Humira) are

monoclonal antibodies that bind TNF both at the cell and when it is in its soluble form. These drugs can also reduce the resistance to infection and promote malignancies. *All of the TNF inhibitors essentially have the same efficacy.* Any one of these agents can be added to MTX. Things to watch for with TNF inhibitors include serious infections (e.g., TB, fungal infections) and malignancies. Rule out TB and hepatitis B before starting TNF inhibitors. There is also a concern for worsening congestive heart failure in those with preexisting disease. Thus, “E” is the correct answer. Mucocutaneous candidiasis is not a contraindication to TNF inhibitors, and routine testing for CMV is not recommended.

HELPFUL TIP:

Does joint replacement work in RA? Yes. Remember, however, that the maximum life span of an artificial joint is about 15 years with current technology. Thus, replacement should not be undertaken lightly in a young patient—or any patient for that matter.

► **Objectives: Did you learn to ...**

- Describe an appropriate diagnostic strategy for polyarthritis?
- Recognize the diagnostic criteria for RA?
- Develop a management strategy for RA?
- Recognize the importance of early DMARD therapy for RA?
- Identify the uses and adverse effects of medications used to treat RA?

QUICK QUIZ: AN ILL CHILD

A concerned mother brings in her 2-year-old son with a 1-week history of fever. She is worried because she had expected the fever to resolve by now. According to his mother, the patient also has a rash, poor appetite, and lethargy. On examination, he looks ill and his temperature is 39.0°C. There is a diffuse, erythematous, macular rash, and peeling skin on the fingertips. The oropharynx is injected and the tongue is bright red with white papillae. Cervical lymph nodes are enlarged and tender.

Based on the available information, what is your leading diagnosis?

- A) Rheumatic fever
- B) Parvovirus B19 infection
- C) Kawasaki syndrome
- D) Juvenile idiopathic arthritis (JIA)
- E) Varicella infection

The correct answer is “C.” Kawasaki syndrome is an acute vasculitis of unknown etiology, which is most often seen in children. Kawasaki syndrome presents *with at least 5 days of fever* (required fever duration for the diagnosis of Kawasaki disease), polymorphous rash, conjunctival injection, mucous membrane involvement (e.g., “strawberry” tongue), cervical lymphadenopathy, and extremity findings of erythema and desquamation. The usual treatment is aspirin and IVIG. Corticosteroid therapy

is controversial and does not seem to improve outcomes. There may be cardiac involvement with the formation of coronary artery aneurysms.

“A,” rheumatic fever, which is rare in developed countries, is recognized by the Jones criteria. The major Jones criteria consist of polyarthritis, carditis, Sydenham chorea, erythema marginatum, and subcutaneous nodules. Here’s a fun mnemonic: “JONES” with a heart shape in place of the “O,” so that J = joints, O = carditis, N = nodules, E = erythema marginatum, and S = Sydenham chorea. “B” is incorrect. Generally, children do not appear this ill with parvovirus B19 infection (fifth disease). “D,” JIA, would be unusual at such a young age, and is discussed in Chapter 13. “E” is incorrect, as this is obviously not varicella.

► CASE 11.2

A 62-year-old male who you have followed for hypertension for several years presents with complaints of worsening fatigue and aching in his back, shoulders, and neck. He notes 3 months of symptoms unresponsive to acetaminophen.

Further history reveals that your patient has experienced stiffness of the neck and shoulders each morning for over 30 minutes. He occasionally has difficulty getting out of bed due to pain. Vital signs are within normal limits. There is no evidence of synovitis of the hands, wrists, or elbows. Active range of motion in the neck and shoulders is slow but full. There is tenderness to palpation of the shoulders, upper back, and neck, but no apparent muscle atrophy.

Question 11.2.1 Which of the following is the most appropriate next step in the diagnosis of this illness?

- A) Obtain an ESR and CRP
- B) Obtain a urinalysis
- C) Prescribe a diagnostic trial of corticosteroids
- D) Order a rheumatology panel, including ANA, uric acid, ESR, CRP, and RF
- E) Perform shoulder radiograph

Answer 11.2.1 The correct answer is “A.” This patient’s presentation is consistent with the diagnosis of polymyalgia rheumatica (PMR). Elevations of ESR and/or CRP contribute further evidence to such a diagnosis and are useful in following the treatment of PMR. While a urinalysis (“B”) may be important in some rheumatologic illnesses (e.g., lupus, Behçet syndrome), PMR is not likely to be associated with renal disease.

A trial of corticosteroid therapy (“C”), may be appropriate, but an ESR should be obtained first to more conclusively establish the diagnosis. At this point all we know is that he has bilateral shoulder and neck pain, which could be mechanical from the cervical spine, etc. As you already know from earlier discussion, “D” is incorrect; a “rheumatology panel” will typically include tests that are not indicated, and positive results can be misleading. In the absence of small joint symptoms or examination findings, an RF is not indicated in this case. Likewise, there is no history to suggest an ANA-related

TABLE 11-2 EUROPEAN LEAGUE AGAINST RHEUMATISM AND AMERICAN COLLEGE OF RHEUMATOLOGY CLASSIFICATION CRITERIA FOR POLYMYALGIA RHEUMATICA

Required Criteria	
Age > 50 years	
Bilateral shoulder pain	
Elevated ESR and/or CRP	
Clinical Criteria	
Morning stiffness lasting over 45 minutes	2 points
Hip pain or restricted range of motion	1 point
Negative RF and ACPA	2 points
Absence of other joint involvement	1 point
Ultrasound Criteria	
> 1 shoulder with subdeltoid bursitis, biceps tenosynovitis, or glenohumeral synovitis, AND > 1 hip with synovitis or trochanteric bursitis	1 point
Both shoulders with subdeltoid bursitis, biceps tenosynovitis, or glenohumeral synovitis	1 point

ACPA, anti-citrullinated peptide antibodies; CRP, c-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

A score ≥ 4 points without ultrasonography, or > 5 with ultrasonography, in addition to fulfillment of the required criteria, is categorized as polymyalgia rheumatica.

Adapted from Dasgupta B, et al. 2012 provisional classification criteria for polymyalgia rheumatica. *Arthritis Rheum.* 2012;64(4):943–954.

disorder. “E” is incorrect. This patient does not need shoulder radiographs. In a patient with bilateral shoulder pain and neck pain, a neck radiograph may be more useful than shoulder imaging. Neck radiographs help to evaluate for cervical canal narrowing and degenerative disc disease, which may result in pain and neurologic findings in the upper extremities. An MRI of the neck might be useful if cervical spine disc disease or a syrinx were suspected. Diagnostic criteria for PMR are given in Table 11-2. Small joint synovitis, or puffy swelling of hands and feet, will occur in 20% of patients with PMR; and in these cases, it is appropriate to check RF and ACPA during your initial evaluation.

HELPFUL TIP:

Physical examination findings of PMR are subtle. Active ROM in the affected areas is often limited by pain, but passive ROM should be full. Strength is intact. In general, PMR affects shoulders to a greater degree than hips, and the hips more than the neck. The essential pathology is inflammation of the synovia, and muscles are not directly involved.

Question 11.2.2 The sensitivity of an elevated ESR in the diagnosis of PMR and giant cell arteritis (GCA) is:

- A) 100%
- B) 85%
- C) 50%
- D) 25%

Answer 11.2.2 The correct answer is “B.” Up to 15% of patients with PMR or GCA (a closely related disorder—keep reading) have a false-negative ESR. Using ESR and CRP together is 97% to 99% sensitive for GCA. Double false negatives of ESR and CRP are uncommon but do occur. Thus, in the patient in whom GCA is suspected but in whom there is a normal ESR and/or CRP, biopsy is still recommended. In those suspected of PMR with normal ESR and/or CRP, a trial of empiric therapy is warranted.

HELPFUL TIP:

Patients with PMR often have a low-grade fever and a normocytic anemia.

HELPFUL TIP:

PMR is uncommon in non-white populations. The mean age of onset is approximately 70 years. Women are affected twice as often as men.

You order radiographs of the neck, which demonstrate mild degenerative disease. A CBC is unremarkable, except for a mild thrombocytosis. The ESR is 80 mm/hr. You relate these findings to the patient and tell him that your presumptive diagnosis is PMR.

Question 11.2.3 Which of the following is the most appropriate initial treatment in this case?

- A) Naproxen 500 mg twice daily
- B) Prednisone 15 mg daily
- C) Aspirin 650 mg twice daily
- D) Prednisone 50 mg daily
- E) Referral to physical therapy

Answer 11.2.3 The correct answer is “B.” Prednisone is the treatment of choice in PMR. Doses of prednisone ranging from 10 to 20 mg daily are usually sufficient to control the disease. Higher doses (up to 30 mg/day) should be tried if there is no response in 1 to 2 weeks. If the patient fails to respond to 30 mg or less of prednisone, the diagnosis of PMR should be reconsidered. “A” is incorrect. NSAIDs may provide some symptomatic relief, but are not the treatment for PMR. It remains controversial whether low-dose aspirin 81 mg/day may decrease the risk of vision loss in giant cell arteritis. In general, use it only in patients in whom it is indicated for another diagnosis. However, high-dose aspirin therapy (“C”) without corticosteroids is not recommended. “E” is incorrect.

Since patients usually respond quickly to corticosteroids, physical therapy is not necessary—although you could hardly be faulted for employing physical therapy as part of your overall treatment approach.

HELPFUL TIP:

Looking at the long-term outcomes, initial low-dose therapy prednisone for PMR works better than high-dose therapy. Patients have fewer relapses and are spared some of the adverse effects of high-dose corticosteroids.

You prescribe prednisone 15 mg daily, aspirin 81 mg daily, and calcium and vitamin D supplementation. Your patient presents for follow-up 4 weeks later, reporting marked improvement. On examination, there is no joint inflammation, or muscle tenderness with a range of motion exercises. His ESR is 20 mm/hr. You believe that the patient’s disease is now in remission.

Question 11.2.4 Which of the following is the most appropriate next step in his management?

- A) Discontinue prednisone and initiate naproxen
- B) Continue the current dose of prednisone for the next 12 months
- C) Continue the current dose of prednisone for the next 6 months
- D) Taper prednisone by 1 to 2 mg every 2 weeks to reach the minimum effective dose
- E) Taper prednisone by 5 mg over 2 weeks and then discontinue the drug

Answer 11.2.4 The correct answer is “D.” Relapse of PMR occurs more frequently when corticosteroids are abruptly discontinued or tapered too quickly. However, due to complications associated with corticosteroid therapy, the dose should be reduced as soon as possible; therefore, maintaining prednisone 15 mg daily for 6 to 12 months is inappropriate. The usual recommendation is to reduce the dose of prednisone by 10% every 1 to 2 weeks until the minimum effective dose is reached. While tapering prednisone, the patient should be monitored with an ESR and/or CRP every 2 to 4 weeks. If symptoms worsen, prednisone should be increased slightly to achieve symptomatic control. If the ESR increases to 40 mm/hr or greater and the patient is asymptomatic, consider continuing the same dose of prednisone until the ESR normalizes, then continue the taper. *However, an isolated elevation in ESR without symptoms is not a reason to increase prednisone.*

Question 11.2.5 Which of the following is true regarding the prognosis of PMR?

- A) PMR is associated with an increased risk of mortality
- B) Most patients with PMR will require corticosteroid therapy for life

- C) Up to 50% of patients who initially have a successful remission will experience a relapse while tapering prednisone
- D) A relapse of PMR requires high-dose corticosteroids (prednisone 50 mg daily) for successful treatment

Answer 11.2.5 The correct answer is “C.” Relapses occur in 30% to 50% of patients after induction of remission and should be treated by resuming or increasing prednisone. Usually, successful treatment of a relapse requires increasing the prednisone dose by a few milligrams. “A” is incorrect. Although the pathogenesis of PMR is incompletely understood, it has features in common with vasculitides, including potential vascular complications of GCA. However, PMR is not associated with an increase in mortality. “B” is incorrect because PMR is a self-limited disease, and most patients recover within a few months to a few years. Thus, patients require prednisone for 6 months to 2 years, but prednisone therapy is typically not lifelong. Remote relapses of PMR after prednisone has been successfully stopped are seen in about 20% of cases and can occur up to years later.

.....

Your patient does well and is able to taper off prednisone over a year. Twelve months after stopping corticosteroids, he presents to the ED one weekend. His shoulder and neck pain and stiffness have returned, as well as severe fatigue and subjective fevers. He has lost 5 pounds over 2 weeks. He is now experiencing frequent left-sided headaches. Finally, he is most concerned about a new visual disturbance starting today. He notes that he has a “hole” in his vision. On physical examination, there is a prominent, tender vessel palpable at the left temporal area. Funduscopic examination of the left eye shows a pale disc with blurred margins. The remainder of the neurologic examination is normal. The ESR is 70 mm/hr.

Question 11.2.6 Which of the following is the most likely diagnosis for the visual symptoms?

- A) Polymyalgia rheumatica (PMR)
- B) Stroke (CVA)
- C) Giant cell arteritis (GCA)
- D) Multiple sclerosis (MS)
- E) Acute angle-closure glaucoma

Answer 11.2.6 The correct answer is “C.” Many of the patient’s symptoms can be explained by PMR (“A”), but visual symptoms do not occur with this disease. GCA (aka temporal arteritis) is a related diagnosis that is commonly seen in conjunction with PMR. Most experts now agree that PMR and GCA are different presentations of the same disease process. With the new symptoms of localized headache and tenderness of the temporal artery and the previously known findings consistent with PMR, this patient now meets diagnostic criteria for GCA (see Table 11-3). The visual symptoms described are typical of GCA and can occur acutely or chronically. As to the other answers, vision loss in multiple sclerosis is attributable to optic neuritis, which is associated with pain and presents initially in a younger population. Acute angle-closure glaucoma is associated with eye pain and redness. The lack of other neurological symptoms makes stroke less likely.

TABLE 11-3 AMERICAN COLLEGE OF RHEUMATOLOGY CLASSIFICATION CRITERIA FOR GIANT CELL ARTERITIS

A patient with vasculitis may be classified as having giant cell arteritis if she or he fulfills three of the following five criteria:

- Age \geq 50 years at onset of symptoms
- New localized headache, jaw claudication, visual symptoms
- Temporal artery tenderness or decreased pulsation
- ESR \geq 50 mm/hr
- Abnormal temporal artery biopsy findings

HELPFUL TIP:

The initial visual loss in GCA is peripheral, while the vision loss in macular degeneration is initially central. If you think about it, this makes sense. GCA basically causes an anterior ischemic optic neuropathy (AION) secondary to involvement of the retinal artery by vasculitis. Areas further from the artery will have poorer perfusion.

Question 11.2.7 Which of the following is the most appropriate initial management of this patient?

- A) Withhold treatment for now and arrange for temporal artery biopsy within 48 hours
- B) Withhold treatment for now and arrange for an ultrasound of his temporal artery next week
- C) Refer to an ophthalmologist as soon as possible
- D) Initiate prednisone 20 mg daily and refer for temporal artery biopsy
- E) Admit and administer methylprednisolone 1 g intravenously (IV) and arrange for temporal artery biopsy

Answer 11.2.7 The correct answer is “E.” When symptoms of vision loss occur, IV methylprednisolone 15 mg/kg/day (up to 1 g) daily for 3 days, followed by prednisone 40 to 60 mg daily is the standard of care. Compared to PMR, higher doses of corticosteroids are necessary to treat GCA. In the absence of vision loss, prednisone doses of 40 to 60 mg daily are usually required to relieve symptoms. Consultation with ophthalmology is also necessary in providing proper care to the patient. “A” is incorrect. You do not want to withhold treatment from this patient whose vision is at risk (see “Helpful Tip” below). Ultrasonography for the “Halo Sign” is being actively investigated. It has a high specificity (94%) but low sensitivity (42%) and so should not be used to rule out cases of GCA. “B” and “C” are incorrect for the same reason. “D” is incorrect because a dose of 20 mg of prednisone is too low to be effective in GCA.

HELPFUL TIP:

Temporal artery biopsy is the gold standard test for the accurate diagnosis of GCA. Characteristic giant cell inflammation pathology can be seen for up to 4 weeks after initiating high-dose corticosteroids. However, corticosteroid therapy should never be delayed for fear of reducing the inflammatory findings on the temporal artery biopsy.

Six years after his diagnosis of GCA, your patient has experienced several remissions and relapses. Although he has been able to discontinue prednisone on occasion, he is now taking 5 mg daily with good symptomatic control. He asks about whether there are other treatments that may help him to wean off prednisone.

Question 11.2.8 Which of the following medications may be used as a part of a steroid-sparing regimen for the treatment of GCA?

- A) Hydroxychloroquine
- B) Adalimumab
- C) Tocilizumab
- D) Azathioprine
- E) All of the above

Answer 11.2.8 The correct answer is “C.” It is believed that in patients with GCA, elevated serum levels of interleukin-6 correlate with disease activity. Tocilizumab, an interleukin-6 receptor alpha inhibitor, allows for reductions in glucocorticoid doses that are used to control GCA and to maintain remission. It is currently FDA approved for subcutaneous use in the treatment of GCA. Hydroxychloroquine (“A”), TNF inhibitors (including adalimumab, “B”), and azathioprine (“D”) are incorrect. There have been no studies supporting their use in GCA.

One dark and stormy night, 3 AM in the ED—the weather is cold and the coffee is colder—your patient presents with tearing substernal chest pain radiating to his back. He is alert but anxious and diaphoretic. His left radial pulse is diminished compared to the right. His heart rate is 120 bpm, and his blood pressure is 92/56 mm Hg.

Question 11.2.9 Which of the following studies will confirm the most likely diagnosis?

- A) Chest radiograph
- B) Chest CT
- C) ECG
- D) Venous blood gas
- E) Troponin-T

Answer 11.2.9 The correct answer is “B.” Your patient’s symptoms are classic for a dissecting thoracic aortic aneurysm, which is often mistaken for a myocardial infarction. Thoracic aortic aneurysm is a late complication of GCA; aortic aneurysms generally occur an average of 6 to 7 years after the initial diagnosis of GCA. Thoracic aortic aneurysms occur 17 times more often in patients with GCA when compared to the general population. The diagnosis of thoracic aortic aneurysm is confirmed by CT scan of the chest, transesophageal echocardiogram, or angiogram. While the other studies listed should be done, none of them are going to make the diagnosis of a dissecting aneurysm for you.

HELPFUL TIP:

With the initiation of corticosteroids in PMR or GCA, start calcium 1,200 to 1,500 mg daily and vitamin D 400 to 800 IU daily for osteoporosis prevention. Once the diagnosis is confirmed (and prednisone will be continued for an extended period), bone mineral density should be measured with a DEXA scan and bisphosphonates instituted on the basis of FRAX calculated risk of fracture or DEXA results (do you see a pattern here of prophylaxis for osteoporosis when starting corticosteroids?).

► Objectives: Did you learn to ...

- Describe the appropriate evaluation, including physical examination and laboratory tests, of diffuse pain in the older patient?
- Recognize the diagnostic criteria for PMR and GCA?
- Describe the appropriate management, including medical therapy, of PMR and GCA?
- Identify complications of PMR and GCA?

► CASE 11.3

A 22-year-old graduate student presents to the ED on a Monday night with an acutely swollen left knee. He admits to “wild partying” over the weekend but only had “a couple of beers” (that is the “college couple”... so, 6 or 7). His knee was OK then. However, when he woke up this morning, he noticed the knee was swollen and painful (so was his head, but that’s another matter). By early afternoon, he had difficulty bearing weight. He denies fever, but feels tired.

He reports a history of JIA (juvenile idiopathic arthritis) and has had ankle and knee swelling previously, but not to this degree. He took prednisone intermittently, as well as hydroxychloroquine and methotrexate, for his JIA until age 18. He then continued on hydroxychloroquine until 8 months ago, when he stopped it because he felt fine. He denies any other medical problems. He smokes only when drinking—which happens way too often.

Question 11.3.1 What other information from the history would be most helpful in establishing the diagnosis?

- A) Sexual history, including sexual orientation, practices, and last contact
- B) Personal or family history of gout or kidney stones
- C) History of IV drug use
- D) Family history of pseudogout
- E) A, B, and C

Answer 11.3.1 The correct answer is “E.” While all of these points are important in the history, this patient is too young to have pseudogout. While gout is unusual in young adults, there are uncommon syndromes of familial hyperuricemia and early

gout. Although there are several possible etiologies for this patient's presentation, septic arthritis should be considered first and foremost due to its high morbidity and mortality. As such, the history and examination should focus on those clues that point toward an infectious etiology and its source. The clinician must also consider noninfectious inflammatory arthropathies. IV drug abuse can lead to a septic joint as can gonorrhea. Thus "A" and "B" are important parts of the history.

Your patient is heterosexual and *thinks* he had intercourse Saturday night (2 nights ago), but admits that his memory is somewhat blurry (maybe he had more than the "couple" of beers he claims). He denies a history of gout and IV drug use. He complains of poor sleep and feeling stiff in the mornings and evenings lately.

Question 11.3.2 What findings on physical examination would be LEAST helpful in determining the diagnosis?

- A) A few vesiculopustular lesions on the back, arms, and legs
- B) Swollen, tender, nonerythematous MCP joints
- C) Nontender hepatomegaly
- D) Diastolic murmur at the right sternal border
- E) Whitish discharge from the tip of penis

Answer 11.3.2 The correct answer is "C." Although nontender hepatomegaly may indicate presence of liver disease, it is unlikely to help identify the etiology of this patient's arthritis. Hepatitis B arthritis usually presents as a symmetric polyarthritis, although it can be migratory or additive (sequential joints becoming involved without resolution in the initial joints). Our patient has a single swollen, hot joint, which is unlikely to occur as a result of hepatitis. "A" is helpful: a vesiculopustular rash occurs in disseminated gonococcal infections. "B" is also helpful: the presence of other swollen joints should prompt consideration of noninfectious inflammatory arthritis, and the swelling of the MCPs in particular may be a clue for active RA. The detection of a diastolic murmur ("D") is significant, since diastolic murmurs are almost always pathologic in adults, and may represent infective endocarditis. Finally, "E," penile discharge, can result from acute gonorrheal infections.

On examination, vital signs are significant only for tachycardia and fever (pulse 112 bpm, temperature 38.2°C). He has no other swollen joints, rashes, heart murmurs, or penile discharge. You palpate a smooth, nontender liver edge 2 cm below the costal margin; it percusses to 15 cm. You note mild cervical lymphadenopathy and whitish pharyngeal exudates.

Question 11.3.3 Which of the following is the most appropriate next step in the management of this patient?

- A) Order hepatitis serologies
- B) Order blood cultures, urine PCR for chlamydia and gonorrhea, and abdominal ultrasound
- C) Administer ceftriaxone 1 g IV and inject the knee with triamcinolone

- D) Perform knee aspiration
- E) Prescribe prednisone 20 mg PO QD and arrange consultation with a rheumatologist

Answer 11.3.3 The correct answer is "D." Did you get distracted by a big liver? If so, redirect your attention to the knee. The single most important step in evaluating acute monoarthritis is joint aspiration, which will allow differentiation between inflammatory and noninflammatory disease. Although blood cultures and urine PCR for chlamydia and gonorrhea should also be sent in this case, obtaining these studies must not delay joint aspiration. Without determining whether the arthritis is infectious, it would be inappropriate—and potentially hazardous to the patient—to start treatment with corticosteroids. "C" and "E" are incorrect because you would **not** want to give corticosteroids—especially intra-articular corticosteroids—to a patient with an infected joint. Analysis of the synovial fluid will aid in determining the appropriateness of treating with antibiotics or anti-inflammatory medications. Joint aspiration will also provide a specimen for crystal examination. While you would probably use empiric antibiotics (treat as septic until proven otherwise), you will need to first obtain cultures (from the knee aspiration and blood).

HELPFUL TIP:

CBC, ESR, and CRP are not useful in diagnosing a septic joint. While they may be somewhat sensitive, they are hopelessly nonspecific. You have to tap the joint if they are normal or if they are abnormal. There's just no getting around it. Just do it!

You have obtained blood cultures and urine PCR for chlamydia and gonorrhea. A metabolic profile, CBC, and hepatitis B and C serologies are pending. Knee aspiration yields 45 cc of turbid, blood-tinged fluid.

Question 11.3.4 You send the synovial fluid for all of the following studies EXCEPT:

- A) Cell count and differential
- B) Crystal analysis
- C) Culture
- D) Glucose and protein
- E) Gram stain

Answer 11.3.4 The correct answer is "D." In contrast to analysis of some other bodily fluids (e.g., cerebrospinal fluid [CSF], pleural fluid, and ascitic fluid), chemistry analysis on synovial fluid is of little diagnostic value. Low glucose levels in synovial fluid are associated with the degree of inflammation but do not help to determine its cause. Likewise, synovial protein levels do not help differentiate between types of arthritis. Cell count with differential, Gram stain, and cultures should be routine when suspecting infection; crystal analysis is also part of the standard examination, but positive crystal analysis does not rule out concomitant infection.

The synovial fluid analysis reveals the following findings: 50,000 WBC/mm³, 95% polymorphonuclear cells, and no crystals. Gram stain shows Gram-negative diplococci. Cultures are pending. Gonorrhea and chlamydia PCR tests are also pending.

Question 11.3.5 What is the sensitivity of a synovial fluid white count of 100,000/mm³ for infection?

- A) 30%
- B) 40%
- C) 50%
- D) 60%
- E) 75%

Answer 11.3.5 The correct answer is "A." Unfortunately, a synovial white count of 100,000/mm³ is only 30% sensitive for a septic joint but is 99% specific. 50,000 WBC/mm³ is 62% sensitive and 92% specific while a WBC count of 25,000/mm³ is 75% sensitive and 73% specific. The point is that what we were taught in school about the synovial WBC count being >100,000/mm³ in a septic joint is wrong.

Question 11.3.6 Which of the following studies will be most important to the OVERALL care of this patient?

- A) HIV testing and RPR
- B) Chest x-ray
- C) ANA and RF
- D) Uric acid
- E) ESR and CRP

Answer 11.3.6 The correct answer is "A." His presentation is very suggestive of disseminated gonococcal infection with acute arthritis, and the presence of diplococci is virtually diagnostic. Therefore, the clinician must also consider the presence of other sexually transmitted diseases and screen the patient appropriately. Assays for hepatitis B and C and chlamydia have been sent, and tests for HIV and syphilis should now be performed. Also, the patient must be counseled regarding safe sexual practices (e.g., condom use, reduced alcohol use, become a monk...). In this setting, the other studies are less relevant to his overall health.

HELPFUL TIP:

Gonococcus is cultured from the joint fluid only about 50% of the time in patients with gonococcal arthritis. Thus, urine and joint fluid PCR should be done even if the Gram stain is negative.

Question 11.3.7 Which of the following is the most appropriate treatment plan for this patient's septic arthritis?

- A) Ceftriaxone 1 g IV once, followed by cefixime 400 mg twice daily by mouth for 14 days; follow-up in 7 days
- B) Admit to hospital, administer ceftriaxone 1 g IV daily, and perform repeat knee aspirations

- C) Admit to the hospital and administer IV and intra-articular ceftriaxone 1 g daily
- D) Ciprofloxacin 500 mg by mouth twice daily for 14 days; follow-up in 7 days
- E) Penicillin G 4 million units IV once, followed by amoxicillin 500 mg PO three times daily for 14 days; follow-up with a rheumatologist

Answer 11.3.7 The correct answer is "B." In order to ensure the best outcome, this patient should be admitted for monitoring and repeated joint aspiration. Purulent fluid tends to collect rapidly in the joint spaces in patients with septic arthritis, necessitating frequent drainage until antibiotics work and inflammation begins to subside. Most cases of gonococcal arthritis respond to needle aspiration plus antibiotics, but arthroscopic or open debridement is occasionally necessary. Because IV antibiotics have good penetration into synovial fluid, intra-articular antibiotics are not recommended. When culture, PCR, and sensitivity results become available, antibiotic therapy should be tailored to the particular infectious agent and its susceptibilities.

HELPFUL TIP:

The initial antibiotic of choice in gonococcal arthritis is ceftriaxone, administered IV. Spectinomycin IV is an acceptable alternative when ceftriaxone is contraindicated. Remember that there is now fluoroquinolone-resistant gonococcus. Because of this, fluoroquinolones are no longer recommended as treatment of gonorrhea.

Within 48 hours, your patient shows signs of improvement. His knee appears much better, there is no recurrent effusion, and he is afebrile. He wants to leave the hospital. By the way, his chlamydia PCR turned up positive.

Question 11.3.8 Which of the following management strategies do you recommend?

- A) Continue the hospital admission and ceftriaxone 1 g IV daily
- B) Discharge with ciprofloxacin 500 mg by mouth twice daily
- C) Discharge with penicillin V 500 mg by mouth three times daily
- D) Discharge with cefixime 400 mg by mouth twice daily, and doxycycline 100 mg by mouth twice daily

Answer 11.3.8 The correct answer is "D." Since the patient is improving, continued hospitalization and IV antibiotics are not needed. Thus, "A" is incorrect. Without knowing the antibiotic sensitivities of the gonococcus, you should assume that it is penicillin-resistant, making "C" a poor choice. Once local and systemic signs are resolving, you can safely discharge the patient with oral antibiotic therapy, using cefixime 400 mg twice daily (or an acceptable alternative based on culture and susceptibilities) to complete a 7- to 14-day course. In cases of gonococcal infection, you should *always* presumptively treat for concurrent chlamydia infection.

**HELPFUL TIP:**

Septic arthritis occurs most often in large joints, such as the knee and hip. Factors that predispose a patient to septic arthritis include advancing age (especially >80 years), RA, joint prostheses, recent joint surgery, diabetes, and skin infection.

Question 11.3.9 What is the mortality rate of septic arthritis?

- A) 0.5%
- B) 5%
- C) 10%
- D) >15%

Answer 11.3.9 The correct answer is “C.” The mortality rate of septic arthritis is 10%, with up to one-third of survivors having persistent joint problems, such as limited range of motion, pain, and swelling. Note that the mortality is probably not due to the infection alone but rather due to a combination of the underlying illness (e.g., immunosuppression) and the infection.

► Objectives: Did you learn to ...

- Describe the appropriate evaluation of monoarthritis?
- Appropriately manage a patient with septic arthritis?
- Identify risk factors for septic arthritis?
- Recognize the prognosis of septic arthritis?

► CASE 11.4

A 55-year-old male presents to your office complaining of severe left knee pain of 2 days duration. Although he was also out partying over the weekend (is there a pattern here to the patients in our practice?), he went home early (say, 2 or 3 o'clock). He denies any previous history of knee pain or arthritis. He has felt feverish over the last 2 days. He recalls a similar episode of pain in his right great toe 2 years before, but the pain resolved in a few days and he did not seek medical attention. He has hypertension treated with chlorthalidone but is otherwise healthy. He drinks about a case of beer per week—unless he's been partying, in which case he doubles his effort. His family history is remarkable for osteoarthritis.

Physical examination reveals an uncomfortable-appearing obese male in no acute distress. His temperature is 37.9°C, blood pressure 168/98 mm Hg, and pulse 84 bpm. The left knee is red, warm, and diffusely tender with a palpable effusion. There are no visible or palpable subcutaneous nodules on the fingers, toes, or at the elbows.

Question 11.4.1 Which of the following is the most appropriate next step to accurately diagnose this condition?

- A) Radiograph of the affected knee
- B) CBC
- C) Serum uric acid level

- D) Knee aspiration and synovial fluid analysis
- E) Diagnostic corticosteroid injection

Answer 11.4.1 The correct answer is “D.” We don't mean to sound like a broken record, but the diagnostic study of choice in a monoarthritis is synovial fluid analysis. Synovial fluid analysis allows the clinician to determine whether there is an inflammatory, infectious, or crystalline cause of the arthritis. “A” is incorrect. Radiographs are typically not helpful acutely in inflammatory arthritis (but would be indicated if there was trauma or suspicion of tumor). “B” and “C,” a CBC is nonspecific and uric acid may be normal during an acute attack of gout. Neither of these laboratory results will be diagnostic. Finally, corticosteroid injection must be avoided in monoarthritis until the possibility of infection is eliminated.

You successfully aspirate 5 cc of slightly cloudy yellow synovial fluid from the left knee. While the patient is waiting, the laboratory reports the following findings: 5,000 WBC/mm³, Gram stain negative for bacteria, and many needle-shaped negatively birefringent crystals.

Question 11.4.2 These synovial fluid findings are most consistent with which of the following diagnoses?

- A) Osteoarthritis
- B) Septic arthritis
- C) CPPD (“pseudogout”)
- D) Gout

Answer 11.4.2 The correct answer is “D.” Monosodium urate crystals of gout are needle-shaped as seen in this patient's synovial fluid (a good way to remember this is that being stuck with a needle hurts and so does gout). Calcium pyrophosphate dihydrate crystals are rod-, square-, or rhomboid-shaped and positively birefringent in polarized light. Thus, the synovial fluid findings given above are most consistent with gout. “A” and “B” are incorrect. Normally, synovial fluid contains <180 WBC/mm³, but it is generally considered noninflammatory if the WBC count is still <2,000/mm³. Low WBC counts are seen in the synovial fluid of osteoarthritic joints. Synovial fluid containing ≥2,000 WBC/mm³ is consistent with an inflammatory process. When there are >100,000 WBC/mm³, the monoarthritis is considered septic until proven otherwise (although as noted above this is only 30% sensitive for septic arthritis). See Table 11-4 for the diagnostic criteria for gout. Note that up to 20% of patients with a crystalline arthritis will have a coexisting septic arthritis (*J Rheumatol.* 2012; 39:157) so be sure to do the gram stain and culture.

**HELPFUL TIP:**

Serum uric acid is often normal during an acute attack of gout (probably because it precipitates in the affected joints); thus, you cannot rely on serum uric acid levels alone to diagnose gout or refute this diagnosis.

TABLE 11-4 CLASSIFICATION CRITERIA FOR ACUTE GOUT

The presence of characteristic urate crystals in the joint fluid or tophus proved to contain urate crystals by chemical means or polarized light microscopy or the presence of 6 of the following 12 phenomena:

1. More than 1 attack of acute arthritis
2. Maximal inflammation developed within 1 day
3. Attack of monoarticular arthritis
4. Joint redness observed
5. First MTP joint painful or swollen
6. Unilateral attack involving first MTP joint
7. Unilateral attack involving tarsal joint
8. Suspected tophus
9. Hyperuricemia
10. Asymmetric swelling within a joint (radiograph)
11. Subcortical cysts without erosion (radiograph)
12. Negative joint fluid culture for microorganisms during attack of joint inflammation

Used with permission from Wallace SL, Robinson H, Masi AT, Decker JL, McCarty DJ, Yu TF. Preliminary criteria for the classification of the acute arthritis of primary gout. *Arthritis Rheum.* 1977;20(3):895–900.

Question 11.4.3 Which of the following may be used as a noninvasive imaging modality to diagnose gout at joints that are inaccessible to an arthrocentesis?

- A) Bone scan
- B) Dual energy CT
- C) MRI
- D) X-rays

Answer 11.4.3 The correct answer is “B.” A diagnosis of gout is usually reached by evaluating clinical, laboratory, and radiologic findings. In uncertain cases, dual energy CT scan may be useful (sensitivity 90% and specificity 82% in one literature review [*Ann Rheum Dis.* 2015;74(6):1072–1077]). It may also identify subclinical tophi and quantify burden of disease. While a bone scan (“A”), MRI (“C”), and x-rays (“D”) may help to identify joint/bony abnormalities commonly seen in gout, findings may not be specific for gout.

Question 11.4.4 In general, all of the following are risk factors for gout EXCEPT:

- A) Tobacco use
- B) Alcohol use
- C) Obesity
- D) Diuretic use
- E) Family history

Answer 11.4.4 The correct answer is “A.” Your patient exhibits many of the risk factors for gout, which include male sex, obesity, high-protein diet, use of diuretics (either loop or thiazide), alcohol, and family history. However, tobacco use is not associated with gout.

HELPFUL TIP:

Many patients with hyperuricemia do **not** develop gout or nephrolithiasis; it is unclear whether asymptomatic hyperuricemia should be treated with uric

acid-lowering agents, and research is ongoing to answer this question. What is the risk at 5 years? Risk is 0.33% if the uric acid is <6 mg/dL, and 26% if the baseline level is >10 mg/dL. At 15 years, it is 49% for the highest risk group (baseline uric acid >10 mg/dL). Let the uric acid level guide you when deciding whether to treat otherwise asymptomatic hyperuricemia (*Ann Rheum Dis.* 2018;77:1048).

Question 11.4.5 Which of the following is the *next step* in the management of this patient?

- A) Prescribe allopurinol
- B) Prescribe acetaminophen
- C) Discontinue chlorthalidone
- D) Prescribe naproxen at a full anti-inflammatory dose
- E) Perform a therapeutic joint aspiration

Answer 11.4.5 The correct answer is “D.” An acute attack of gout should first be treated with NSAIDs, such as naproxen or indomethacin. The doses prescribed should be at the upper limit for the particular NSAID (e.g., naproxen 500 mg three times daily). Earlier treatment is associated with greater relief of symptoms and shorter duration of the acute event. Other potential first-line agents are colchicine and corticosteroids. The effectiveness of colchicine is best if started within 36 hours of onset of symptoms. Colchicine is typically prescribed as one dose of 1.2 mg, followed by 0.6 mg twice daily for 1 to 2 weeks, and then 0.6 mg daily for 2 to 6 months. Note that this is a much lower dose than we have prescribed in the past! Due to significant toxicity at high doses, it is no longer recommended to “titrate to diarrhea.” Oral or intra-articular corticosteroid administrations are also options for patients who have contraindications to NSAIDs, who have failed NSAID therapy, or who have more severe attacks. Corticosteroids are just as efficacious as NSAIDs and may be more appropriate for patients with heart failure, ulcers, or kidney disease. Prednisone, 30 mg/day for five days is a reasonable dose (this is the authors’ choice). Narcotic pain medication may be needed as an adjunct to your anti-inflammatory but will do nothing to shorten the duration of an attack.

“A” is incorrect. Allopurinol is indicated to treat hyperuricemia and prevent the next gout attack in patients *who have had more than one attack in the last year, when tophi are present, or, when a single gout attack occurs with chronic kidney disease grade 2 or higher.* Some will treat those with a particularly bad attack (e.g., polyarticular gout, disabling pain resistant to treatment) without regard to the frequency of attacks. “B” is incorrect because acetaminophen lacks the anti-inflammatory properties of NSAIDs and is less effective. Discontinuing chlorthalidone, “C” (a thiazide diuretic), and switching to a nondiuretic antihypertensive is probably appropriate but will not treat this gout attack. Joint aspiration is not therapeutic in gout but may be helpful in pseudogout.

**HELPFUL TIP:**

Other drugs that increase the risk of gout include ACEIs, ARBs, and beta-blockers. Calcium-channel blockers do not increase the risk of gout (*BMJ*. 2012;344:d8190).

You start an NSAID. He returns in a few days to discuss his labs and x-rays. A radiograph of the left knee demonstrates an effusion but is otherwise unremarkable. His knee pain is much improved, and knee effusion is nearly resolved. His uric acid level is 10.1 mg/dL (the upper limit of normal for your lab is 7.2 mg/dL). CBC, creatinine, sodium, and potassium are normal. You instruct the patient to reduce his alcohol intake (especially beer) and try to lose weight to decrease his risk of gout attacks and for overall health. You schedule a follow-up visit, but he is a no-show and you don't see him again for more than a year (was it something you said?). When the patient returns 18 months later, he reports frequent use of naproxen, and at least five more acute attacks of gout. He continues to consume alcohol. His examination reveals no swollen or tender joints today, but there is a small whitish subcutaneous nodule overlying a toe PIP joint. Creatinine is 1.1 mg/dL, serum uric acid 10.5 (normal < 7.2 mg/dL); liver enzymes and CBC are normal.

Question 11.4.6 Which is the most appropriate regimen to start now in this patient to reduce the frequency of gout attacks?

- A) Twice daily colchicine
- B) Daily allopurinol 300 to 600 mg
- C) Daily probenecid
- D) Daily allopurinol 100 mg, with once or twice daily colchicine
- E) Daily probenecid and allopurinol

Answer 11.4.6 The correct answer is “D.” The presence of a tophus and the history of more than one attack in the last year are both indications for starting long-term urate-lowering therapy. Colchicine administered once or twice daily has been shown to reduce the frequency of gout attacks 75% to 85% and is especially useful as prophylaxis (prevention of the next gout attack) during the first 6 to 12 months of urate-lowering therapy. But “A,” colchicine alone, is incorrect in this case because the patient now has tophaceous gout and allopurinol is indicated.

Starting allopurinol at a low dose of 100 mg daily and then increasing the dose every few weeks is less likely to provoke new gout attacks than starting at a larger dose. “B” is incorrect because it is a higher dose of allopurinol, given without prophylaxis, and could induce new gout attacks (which will make this patient think that your treatment is not very good, and that you are not a very good doctor).

Probenecid (“C” and “E”) is a uricosuric agent that also reduces the frequency and severity of acute gout attacks but has multiple drug interactions (including with allopurinol) and contraindications (e.g., decreased renal function, kidney stones, or presence of tophi). Another option for a uricosuric drug is lesinurad (Zurampic). It is more expensive than probenecid,

and can lead to increased creatinine, an influenza-like syndrome, etc. It should *only be used in combination* with allopurinol or febuxostat; otherwise it increases the risk of renal failure and kidney stones. It may not add anything to maximize allopurinol or febuxostat. In combination, it is less effective than probenecid. Bottom line: just say no to lesinurad.

You prescribe allopurinol 100 mg daily and once daily colchicine and schedule the patient to return every 2 to 4 weeks to re-check his uric acid level and make further allopurinol dose adjustments.

Question 11.4.7 The target for uric acid lowering in this patient is:

- A) Less than 7.2 mg/dL, because this is the upper limit of normal for a man his age
- B) Less than 6.0 mg/dL
- C) Less than 5.0 mg/dL
- D) Less than 3.14159 mg/dL, because precision counts
- E) As low as possible

Answer 11.4.7 The correct answer is “C.” This patient has a tophus; in order to resolve tophi, and minimize the risk for further attacks, allopurinol should be increased in 100-mg steps until his uric acid level is consistently less than 5.0 mg/dL. Uric acid crystals start to form at serum levels >6.7 mg/dL, which is within the 95% confidence range in the adult population, so within the “normal”—but not necessarily “harmless”—range. “A” is not correct, as levels higher than 6.7 mg/dL would continue to cause gout attacks and will not resolve tophaceous deposits. “B” is the correct target for patients without evidence of tophi, but <6.0 mg/dL is not sufficient in this patient. “D” is the first few digits of the mathematical constant pi. We know you didn't fall for “D.” In fact, in this patient with gout, we should encourage him to avoid pie (but not pi). Please also note that these are guidelines from the American College of Rheumatology. Like the name suggests, these are meant to guide practitioners. Depending on the patient, the target can be modified to account for individual risks and benefits. Uric acid is a normal product of purine metabolism. There have been some studies that show it may have some role in neuroprotection as well as fighting infection. Too much is bad, but too little (“E”) could be a problem as well, so we do not target uric acid to zero.

**HELPFUL TIP:**

Febuxostat (Uloric) is an alternative to allopurinol. However, it is rather expensive (10× the cost of allopurinol), and the FDA now states that there is a higher incidence of cardiovascular events in those on febuxostat when compared to allopurinol and a *higher risk of death*. Febuxostat should be reserved for use in patients who fail allopurinol. Febuxostat can be started low and titrated up, like allopurinol. It well may be off the market some time during the life of this publication because of the increased cardiac mortality.

**HELPFUL TIP:**

Although colchicine is recommended as prophylaxis when allopurinol is initiated, it should be discontinued within 6 months (if possible) due to the potential side effects of GI irritation, diarrhea, and myopathy.

Question 11.4.8 All of the following are side effects of allopurinol EXCEPT:

- A) Aseptic meningitis
- B) Rash
- C) Leukopenia
- D) Fever
- E) GI disturbance

Answer 11.4.8 The correct answer is “A.” Additional side effects include elevated liver enzymes, glomerulonephritis, aplastic anemia, and vasculitis. Hypersensitivity reactions are especially common—with incidence rates as high as 15%—in some Asian populations (e.g., Chinese, Koreans, Thais). Consider checking for HLA-B*5801 in these groups before starting allopurinol. Not a pretty drug, but look on the bright side... it’s not associated with meningitis!

**HELPFUL TIP:**

Probenecid should be avoided in patients with a creatinine of clearance <50 mL/min, as it is ineffective and there may be an increased risk of toxicity.

It is 9 years later. Congress has passed a law banning the Kardashians from being on TV (the sad part is that we have had this same joke in multiple editions and the Kardashians *still* haven’t gone away!). Your favorite gout patient is back. He’s had 9 years of acute intermittent gout attacks (“Of course I took my medication, Doc, but it didn’t work so I stopped taking it”). He presents complaining of pain in his knees and feet that has been present for several months. He has also developed swelling and pain in his hands. The pain is less intense than his attacks of gout, but occurs in the same areas and never completely resolves between attacks. He has no morning stiffness, no muscle complaints, and no other systemic complaints. You find diffuse edema of both hands and palpable hard nodules on the knees, fingers, toes, and in the olecranon bursa.

Question 11.4.9 Which of the following is the most likely cause of his current symptoms?

- A) RA
- B) Osteoarthritis
- C) Tophaceous gout
- D) PMR

Answer 11.4.9 The correct answer is “C.” This patient has a long history of acute intermittent gout. After years of acute attacks, patients with gout may develop a form of the disease called chronic tophaceous gout (the nodules are deposits of uric

acid called tophi; tophus for a single nodule), in which the intercritical periods are no longer free of pain. There are no clinical associations between gout and the other rheumatic conditions mentioned and, therefore, no reason to suspect that another rheumatic disorder is causing the chronic pain.

**HELPFUL TIP:**

Hyperlipidemia occurs in 80% of patients with gout—check lipids. Recall also that there can be renal injury with longstanding gout as well as an increased risk of urate stones.

**HELPFUL TIP:**

In addition to being a fun word, podagra (from the Greek meaning “foot seizure”) is a useful diagnostic tool. The first MTP joint is affected in 90% of patients with gout, and the initial attack involves the first MTP joint in 50%.

► **Objectives: Did you learn to ...**

- Evaluate recurrent monoarthritis?
- Describe the diagnostic synovial fluid findings in gout?
- Define diagnostic criteria for gout?
- Manage a patient with gout and describe adverse effects of the medications used to treat gout?
- Identify the appropriate target uric acid level for urate-lowering therapy?

► **CASE 11.5**

Citing your characteristic compassion and attention to detail, your “gout guy” (as he now calls himself) refers a friend he met at a meeting of his favorite club, Gouty Retirees in Love with Life (“GRILL”). This friend of his is a 65-year-old female who reports a history of joint swelling, pain, and redness, usually involving her knees, wrists, and hands; she has never had first MTP joint involvement. Although she has never had a joint aspiration performed, she has been treated for gout for 5 years. She faithfully takes her medication but has found allopurinol unhelpful. She is currently asymptomatic but uses ibuprofen for acute attacks. The joint examination is notable only for some knee crepitus and reduced wrist range of motion—but, again, she is currently asymptomatic.

Question 11.5.1 Which of the following studies is most appropriate for this patient?

- A) Diagnostic knee injection with corticosteroids
- B) CBC
- C) RF
- D) Radiographs of the knees and wrists

Answer 11.5.1 The correct answer is “D.” The initial evaluation should include radiographs of the affected joints, which may lend clues to the diagnosis. Radiographs may reveal

osteophyte formation typical of osteoarthritis, subchondral cysts, chondrocalcinosis typical of CPPD (calcium pyrophosphate dehydrate crystal deposition disease), or erosions with an overhanging edge typical of gout. Chondrocalcinosis is most often seen in the knees and triangular fibrocartilage of the wrists. “A,” an injection of corticosteroids, might help relieve symptoms, but it will not be diagnostic. “B,” CBC, is nonspecific and will not be helpful. “C,” RF, is also unlikely to be helpful, given this patient’s symptoms, which are not suggestive of RA. Also, RF may be elevated in inflammatory arthritides other than RA.

HELPFUL TIP:

The crystals of gout (uric acid) and pseudogout (calcium pyrophosphate) can be seen in synovial fluid during intercritical periods. If there is an effusion even in the absence of acute symptoms and you are thinking gout or pseudogout, tap that joint!

HELPFUL TIP:

The diagnosis of pseudogout (CPPD) is not as straightforward as gout. To confuse the clinician all the more, CPPD tends to travel with other types of arthritis (e.g., osteoarthritis, gout). Patients with CPPD are more likely older than 65 and have knee arthritis, but clinical criteria alone are insufficient for the diagnosis, which requires demonstration of crystals in the joint fluid.

Your patient’s knee radiographs demonstrate chondrocalcinosis (see Fig. 11-1). Examination of synovial fluid from the knee shows positively birefringent, rhomboid crystals consistent with CPPD (pseudogout). Maybe this is why her gout medicine wasn’t working....

FIGURE 11-1. Chondrocalcinosis of the knee joint. (Note arrows highlighting calcification.)

Question 11.5.2 Which of the following do you recommend to decrease her risk of recurrent acute attacks of pseudogout?

- A) Serial joint aspiration
- B) Daily allopurinol
- C) Twice daily colchicine
- D) Serial intra-articular corticosteroid injections
- E) Chondroitin sulfate

Answer 11.5.2 The correct answer is “C.” Pseudogout is diagnosed by the presence of CPPD crystals (as described) in synovial fluid and/or typical x-ray findings (basically, chondrocalcinosis). Although prophylaxis is more predictably successful in gout, colchicine 0.6 mg BID has been shown to reduce the frequency of pseudogout attacks in CPPD. NSAIDs or colchicine may be used in acute attacks with prednisone/steroids as third line (whereas they can be used as first line in gout). “A” and “D” are incorrect. While joint aspiration and corticosteroid injection may be helpful during acute attacks, they have no role in prophylaxis. “B” is also incorrect. Since CPPD is not caused by abnormalities in uric acid metabolism, allopurinol has no role in the management of pseudogout. Finally, chondroitin sulfate (“E”) is not useful in pseudogout (or much of anything else, for that matter).

HELPFUL TIP:

Gout is more likely to occur during middle age and is more common in men. Pseudogout has a peak incidence later in life and is about equally prevalent in both males and females.

Question 11.5.3 CPPD (pseudogout) is associated with which of the following?

- A) Hypothyroidism
- B) Hyperparathyroidism
- C) Amyloidosis
- D) Hemochromatosis
- E) All of the above

Answer 11.5.3 The correct answer is “E.” All of the above are associated with pseudogout. Additional associated conditions include hypophosphatemia and hypomagnesemia. For this reason, order the following studies in patients newly diagnosed with CPPD: thyroid-stimulating hormone (TSH), calcium, phosphate, magnesium, transferrin saturation, and alkaline phosphatase.

HELPFUL TIP:

Precipitants of acute attack of gout and pseudogout (CPPD) include trauma, surgery, severe medical illness, and alcohol overindulgence.

► Objectives: Did you learn to ...

- Identify clinical and diagnostic characteristics of CPPD?
- Implement appropriate therapy for CPPD?

QUICK QUIZ: CRYOGLOBULINEMIA

Cryoglobulinemia, a vasculitic disease caused by antibodies that precipitate in cold temperatures, is most often caused by which of the following viral infections?

- A) HIV
- B) Hepatitis B
- C) Hepatitis C
- D) Parvovirus B19

The correct answer is “C.” Hepatitis C is found in 80% of vasculitis cases associated with mixed cryoglobulinemia. Although up to 50% of patients with hepatitis C will eventually express cryoglobulins, only a minority of patients have clinical vasculitis. As to the other options, hepatitis B and parvovirus B19 infection may cause a symmetric polyarthritides. HIV is less commonly a cause of cryoglobulinemia and is associated with reactive arthritis. The symptoms of mixed cryoglobulinemia associated with HCV infection typically include arthralgias, fever, renal disease, palpable purpura, and neuropathy.

► CASE 11.6

A 13-year-old male presents to your office with his father. The patient complains of pain in his wrists, elbows, and knees bilaterally. He has felt fatigued and has been unable to work his usual summer job as a busboy at his father’s restaurant (what happened to child labor laws?). He complains of intermittent fevers and an evanescent rash that appears during febrile episodes but which is short-lived. All of these symptoms have emerged in the last 6 weeks, after a week-long backpacking trip in the tick-infested woods of Minnesota. He has no significant past medical history. His only medication is acetaminophen daily for joint pain. He denies tobacco use, alcohol use, and sexual activity.

Question 11.6.1 The differential diagnosis should include all of the following EXCEPT:

- A) Lyme disease
- B) JIA
- C) PMR
- D) Viral illness

Answer 11.6.1 The correct answer is “C,” of course. From earlier in the chapter, you will recall that the diagnosis of PMR is highly unusual in adults under the age of 50. JIA is a chronic arthritis of childhood that can present in a variety of ways, but must include arthritis of one or more joints, lasting 6 weeks or more, with symptom onset before age 16 years. Likewise, Lyme disease has several presentations, presenting with arthritis early or late in the course. Many viral illnesses can result in arthralgia and/or arthritis. Any of the diseases listed may have associated

symptoms of fatigue, malaise, headache, and myalgia. One factor that makes Lyme disease a more likely diagnosis is the history of being outdoors in an endemic area (90% of Lyme disease in the United States occurs in New York, New Jersey, Connecticut, Rhode Island, Massachusetts, Pennsylvania, Wisconsin, and Minnesota—although the geographic distribution is widening slightly).

Question 11.6.2 Which of the following findings on physical examination would be more consistent with Lyme disease than JIA?

- A) Bell palsy
- B) Temperature $\geq 38^{\circ}\text{C}$
- C) Rash
- D) Lymphadenopathy
- E) A and C

Answer 11.6.2 The correct answer is “A.” All of the other findings are seen in both Lyme disease and JIA. Neurologic symptoms, including Bell palsy (“A”) and even meningitis, may occur with Lyme disease but not JIA. Rash (“C”) is present in both diseases but differs substantially. The characteristic rash of Lyme disease is erythema migrans. The rash of systemic-onset JIA (also known as Still disease) is macular, salmon-pink, and brought on by heat. Erythema migrans occurs in about 80% of patients with acute Lyme disease. The lesion is often described as “targetoid,” meant to convey a red circular rash with central clearing. However, most patients do not have the classic lesion. Instead, most patients present with a mildly to brightly erythematous patch in the axilla or belt line, where the tick bite occurs. The tick itself is rarely seen. Erythema migrans is usually not painful or pruritic. Both Lyme disease and JIA may have associated systemic findings, including fever and lymphadenopathy, so neither “B” nor “D” is a good discriminator.

HELPFUL TIP:

There is a “new” form of Lyme disease in the upper Midwest caused by *Borrelia mayonii* (why does this have to happen to Iowa?). Rather than the typical bull’s eye rash, it can present with a diffuse rash, perhaps neurologic symptoms, nausea, vomiting, and a spirochetemia often visible on dark-field examination. So far it is uncommon and limited to the upper Midwest (see <https://www.cdc.gov/ticks/mayonii.html>).

Physical examination reveals a thin male in no acute distress. His temperature is 37.3°C , pulse 100 bpm, and blood pressure 120/70 mm Hg. Small, nontender, mobile lymph nodes are palpable in the neck and axillae. There is a large, warm, erythematous patch with central clearing at the patient’s left axilla. There is limited range of motion in his right wrist and left elbow. An effusion is palpable at the left knee, which is diffusely tender.

Question 11.6.3 If you were to aspirate the patient's knee—so often the right answer in this chapter—which of the following would you expect to find in the synovial fluid?

- A) Greater than 100,000 WBC/mm³
- B) Predominance of eosinophils
- C) Monosodium urate crystals
- D) Spirochetes
- E) Predominance of polymorphonuclear cells

Answer 11.6.3 The correct answer is “E.” This patient is presenting now with classic features of Lyme disease. If synovial fluid is obtained in a patient with Lyme arthritis, analysis of the fluid reveals leukocytes, most commonly polymorphonuclear cells. “A” is incorrect. If the synovial fluid has >100,000 WBC/mm³, you should consider septic arthritis (arthritis in Lyme disease is mostly an immunological phenomenon rather than true septic arthritis. But remember that more often patients with a septic joint have <100,000 WBC/mm³). “B” is incorrect because eosinophils are not the predominant cell in synovial fluid of Lyme arthritis. “C” is wrong since monosodium urate crystals are observed in gout—an unlikely cause of this patient's joint complaints. Finally, “D” is wrong. In general, *Borrelia burgdorferi* spirochetes, the causative organism in Lyme disease, are not observed in the synovial fluid.

You strongly suspect Lyme disease. Because it is so swollen, you aspirate the joint and find slightly cloudy yellow fluid, with cell count 10,000/mm³, and 95% polymorphonuclear cells. Gram stain is negative, and culture was subsequently found to be negative.

Question 11.6.4 Which of the following is true regarding laboratory tests for Lyme disease?

- A) Serologic tests are reliable within 1 week of the tick bite
- B) Serologic tests are useful in screening for Lyme disease
- C) Blood cultures remain positive for *B. burgdorferi* for months after the tick bite
- D) Serologic tests remain positive for up to 10 years after antibiotic treatment
- E) The diagnosis of Lyme disease is based on serologic tests

Answer 11.6.4 The correct answer is “D.” Serologic tests for Lyme disease can remain positive for up to 10, and in some cases 20, years after exposure. Thus, serologic tests alone are not diagnostic of active Lyme disease. “E” is incorrect: the diagnosis of Lyme disease is clinical with laboratory tests used to confirm the diagnosis. A positive ELISA test is not adequate to make the diagnosis of Lyme disease. Positive or equivocal ELISA tests should be confirmed with Western blot analysis. “A” is incorrect: serologic assays may be falsely negative early in infection. Only 20% to 40% will have a positive serology at the time of presentation (e.g., when the rash is present). Serology is more likely to be positive if they present with Lyme carditis or CNS *Borrelia*. “B” is incorrect. Lyme serology is set to be a very sensitive test: there are few false negatives assuming enough time has elapsed since *Borrelia* exposure, but it is not highly specific and there are many false positives. Because of the high false-positive

rate, serologic assays should not be used as a screening tool in the general population but are a good step when Lyme disease is suspected. Most laboratories will automatically do a Lyme Western Blot study to confirm positive Lyme serology. “C” is incorrect: positive blood cultures for *B. burgdorferi* are rarely obtained. When cultures do grow *B. burgdorferi*, it is only early in the disease. Cultures of skin biopsied from the erythema migrans lesion are more likely to be positive. **The CDC now also endorses doing two FDA approved ELISA (EIA) tests either simultaneously or serially instead of a Western Blot.** (see: MMWR August 16, 2019 / 68(32);703).

Question 11.6.5 For this 13-year-old patient, whose weight is 50 kg and who has no known allergies, which course of therapy is safest and most efficacious?

- A) Amoxicillin 500 mg by mouth three times daily for 1 week
- B) Ceftriaxone 2 g IM, single dose
- C) Doxycycline 100 mg by mouth twice daily for 4 weeks
- D) Levofloxacin 250 mg by mouth daily for 2 weeks
- E) Erythromycin 250 mg by mouth four times daily for 4 weeks

Answer 11.6.5 The correct answer is “C.” Recommended therapy for Lyme arthritis (without neurologic disease) is 4 weeks of either amoxicillin 500 mg three times daily, doxycycline 100 mg twice daily, or cefuroxime axetil 500 mg twice daily. The old chestnut that *doxycycline* causes tooth staining has been disproven (<https://www.cdc.gov/rmsf/doxycycline/index.html>). So, doxycycline can be used in younger patients (even children <5 year olds) if needed (e.g., Rocky Mountain Spotted Fever). *The same thing is not true for tetracycline which does stain the teeth.* The duration of amoxicillin prescribed here is too short, so “A” is wrong. Ceftriaxone is prescribed when neurologic abnormalities are present (such as Bell palsy or meningitis), and it must be dosed daily for 2 to 4 weeks. Levofloxacin is not indicated for Lyme disease. Treatment with erythromycin for 4 weeks, while an acceptable alternative, appears to be less efficacious.

HELPFUL TIP:

There is no known resistance of *B. burgdorferi* to standard antibiotic regimens. One round of treatment is enough.

Several hours after starting antibiotics, the patient's father calls to report worsening symptoms of fever, shaking, and dizziness. You hear his lawyer talking in the background...

Question 11.6.6 You recognize this condition as which of the following?

- A) An allergic reaction to the antibiotic
- B) *B. burgdorferi* sepsis
- C) Secondary bacterial infection
- D) A cytokine-mediated reaction to the antibiotic-mediated killing of spirochetes (Jarisch–Herxheimer reaction)
- E) The expected, natural course of Lyme disease

Answer 11.6.6 The correct answer is “D.” A Jarisch–Herxheimer reaction occurs in 5% to 15% of patients treated with antibiotics for Lyme disease. (Remember syphilis? Lyme is also a spirochete disease.) The reaction is mediated by the release of cytokines and occurs within hours of initial administration of antibiotics. In Lyme disease, the reaction is self-limited and usually resolves within a day. Only supportive treatment is necessary, and antibiotics should be continued (but hey, you know you got the diagnosis right!). “A” is incorrect because this reaction is not typical of a drug allergy. “B” is incorrect because *B. burgdorferi* does not cause sepsis. “C” is incorrect because it is unlikely that a secondary bacterial infection has occurred so quickly. Finally, this does not represent the natural history of Lyme disease (“E”). See Table 11-5 for more on the natural history of Lyme disease.

HELPFUL TIP:

Lyme disease symptoms typically improve a few days after starting antibiotics.

Since he spends much of his free time hunting deer in Minnesota (trying to shoot Bambi), your patient’s father is worried about contracting Lyme disease himself.

Question 11.6.7 What do you recommend for primary prevention of Lyme disease?

- A) Weekly tick checks
- B) N,N-diethyl-m-toluamide (DEET) application prior to hunting
- C) Daily doxycycline when in endemic areas
- D) Lyme vaccine
- E) Kill as many deers as possible in order to reduce the risk of Lyme disease transmission to humans

Answer 11.6.7 The correct answer is “B.” Primary prevention is best accomplished with the use of insect repellents when in endemic areas. Also, when in endemic areas, tick checks should be performed daily (not weekly as in answer “A”). A tick that has been attached for <24 hours is not likely to transmit

B. burgdorferi. Unfortunately, the species that transmit Lyme disease (ticks of the *Ixodes ricinus* complex) are very small and difficult to see. “C” is incorrect. There is no role for routine prophylactic antibiotics. However, if a tick bite from the appropriate species is noticed, a single dose of doxycycline 200 mg administered orally reduces the risk of erythema migrans (see “Helpful Tip” below for prophylaxis criteria). The dose should be administered within 72 hours of a known *I. ricinus* tick bite. “D” is not an option for this patient. In 2002, the vaccine was removed from the U.S. market due to low demand. When it was available, antibody titers tended to wane quickly and protection was not complete. After the administration of three vaccinations, the efficacy of the vaccine to prevent Lyme disease was 76% at best. “E” is just plain wrong ... what with Bambi and all ... And furthermore, the white-footed field mouse, not the white-tailed deer, is the major reservoir of *B. burgdorferi* bacteria.

HELPFUL TIP:

Who should get prophylactic doxycycline for a tick bite? According to the CDC **ALL of the following need to be present** (<https://www.cdc.gov/ticks/tickbornediseases/tick-bite-prophylaxis.html>).

Prophylaxis is doxycycline 200 mg as a single dose.

1. Doxycycline is not contraindicated.
2. The attached tick can be identified as an adult or nymphal *I. scapularis* tick.
3. The estimated time of attachment is ≥ 36 hours based on the degree of tick engorgement with blood or likely time of exposure to the tick.
4. Prophylaxis can be started within 72 hours of tick removal.
5. Lyme disease is common in the county or state where the patient lives or has recently traveled to (i.e., CT, DE, MA, MD, ME, MN, NH, NJ, NY, PA, RI, VA, VT, WI).

HELPFUL TIP:

Repeat after us: there is no such thing as “chronic Lyme disease” requiring months-to-years of antibiotics. The CDC does recognize an entity called “post-Lyme disease syndrome” that may include fatigue, myalgia, cognitive slowing, and numbness. However, post-Lyme disease syndrome does NOT improve with prolonged antibiotics. Focus on looking for other causes (e.g., depression, fibromyalgia, hypothyroidism) in these patients, as most of them do not have post-Lyme disease syndrome, and work to alleviate symptoms. However, avoid the temptation to prescribe antibiotics that do not work.

HELPFUL TIP:

If Lyme meningitis is suspected, confirm by analysis of CSF. Lyme meningitis must be treated with IV ceftriaxone or penicillin G.

TABLE 11-5 STAGES OF LYME DISEASE

Early localized disease (Stage I): Occurs days to a month after the tick bite and includes erythema migrans, fatigue, fever, malaise, myalgias, arthralgia, arthritis, headache, and lymphadenopathy. Except for erythema migrans, it can be confused with a viral illness.

Early disseminated disease (Stage II): Occurs weeks to months after the tick bite; 5–10% have cardiac manifestations (atrioventricular block of any degree, myocarditis/pericarditis, and heart failure); and 10–15% have neurologic manifestations (see below).

Late disease (Stage III): Occurs months to years after the tick bite and includes myalgias, arthralgias, fatigue, polyarthritis, and neurologic symptoms (encephalopathy, cognitive dysfunction, and peripheral neuropathy).

Adapted from Bhate C, Schwartz RA. Lyme disease: Part I. Advances and perspectives. *J Am Acad Dermatol*. 2011;64(4):619–636.

► **Objectives: Did you learn to ...**

- Generate a differential diagnosis for a young patient presenting with polyarthritis?
- Diagnose Lyme disease?
- Describe the stages of Lyme disease?
- Implement appropriate therapy for Lyme disease?
- Discuss preventive strategies for Lyme disease and describe some of the complications of the disease?

► **CASE 11.7**

A 42-year-old female who was referred by an orthopedic surgeon presents to your office with multiple joint complaints. The orthopedist has seen her for left knee pain, intermittent swelling, occasional “clicking and locking,” present for about 10 years. After knee radiograph and examination, the orthopedist diagnosed a chronically damaged meniscus, but he wants the patient evaluated by you for her other joint complaints.

Laboratory data ordered by her orthopedist (apparently, just to confuse you) show an ANA 1:320 (speckled pattern), an elevated rheumatoid factor, and an ESR 20 mm/hr. The patient moved to the United States from Guam 4 years ago. She reports poor sleep and feeling quite depressed. She feels that she has no friends, and she has had trouble adjusting to the colder weather. You notice she has a bottle of water with her and upon your specific questioning she states, “I have to sip some water throughout the day. I’ve done this for the last 15 years because my mouth gets so dry.” Over the past 20 years, she has had numerous fillings for dental cavities. She denies problems with skin rash, swallowing, and eye pain. She does not use artificial tears.

Question 11.7.1 Which of the following findings in *this* patient is most likely to be a *sign of inflammatory arthritis*?

- Spider angiomas (telangiectasia) on the back and abdomen
- A small cool left knee effusion (“bulge sign”) with crepitus
- Presence of 16/18 fibromyalgia tender points, with non-tender control points
- Incomplete left grip
- Presence of a holosystolic murmur at the left sternal border, without radiation

Answer 11.7.1 The correct answer is “D.” Although her symptoms are suggestive of fibromyalgia and depression, it is critical to differentiate between an inflammatory and a noninflammatory condition, especially since many inflammatory disorders (e.g., SLE, RA, Sjögren syndrome) may masquerade as fibromyalgia. An incomplete grip in an otherwise healthy woman is suggestive of synovitis, which can be further assessed by careful small joint examination. When synovitis is present, it is always abnormal and suggests an inflammatory arthritis, requiring further evaluation. “A” is incorrect because telangiectasias on the abdomen and trunk are typically related to liver disease,

while those found on hands and nail beds are associated with systemic sclerosis and other rheumatic diseases. “B,” a positive knee “bulge sign” (swelling of the knee joint that bulges inferiorly when compressed superiorly) indicates fluid in the left knee joint. But from the patient’s history and your orthopedic colleague’s determination, this finding is chronic and mechanical in nature. “C,” the presence of 16/18 tender points, would argue for fibromyalgia but is not a sign of inflammatory arthritis. Additionally, identifying greater than 11 out of 18 tender points is no longer part of the diagnostic criteria for fibromyalgia (keep reading for details). Finally, a holosystolic murmur (“E”), localized to the left sternal border and present in a healthy young woman, is nonspecific and most likely functional. If there were other signs and symptoms of cardiac disease, the murmur might indicate a more serious disorder.

On physical examination, you find a “bulge sign” on the left knee, but no other joint swelling. She has 16/18 tender points and normal range of motion and strength. The neurological examination is grossly normal, except for poorly defined numbness and pain to touch on the left side of her face. You also notice a mildly tender, hard, nodular swelling behind the angle of the mandible on the left in the area of the parotid gland. Her oral mucosa appears dry. Her conjunctiva is mildly, symmetrically injected.

Question 11.7.2 All of the following studies and interventions are appropriate EXCEPT:

- CBC, transaminases, ESR, CRP
- Anti-SS-A (Ro), anti-SS-B (La), anti-dsDNA, RF, serum protein electrophoresis
- Prescribe trazodone 50 mg PO at bedtime and recommend aerobic exercises
- Prescribe prednisone 20 mg PO daily, with calcium and vitamin D supplement
- Maxillofacial MRI

Answer 11.7.2 The correct answer (and the thing to avoid right now) is “D.” Although prednisone may be used to treat symptoms of autoimmune diseases, at this time the diagnosis is not secure, and initiating corticosteroid therapy exposes the patient to potentially unnecessary risk. She has findings of Sjögren syndrome—red (possibly dry) eyes, dry mouth, and enlarged parotid glands. However, the differential of mass in the parotid gland must include malignancy (e.g., lymphoma), sarcoidosis, and other autoimmune diseases. The laboratory tests offered in answers “A” and “B” may help assess other organ involvement of Sjögren syndrome and also aid in confirming the diagnosis. Other potential manifestations of Sjögren syndrome include generalized vasculitis, interstitial lung disease, cirrhosis, peripheral and cranial neuropathies, possibly thyroid disease, and renal disease leading to proteinuria and renal tubule dysfunction. Although not listed as an option, chest radiograph may also be helpful, assessing for findings associated with the diseases on your differential: Sjögren syndrome (interstitial lung disease), sarcoidosis (adenopathy and interstitial

disease), and lymphoma (adenopathy). “E” is also important because although parotid enlargement may be seen in Sjögren syndrome, it is usually symmetrical and nontender. An imaging study is appropriate to rule out a neoplastic process. Finally, “C” is correct. Her symptoms of fibromyalgia, which it sounds like she also has, may respond to trazodone and exercise, and these low-risk interventions are appropriate at this juncture. Remember, the presence of one disease, in this patient likely Sjögren, does not protect against another disease (fibromyalgia).

She starts trazodone and exercise and feels better. The tests you order return as follows: negative SSA, SSB, and dsDNA; elevated RF; no monoclonal protein on SPEP but diffusely elevated globulins. A chest x-ray is normal. Her ESR is 35 mm/hr and CRP 0.5. A maxillofacial MRI shows an enlarged left parotid, with an ill-defined 2 × 3 × 1.5 cm dense signal in the center without neurovascular compromise.

Question 11.7.3 What is the most appropriate next step in the management of this patient?

- A) Continue your current management and adopt a “watchful waiting” approach
- B) Refer for biopsy of the left parotid
- C) Initiate prednisone 20 mg PO daily, with calcium and vitamin D
- D) Refer for minor salivary gland biopsy (lip biopsy)
- E) MRI of the head and neck

Answer 11.7.3 The correct answer is “B.” Wait... We’re performing biopsies on masses in the rheumatology chapter? Yes. Even though her presentation is suggestive of Sjögren syndrome, the presence of a mass-like formation on MRI is concerning for lymphoma, and further evaluation (e.g., biopsy) is required. In addition, the negative SSA and SSB, while not excluding Sjögren syndrome, will make a biopsy necessary for diagnosis. Although a minor salivary gland biopsy (“D”) is the most specific way to confirm a diagnosis of Sjögren syndrome, the first priority is to evaluate the parotid gland mass. The elevated RF and polyclonal gammopathy are consistent with Sjögren syndrome, and the ESR may be elevated due to increased globulins. MRI of the head and neck (“E”) may provide some structural information, but it is not in the diagnostic criteria for Sjögren Syndrome.

Results of the parotid gland biopsy report read, “Lymphocytic infiltrate, no malignant cells noted.” You then order flow cytometry, and it has no markers for lymphoma. Her biopsy scar has healed nicely, and she has no pain or numbness. You believe that she probably has Sjögren syndrome.

Question 11.7.4 What would you do next?

- A) CT chest/abdomen/pelvis
- B) Start prednisone 20 mg by mouth daily, with calcium and vitamin D
- C) Recommend sugarless lemon drops and artificial tears as needed and continued trazodone and exercise
- D) Wide excision of the parotid gland

Answer 11.7.4 The correct answer is “C.” Lemon drops (or anything sour for that matter) will stimulate saliva production, helping with her dry mouth. Artificial tears may also be indicated for dry eyes. At this time your working diagnosis is Sjögren syndrome, and definitive diagnosis by minor salivary gland biopsy (from the buccal mucosa of the lower lip) is not likely to alter your therapy; and “D” is way too aggressive anyway. Since she has responded to trazodone and exercise and there is no evidence of systemic involvement, no further anti-inflammatory therapy (“B”) is warranted. If she were to develop arthritis or other signs of systemic involvement (e.g., cognitive dysfunction or peripheral neuropathy), prednisone would be an option. Further workup for lymphoma, such as CT scanning (“A”), does not appear warranted. However, she will require active surveillance, since patients with Sjögren syndrome carry an increased risk of developing lymphoma.

HELPFUL TIP:

Sicca symptoms (dry eyes and mouth) are extremely common, especially in the elderly, and should be confirmed by objective physical findings. The diagnosis of Sjögren syndrome is suggested by presence of anti-SS-A, or positive ANA titer (1:320 or greater) with elevated RF (as in the patient above), but definitive diagnosis of Sjögren syndrome relies on histopathologic gland findings on minor salivary gland (lip) biopsy.

► Objectives: Did you learn to ...

- Describe the appropriate evaluation of polyarthralgia and sicca symptoms?
- Evaluate a patient with probable Sjögren syndrome?
- Implement appropriate therapy for Sjögren syndrome?

► CASE 11.8

Once again, your fabled diagnostic and therapeutic abilities have earned you a well-deserved referral. Your previous patient is so pleased with the way things are going that she refers her sister-in-law to you. The sister-in-law is 46 years old and reports having been diagnosed with fibromyalgia several months ago. She reports having all-over pain, all the time, which has been worsening for the last 5 years. “Great,” you think to yourself, “Thanks for the referral.” She takes only acetaminophen and codeine as needed for pain (she typically needs it four times per day). She does not exercise because it hurts too much. She drinks 2 liters of Mountain Dew a day, from sun-up to sun-down. Her sleep is reported as poor and nonrestorative.

Question 11.8.1 Which of the following statements is true regarding management of fibromyalgia?

- A) Fibromyalgia pain is increased during exercise, so exercise should be avoided
- B) Regular low-impact exercise, and nonpharmacologic measures to improve sleep are more effective than medications for improving fibromyalgia-type pain

- C) SNRI agents such as duloxetine and milnacipran lead to rapid and long-term remission of fibromyalgia-type pain
- D) Both NSAIDs and prednisone are helpful in reducing fibromyalgia pain
- E) Opioids act on the central nervous system, which is why they are the most effective agents for treatment of fibromyalgia pain

Answer 11.8.1 The correct answer is “B.” Improved sleep through good sleep hygiene and regular low-impact exercise are often more effective than medications for reducing fibromyalgia-type pain. Indeed, improving sleep and exercise (and identifying any underlying sleep disorder) are central to long-term management. “A” is incorrect: even when exercise is poorly tolerated due to pain, a program of stretching and gradually increasing exercise is very helpful in reducing pain over time. SNRI agents are helpful for reducing central pain sensitization, and are important adjunctive treatment to sleep and exercise, but they are not curative and do not provide rapid pain relief. “D” is incorrect: NSAIDs and prednisone are not effective for fibromyalgia-type pain. Opioids do act on the central nervous system and can lead to short-term reduction of fibromyalgia-type pain, but at the same time they increase central pain sensitization which can actually lead to worsening of pain (opioid-induced hyperalgesia).

Question 11.8.2 Which of the following is NOT an appropriate medication for treating fibromyalgia-type pain?

- A) Hydrocodone/acetaminophen
- B) Gabapentin or pregabalin
- C) Amitriptyline
- D) Duloxetine
- E) Combination duloxetine and pregabalin

Answer 11.8.2 The correct answer is “A.” Is there a theme emerging here? Opioids will provide a short-term reduction in pain, but tend to worsen central sensitization and actually increase fibromyalgia pain over time; they should be avoided in managing this type of pain. All of the other agents have shown modest efficacy in improving pain associated with fibromyalgia. Low dose tricyclic antidepressants have the best efficacy. SNRI agents such as duloxetine may be combined with a gabapentin or pregabalin, as can tricyclics.

HELPFUL TIP:

Fibromyalgia is a common syndrome characterized by diffuse chronic pain accompanied by other somatic symptoms such as poor sleep, fatigue, and stiffness, in the absence of another identifiable disease. In order to diagnose fibromyalgia, symptoms must be present for at least 3 months and other chronic pain conditions must be excluded. However, an exhaustive search for occult disease is not recommended. Most diagnoses can be made with history, physical examination, and minimal labs (e.g., CBC, CRP, ESR to rule out inflammatory disease).

The 1990 American College of Rheumatology criteria included identification of pain on palpation at 11 or more of 18 tender points (Fig. 11-2), but as of 2010, this minimum number is no longer required to establish a diagnosis. There is still value in examining these tender points, and a higher number of tender points are associated with higher likelihood of fibromyalgia. However, you need not have 11 of 18. Also, self-administered scales, such as the Widespread Pain Index, may be useful in diagnosing fibromyalgia. There is a female predominance in fibromyalgia, with up to 75% of patients being women.

Question 11.8.3 All of the following are associated with fibromyalgia EXCEPT:

- A) Irritable bowel syndrome
- B) Subjective fullness/swelling of hands and feet
- C) Paresthesias
- D) Fatigue
- E) Night sweats

Answer 11.8.3 The correct answer is “E.” All of the others are associated with fibromyalgia. Additional symptoms include headaches, depression, sleep disturbance (which may actually be the etiology), other GI symptoms, and urethral spasm with dysuria and urgency.

HELPFUL TIP:

Although some SNRIs (Duloxetine, Savella, Venlafaxine) are FDA approved for fibromyalgia, they are not as effective as the TCAs.

► Objectives: Did you learn to ...

- Identify typical symptoms of fibromyalgia?
- Define diagnostic criteria for fibromyalgia?
- Implement appropriate therapy for fibromyalgia?

QUICK QUIZ: SECONDARY OSTEOARTHRITIS

All of the following diseases and conditions are secondary causes of osteoarthritis EXCEPT:

- A) Fibromyalgia
- B) Hemochromatosis
- C) Hyperparathyroidism
- D) Amyloidosis
- E) Previous joint trauma

The correct answer is “A.” One of the most common secondary causes of osteoarthritis is previous joint trauma. Systemic diseases that can lead to osteoarthritis include hemochromatosis, hyperparathyroidism, and amyloidosis. Fibromyalgia does not cause osteoarthritis. Any disease that leads to a neuropathy, such as diabetes, can predispose to osteoarthritis (e.g., Charcot arthropathy).

FIGURE 11-2. Tender points in fibromyalgia.

► CASE 11.9

A 25-year-old female presents to your office complaining of bifrontal headaches, occurring intermittently over the last year. Also, she complains of fatigue that seems to be slowly worsening. Over the last 2 to 3 months, she has developed generalized joint pain and stiffness. The remainder of the history, including a detailed review of systems, is unremarkable.

On physical examination, you find a thin female in no acute distress. She is afebrile with a blood pressure of 110/62 mmHg and a pulse of 72 bpm. The joint examination shows full range of motion and no swelling. There is mild anterior cervical lymphadenopathy. Close inspection of her skin reveals erythema of the malar eminences and the nose laterally, *with involvement of the nasolabial folds*. You note flaking and scaling in the eyebrows.

Question 11.9.1 The RASH is most characteristic of which of the following diagnoses?

- A) Dermatomyositis
- B) Systemic lupus erythematosus (SLE)
- C) Seborrheic dermatitis
- D) Psoriasis

Answer 11.9.1 The correct answer is “C.” The classic rash of SLE is the malar, or “butterfly,” rash with erythema over the malar eminences, bridging over the base of the nose. However,

the nasolabial folds are spared with the lupus malar rash. Involvement of the nasolabial fold characteristically occurs in seborrheic dermatitis. Additionally, the flaking of the eyebrow skin would be consistent with seborrheic dermatitis. In dermatomyositis (“A”), facial lesions involve the upper lids and have a light reddish-purple hue (the so-called “heliotrope rash”). Flat-topped, violaceous papules over the knuckles (Gottron papules) are classic features of dermatomyositis. The typical lesions of psoriasis (“D”) include erythematous papules and plaques with silvery scales, noted more commonly on extensor surfaces.

Question 11.9.2 Which of the following diagnoses or descriptions most accurately describes your patient’s disease process at this point in time?

- A) Fibromyalgia
- B) Somatoform disorder
- C) Polyarthrititis
- D) Polyarthralgia
- E) Rheumatoid arthritis

Answer 11.9.2 The correct answer is “D.” Your patient complains of pain in multiple joints but has no findings of inflammation of the joints; therefore, the designation of “polyarthralgia” fits best at this time. If multiple joints were inflamed, you would

use the term polyarthritis. At this time, you do not have enough information to make any of the other diagnoses.

You screen for depression and anxiety and find neither. You recommend acetaminophen for joint pain and headaches and encourage her to exercise regularly. She returns 2 months later feeling worse. She has severe fatigue and joint pain, most commonly involving her hands and knees. She has taken a leave of absence from her job as a high school English teacher. New symptoms include sores in her mouth as well as chest pain, which is worse with inspiration. On examination, you note the presence of a cardiac friction rub. There is diffuse tenderness to palpation of both knees and a small effusion apparent in the left knee. Her left hand demonstrates slow, incomplete grip. The facial rash is barely noticeable. There are two nontender ulcerations of the oral mucosa. The remainder of the examination is unchanged from her previous visit.

Question 11.9.3 Her disease process and current findings are most suggestive of which of the following diagnoses?

- A) Lymphoma
- B) SLE
- C) Fibromyalgia
- D) Reactive arthritis
- E) Limited scleroderma (CREST syndrome)

Answer 11.9.3 The correct answer is “B.” While she does not meet all the criteria for a diagnosis of SLE, this presentation is more consistent with SLE than any of the other options. Several findings point toward SLE: arthritis, cardiac friction rub (presumably due to pericarditis), and painless oral ulcers. Keep reading for more on the diagnostic criteria for SLE.

Based on your history, you recognize that your patient may be at higher than normal risk for developing SLE.

Question 11.9.4 All of the following groups have a higher incidence of SLE than the general population EXCEPT:

- A) Family members of patients with SLE
- B) Females
- C) Asian Americans
- D) Age in the third to fifth decades
- E) Caucasians

Answer 11.9.4 The correct answer is “E.” Compared to Blacks, Asians, and Latinos, Caucasians have a lower risk of SLE. The peak incidence of SLE occurs in the third to fifth decades of life. Women are 5 to 10 times more likely than men to be diagnosed with SLE. First-degree relatives of patients with SLE are at higher risk as well. Twin studies have shown a 25% to 50% concordance rate among monozygotic twins.

You consider that this might represent drug-related lupus, but your patient denies using any medications except for acetaminophen.

Question 11.9.5 In drug-related lupus, you expect to see all of the following EXCEPT:

- A) Negative ANA
- B) Rapid resolution of symptoms after discontinuing the drug
- C) Polyarthralgia
- D) Negative anti-dsDNA
- E) Low-grade fever

Answer 11.9.5 The correct answer is “A.” Patients with drug-induced lupus will generally have a positive ANA. However, it can be differentiated from SLE by a negative anti-dsDNA. Drug-related lupus presents with a lupus-like syndrome, with the most common features being arthralgias, myalgias, fatigue, malaise, and low-grade fever. Pericarditis and pleuritis are occasionally present. Skin, renal, and neurologic involvement are rare. Some common drugs that cause drug-induced lupus include hydralazine, diltiazem, hydrochlorothiazide, phenytoin, glyburide, infliximab, and etanercept.

Your patient returns with a painful, swollen left knee, and she wants to do something about it. You also discuss the following laboratory test results: WBC 5,100 cells/mm³, Hgb 11.0 g/dL, platelets 309,000 cells/mm³, BUN 10 mg/dL, creatinine 1.0 mg/dL; ESR 77 mm/hr; ANA 1:1,280 with a nucleolar pattern; urinalysis +1 protein, otherwise negative; urine microscopic examination shows no RBCs or casts; chest x-ray shows no cardiomegaly and normal lung fields; ECG shows normal sinus rhythm. You believe that your patient has SLE.

Question 11.9.6 Which of the following management plans do you suggest to the patient?

- A) Start ibuprofen 600 mg by mouth three times daily and refer to a rheumatologist (3–6 month wait—sheesh, they are busy)
- B) Start prednisone 20 mg by mouth daily and hydroxychloroquine 400 mg by mouth daily, schedule for follow-up in 1 month, and refer to a rheumatologist (3–6 month wait)
- C) Start methotrexate 10 mg by mouth weekly, prednisone 60 mg by mouth daily, and hydroxychloroquine 400 mg by mouth daily, and schedule follow-up in 1 month
- D) Start prednisone 60 mg by mouth daily and refer to a rheumatologist (3–6 month wait)
- E) Start ibuprofen 600 mg by mouth daily and adopt a “watchful waiting” approach with follow-up in 6 months

Answer 11.9.6 The correct answer is “B.” Your patient now meets diagnostic criteria for SLE, according to the American College of Rheumatology. See Table 11-6 for the diagnostic criteria for SLE. *Note that a positive ANA is only one of the criteria and is not required for the diagnosis of lupus;* however, the vast majority of patients with SLE will have an elevated ANA and negative results should make you re-think the diagnosis. Prompt treatment of her symptoms is important. NSAIDs, such as ibuprofen, are useful in treating arthralgias, mild arthritis, and mild pleurisy and pericarditis. In this case, oral (or perhaps intra-articular) corticosteroids are indicated for immediate symptomatic relief

TABLE 11-6 CLASSIFICATION CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS

SLE requires the presence of 4 of the 11 following findings, not necessarily occurring at the same time.

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral ulcers (usually painless)
5. Nonerosive arthritis (involving 2 or more peripheral joints with tenderness, swelling, or effusion)
6. Serositis (pericarditis or pleuritis)
7. Renal disorder (persistent proteinuria >0.5 g/day or cellular casts)
8. Neurologic disorder (seizures or psychosis)
9. Hematologic disorder (hemolytic anemia, leucopenia $<4,000/\text{mm}^3$ on 2 occasions, lymphopenia $<1,500/\text{mm}^3$ on 2 occasions, or thrombocytopenia $<100,000/\text{mm}^3$ in the absence of offending drugs)
10. Immunologic disorder (anti-DNA, anti-Smith, or antiphospholipid antibodies, or a false-positive serologic test for syphilis)
11. Positive ANA

Adapted from Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1982;25:1271–1277 and Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus [letter]. *Arthritis Rheum.* 1997;40:1725.

of her arthritis, and a low-to-moderate oral dose should be used (10–20 mg rather than 60 mg). Vitamin D and calcium supplements should be prescribed with the corticosteroids. Methotrexate can be used in recurrent, persistent arthritis. In the event of more serious renal, hematologic, or neurologic disease, high-dose corticosteroids are employed. Hydroxychloroquine may provide relief of musculoskeletal and constitutional symptoms and may also have a corticosteroid-sparing effect, but most important is the observation that SLE patients who take hydroxychloroquine have fewer organ-threatening lupus manifestations and fewer disease flares over time. Lupus patients who take hydroxychloroquine live longer than those who do not. Ideally, this patient should also be referred to a rheumatologist, but appropriate treatment should be started in a timely fashion. Close follow-up is necessary due to the potential adverse effects of these medications (e.g., diabetes with prednisone).

Over the next year, your patient does very well. She establishes care with a rheumatologist and is in remission when she sees you next. She is interested in becoming pregnant and wishes to seek your advice prior to trying to conceive. (“Start a college fund early,” you say. “Oh, that’s not what you meant?”) Fortunately, she has been able to discontinue prednisone and continues to tolerate hydroxychloroquine.

Question 11.9.7 With regard to pregnancy and SLE, your patient is at higher risk for all of the following EXCEPT:

- A) Premature birth
- B) Infertility
- C) Intrauterine fetal demise
- D) Spontaneous abortion

Answer 11.9.7 The correct answer is “B.” Women with SLE have a greater risk of premature birth, spontaneous abortion, and intrauterine fetal demise compared with otherwise healthy women. However, these patients appear to have comparable rates of fertility. Pregnancy outcomes are best when the patient is in remission 6 to 12 months before conception. Pregnancy appears to have a variable effect on SLE, with some patients experiencing exacerbations of the disease.

Your patient does well with her pregnancy but develops recurrent DVTs in the subsequent few years. You wish to evaluate her for antiphospholipid antibody syndrome.

Question 11.9.8 Which of the following results would you expect to find in a patient with antiphospholipid antibody syndrome?

- A) Elevated PT/INR
- B) Low PT/INR
- C) Prolonged dilute Russell viper venom time (DRVVT) that corrects with addition of platelets
- D) Elevated aPTT that corrects with addition of normal serum
- E) High-fibrin degradation products

Answer 11.9.8 The correct answer is “C.” The DRVVT assay is highly sensitive to the presence of proteins that block phospholipids, because the viper venom depletes phospholipid action. The DRVVT may be prolonged when the less sensitive aPTT is normal. When the DRVVT is prolonged, addition of platelets (as source of phospholipid) will correct the DRVVT when prolongation is due to a lupus anticoagulant.

Even though they are prone to clotting, patients with antiphospholipid antibody syndrome often have a paradoxically elevated aPTT. If this abnormality does NOT correct in vitro with addition of normal serum, it is supportive of the presence of a “lupus anticoagulant,” which is presumptive evidence of antiphospholipid antibody syndrome. If the aPTT DOES correct, think about the presence of heparin, an acquired factor deficiency secondary to an antibody (often factor VIII). These antibodies are presumptively present if mixing the patients serum with normal serum causes a prolongation of the aPTT (the opposite of anticardiolipin antibody syndrome where normal serum is mixed with the patient’s serum). “D” is incorrect, as correction of a prolonged aPTT with normal serum implies factor deficiency, not a lupus-anticoagulant, as noted above. Besides venous thrombus formation, women with antiphospholipid antibody syndrome are more likely to have late fetal demise and multiple spontaneous abortions. “A” is incorrect, as a lupus anticoagulant will not affect the prothrombin time.

HELPFUL TIP:

Antiphospholipid antibody syndrome is a clinical syndrome caused by autoantibodies to phospholipids that modulate the coagulation cascade. The term “lupus anticoagulant” refers to a subset of these autoantibodies that interfere with clotting tests such as aPTT; these

can be detected by the DRVVT. Alternatively, the presence of antiphospholipid antibodies can be determined by ELISA for anticardiolipin or beta-2-glycoprotein antibodies. However, there is only an 85% concordance between the presence of antiphospholipid antibody syndrome and laboratory detection of the causative antibodies. Antibodies must be detected on two occasions at least 12 weeks apart, and there needs to be a clinical manifestation, such as pregnancy morbidity or vascular thrombosis (arterial, venous, or small vessel). Pregnancy morbidities include: (1) more than one fetal death of a morphologically normal fetus beyond 10 weeks of gestation, (2) more than one premature birth before the 34th week of pregnancy due to pre-eclampsia, eclampsia, or placental insufficiency, or (3) more than three consecutive (pre)embryonic losses prior to 10 weeks of gestation.

**HELPFUL TIP:**

Only about 10% of patients with lupus have antiphospholipid antibodies.

Question 11.9.9 Which of the following statements is (are) true?

- A) Patients with anticardiolipin antibodies should be treated prophylactically even if they have never had an abnormal clotting event, in order to prevent venous thrombosis, stroke, or other abnormal clotting events
- B) Percent factor II activity is an appropriate way to monitor the response to heparin in patients with antiphospholipid antibody syndrome
- C) Antifactor Xa should be used to monitor the activity of enoxaparin if monitoring is required
- D) A and C
- E) B and C

Answer 11.9.9 The correct answer is “E.” Both “B” and “C” are true statements. Since patients with antiphospholipid antibody syndrome have an elevated aPTT, this value cannot be used to monitor anticoagulation with standard heparin. Percent factor II activity is the most appropriate way to monitor these patients if they are on standard heparin. Antifactor Xa is used to monitor anticoagulation with enoxaparin. “A” is incorrect because there is no evidence that prophylactic treatment reduces complications (although there is significant controversy in this area). Clearly, after a patient has had a thrombotic event, or has another indication, she needs anticoagulation.

**HELPFUL TIP:**

Unfractionated heparin, low-molecular-weight heparin, and aspirin are all used in the treatment of antiphospholipid antibody syndrome in pregnancy. Warfarin is teratogenic and is contraindicated in pregnancy

(remember, it is rat poison!). The newer anticoagulants such as dabigatran, rivaroxaban, and apixaban should not be used in pregnancy: There is not enough experience with their effectiveness, and safety is uncertain.

Question 11.9.10 Which of the following drugs used to treat lupus is associated with macular damage, corneal opacities, and ciliary muscle dysfunction?

- A) Azathioprine
- B) Prednisone
- C) Hydroxychloroquine
- D) Cyclophosphamide
- E) Methotrexate

Answer 11.9.10 The correct answer is “C.” Hydroxychloroquine is associated with macular damage, corneal opacities, and ciliary muscle dysfunction, and its use requires a baseline eye examination, and then yearly exams *after 5 years of continuous use*. The risk for significant ocular toxicity is reduced if the daily hydroxychloroquine dose is kept below 5 mg/kg/day of actual body weight which is approximately 400 mg/day for most women, and 300 mg/day for smaller women. Daily use of an Amsler grid to detect ocular toxicity had been recommended in the past. It is ineffective. Other SLE drugs and side effects are noted in Table 11-7.

► Objectives: Did you learn to ...

- Identify clinical manifestations of SLE?
- Define diagnostic criteria for SLE?
- Recognize the waxing and waning course of SLE?
- Implement appropriate treatment of the patient with SLE?
- Recognize adverse effects of medications used in the treatment of SLE?
- Describe some characteristics of antiphospholipid antibody syndrome?

TABLE 11-7 TOXICITIES ASSOCIATED WITH MEDICATIONS USED TO TREAT SLE

- NSAIDs: gastrointestinal bleeding, renal dysfunction, hypertension
- Steroids: diabetes, hypertension, hyperlipidemia, osteoporosis, cataract formation, weight gain, infections
- Hydroxychloroquine: macular damage, ciliary muscle dysfunction, corneal opacities, myopathy
- Azathioprine: infections, myelosuppression, hepatotoxicity
- Cyclophosphamide: infections, myelosuppression, hemorrhagic cystitis
- Methotrexate: infections, myelosuppression, hepatic fibrosis

► CASE 11.10

A 22-year-old white female presents to your office with the chief complaint of “blue fingers.” She reports a history of intermittent bluish discoloration of the fingertips on both hands when they are exposed to cold temperatures. Although she believes the symptoms are worse now, she cannot recall

how long they have been present. She has never had ulcers on her fingers or toes.

Question 11.10.1 With no further information, what is the most likely explanation for these digital color changes?

- A) Atherosclerotic disease of the extremities
- B) Acrocyanosis
- C) Scleroderma
- D) Physiologic response to cold

Answer 11.10.1 The correct answer is “D.” At this point all we know is that this patient’s fingers turn blue upon exposure to cold. This is a normal physiologic response—vasoconstriction in response to cold. If you’ve never experienced this, you live very close to the equator and never venture far from home. “A” is incorrect. Peripheral vascular disease is the result of atherosclerotic disease of the extremities and typically occurs in older individuals; manifestations include claudication and skin ulceration. “B” is incorrect. Raynaud phenomenon must be distinguished from acrocyanosis (a rare vasospastic disorder of persistent coldness and bluish discoloration of the hands and feet, not just fingers and toes, sometimes following a viral infection). “C” is also incorrect. Scleroderma by itself does not cause blue fingers.

HELPFUL TIP:

Over 80% of cases of Raynaud phenomenon that present to a primary care physician’s office are due to an exaggerated physiologic response to cold or emotional distress, which we call primary Raynaud phenomenon. In most primary cases, patients report the onset of symptoms in their teens or twenties. Although Raynaud phenomenon occurs in most patients with scleroderma (90–95%), scleroderma is a rare disease and is much less common than primary Raynaud phenomenon, so the converse is not true. Thus, the presence of Raynaud phenomenon is not synonymous with the presence of scleroderma. A very important clue to suggest that Raynaud is due to an underlying systemic rheumatic disease is onset after the age of 40—these patients should always have a thorough evaluation for underlying systemic causes. Other clues suggesting secondary Raynaud phenomenon include a history of severe disease (e.g., difficult to reverse attacks, digital ulcerations) or concurrent onset of new cutaneous, musculoskeletal, gastrointestinal, or cardiopulmonary problems. In these patients, an ANA titer may be helpful in further evaluation.

HELPFUL TIP:

Buerger disease (thromboangiitis obliterans) is strongly associated with tobacco abuse and presents with distal small vessel ischemia and symptoms that are similar to Raynaud phenomenon. It eventually progresses to infarction of tissue, frequently requiring digit amputation.

Further history reveals that the patient uses no medications. She has been healthy all of her life. Her mother and aunt have had blue fingers in cold temperature, too. She denies tobacco use. The review of systems is unremarkable.

Question 11.10.2 All of the following are expected findings in patients with primary Raynaud phenomenon EXCEPT:

- A) Symmetric involvement of the hands
- B) Well-demarcated cyanosis
- C) Digital ulcerations
- D) Normal ESR

Answer 11.10.2 The correct answer is “C.” Primary Raynaud phenomenon is diagnosed when other causes of Raynaud phenomenon have been eliminated. Primary Raynaud phenomenon is not typically destructive, and digital ulcerations generally occur when the phenomenon is secondary to some other disease process (e.g., scleroderma and SLE). Primary Raynaud phenomenon is almost always symmetric. Raynaud phenomenon can be differentiated from a normal response to cold temperatures by the demarcation between pale or cyanotic fingertips and normal-appearing skin. A normal response to cold may include mottling, with indistinct borders between pale and purple-colored skin, and paresthesias of the involved area. In patients with Raynaud phenomenon, the distal most portion of the involved digit is pale or cyanotic, and the transition to normal skin color is abrupt. Since primary Raynaud phenomenon is not due to an inflammatory condition, markers of inflammation such as the ESR are usually normal.

HELPFUL TIP:

Nailfold capillary microscopy (NCM) can be used to examine the nailfold capillaries of patients with Raynaud phenomenon. NCM involves placing a drop of oil (a drop of surgical lubricant also works well) on the cuticle of one or more digits and visualization of the nail fold capillaries through an ophthalmoscope set at +40 diopters (40 green). Usually the ring and middle fingers (or symptomatic fingers) are examined. Normal capillaries are symmetric, nondilated loops. Distorted, dilated, or absent capillaries suggest secondary Raynaud phenomenon.

You perform a physical examination, including NCM which is essentially normal. There is currently no discoloration of the fingers.

Question 11.10.3 What is the next most appropriate step in the evaluation and management of this patient?

- A) Cold provocation
- B) Doppler ultrasound of the extremities
- C) Blood viscosity testing
- D) ANA
- E) A trial of therapy, nonpharmacologic and/or pharmacologic

Answer 11.10.3 The correct answer is “E.” Given that she is symptomatic, a trial of drug therapy is warranted. Cold provocation (“A”) is not recommended, as results are inconsistent. Rather, the diagnosis is based on a convincing history of episodic cyanosis. Doppler ultrasound (“B”) might be useful if you were considering large vessel disease from atherosclerosis, etc. However, it is not likely to be helpful in this patient. Blood viscosity testing (“C”) is not something that is done routinely. Measurement of ANA (“D”) can be helpful in ruling out underlying autoimmune disease since patients with Raynaud phenomenon and a positive ANA may have a higher risk of developing a systemic autoimmune disease. However, based on her age, symmetric involvement, lack of ulcerations, and lack of other symptoms, this patient most likely has primary Raynaud phenomenon unrelated to an underlying disease. A secondary cause (e.g., scleroderma) is more likely with any of the following: patients who are age 30 years old or older; attacks are asymmetric or associated with skin ulcers; there are symptoms suggestive of systemic involvement (e.g., arthralgias, dyspnea, reflux, or weight loss). In addition to abnormal nailfold capillaries, other subtle findings to suggest secondary Raynaud include puffy hand swelling and telangiectasias on the fingers or around the mouth. If you are concerned about secondary Raynaud phenomenon, an ANA would be indicated.

HELPFUL (FINGER) TIP:

Most patients with secondary Raynaud phenomenon will develop symptoms of their underlying autoimmune disease within a few years of onset of Raynaud phenomenon. But Raynaud phenomenon may occur years before other symptoms are prominent or bothersome enough for the patient to report them to a doctor.

After reviewing the diagnosis with your patient, you make several recommendations to help reduce the frequency of attacks: avoid cold temperatures, reduce emotional stress (like taking the boards?), and avoid tobacco and medications that cause vasoconstriction (e.g., sympathomimetic drugs).

Your patient returns 10 months later with new complaints. Both hands are swollen, stiff, and painful. She complains of multiple joint aches and fatigue despite sleeping well. Her appetite is normal, and she has no GI complaints. Although she has no rash, she complains of itchy hands (surely a sign of cancer, she thinks). On examination, you note that there is diffuse, nonpitting edema on her fingers and hands. She has difficulty making a fist. She has no skin findings. Her CBC is normal. Her ANA is strongly positive with a nucleolar pattern.

Question 11.10.4 Which of the following is the most likely explanation of these findings and the most appropriate provisional diagnosis?

- A) Raynaud phenomenon
- B) RA
- C) Scleroderma

- D) CREST syndrome
- E) Osteoarthritis

Answer 11.10.4 The correct answer is “C.” This patient is now presenting with symptoms of scleroderma, also called systemic sclerosis. Scleroderma encompasses a heterogeneous group of conditions, which are variable in severity, but share a common pathophysiologic mechanism—fibrosis of the skin and other organs. The pathology of scleroderma also involves small vessel vasculopathy, a process that leads to Raynaud phenomenon and ischemia of other tissues. Scleroderma may affect the joints, skin, lungs, kidneys, heart, and GI system. Fifty percent of patients with scleroderma have depression so don’t overlook this comorbidity.

A positive ANA can be helpful when you suspect scleroderma based on clinical findings. ANA by indirect immunofluorescence will report the type of nuclear staining pattern. Centromere or nucleolar patterns are most highly associated with systemic sclerosis, but other patterns (such as speckled) are also seen. Patients with systemic sclerosis may have a negative ANA.

These findings are now much more than you would expect to see with Raynaud phenomenon; thus, “A” is incorrect. Diffuse swelling and stiffness are present rather than specific synovitis, so “B” (RA) is less likely. Also, osteoarthritis (“E”) should have identifiable specific joint involvement rather than diffuse hand edema. CREST syndrome (“D”) is an acronym standing for calcinosis cutis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia, which are all manifestations that can occur in patients with systemic sclerosis. CREST should be used as a mnemonic to help remember the manifestation of systemic sclerosis, and not as diagnostic criteria. Of note, calcinosis is a relatively uncommon and late manifestation of systemic sclerosis.

HELPFUL TIP:

Further diagnosis and categorization of scleroderma can be accomplished with the aid of more specific serologic tests such as anti-RNA polymerase III antibodies (which predict high risk for renal crisis) and anti-topoisomerase antibodies (Scl-70) that predict higher risk for interstitial lung disease. Treatment for scleroderma is evolving, with some immunosuppressive therapies showing promise in the long-term management (methotrexate, mycophenolate, or cyclophosphamide for skin involvement, prokinetics for pseudo-obstruction due to GI involvement, etc.). Finally, the greatest treatment breakthrough for scleroderma patients is the finding that ACE inhibitors can treat scleroderma renal crisis, leading to sharp reduction in mortality and preservation of renal function. Monitor renal function every 3 months for 4 to 5 years after diagnosis; this is when renal crisis is most likely to occur. Check for CrCl as well as urinary protein-to-creatinine ratio.

Because of digital ulcers you observe and the increasing pain of her Raynaud phenomenon attacks, you decide to prescribe medication for Raynaud phenomenon.

Question 11.10.5 Which of the following is the best therapy for reducing the frequency of attacks of Raynaud phenomenon?

- A) Amlodipine 5 mg daily
- B) Nifedipine 10 mg as needed
- C) Nitroglycerin 2% ointment daily
- D) Diltiazem 30 mg as needed
- E) Prazosin 1 mg twice daily

Answer 11.10.5 The correct answer is “A.” All of the medications listed are potentially helpful treatments when Raynaud phenomenon does not respond to conservative measures. However, the most appropriate choice is daily amlodipine. Dihydropyridine calcium-channel blockers, like amlodipine, have been shown to reduce the frequency of attacks by about 50% compared with placebo. They must be scheduled, rather than used as needed. In the case of nifedipine, it is best to use an extended-release version, as the short-acting preparation is more likely to cause hypotension; it also should not be used PRN (thus, “B” is incorrect). Diltiazem is not as effective as the dihydropyridine calcium-channel blockers. In systemic sclerosis, the benefit of calcium-channel blockers is often offset by their exacerbation of GERD. Alternatives include (in order of recommendation) sildenafil and other phosphodiesterase inhibitors, topical nitrates, ACE inhibitors, and ARBs. In addition, all patients should get aspirin in antiplatelet doses (81 mg daily). There is less evidence that prazosin is effective, but alpha-antagonists have a role if other therapies are unsuccessful. Sympathectomy is a last resort.

Question 11.10.6 Which of the following is NOT indicated for acute ischemic crisis related to Raynaud phenomenon?

- A) Aspirin
- B) Beta-blocker
- C) Nifedipine
- D) Digital or wrist nerve block
- E) Topical nitroglycerin

Answer 11.10.6 The correct answer is “B.” Beta-blockers are not indicated in the treatment of an ischemic crisis related to Raynaud phenomenon. Beta-blockers actually cause peripheral vasoconstriction and may worsen the problem. Peripherally, beta-agonists cause vasodilatation. When a beta-blocker is used, the patient ends up with an unopposed alpha-adrenergic response, which worsens vasoconstriction. All of the other therapies are useful in acute ischemic crisis. Of particular note is “D.” A nerve or wrist block with lidocaine effectively causes a sympathectomy, leading to decreased vascular tone. As mentioned above, sildenafil appears to be beneficial in healing ischemic ulcers and for acute ischemic crisis.

► **Objectives: Did you learn to ...**

- Identify complications of Raynaud phenomenon and diseases associated with it?
- Develop a strategy for the prevention and treatment of symptoms of Raynaud phenomenon?
- Recognize clinical features of scleroderma?

► **CASE 11.11**

A 17-year-old male presents to your office with a history of low-back pain worsening over the past few months. He recalls having intermittent back pain for at least a year. The pain does not radiate. He runs cross-country and track without exacerbating his back pain. He denies fevers, weight loss, weakness, incontinence, and history of trauma. He is unaware of any family history of back pain. He is otherwise healthy.

Question 11.11.1 What further information will help you differentiate between potential causes of his back pain?

- A) Relief with acetaminophen
- B) Morning stiffness
- C) Relief with rest
- D) A and C
- E) B or C

Answer 11.11.1 The correct answer is “E.” Determining the pattern of the pain is critical. Inflammatory causes of back pain are characterized by morning stiffness and improvement with activity. In contrast, degenerative back disease causes pain that is exacerbated by activity and relieved with rest. Inflammatory back pain typically presents in younger patients; degenerative back pain typically does not present before age 30 or 40. Acetaminophen and other analgesics may relieve pain from either category of disease and so will not help you narrow the diagnosis.

HELPFUL TIP:

In a young patient with back pain, also consider fractures (e.g., spondylolysis, a bilateral pars defect), infection (discitis, osteomyelitis), disc disease, and osseous malignancies.

On further questioning, your patient reports morning stiffness and pain that improves with stretching. Activity does not seem to aggravate his back but inactivity does. He has had no penile discharge, rash, or conjunctivitis, and denies diarrhea or other GI symptoms. On physical examination, your patient is surprised to find that he cannot reach his toes as he had been able to do just a few months ago in track practice. Range of motion in the neck, arms, and legs is normal. A focused neurologic examination is normal. There is mild, diffuse tenderness over the lumbosacral spine and with percussion over the sacroiliac joints. When supine on the

examination table, a FABER maneuver (flexion, abduction, external rotation) reproduces sacral pain.

Question 11.11.2 The history and physical examination are most consistent with a diagnosis of:

- A) Reactive arthritis (formerly termed Reiter syndrome)
- B) Osteoarthritis of the lumbar spine
- C) Degenerative disc disease
- D) Ankylosing spondylitis
- E) Vertebral body tumor

Answer 11.11.2 The correct answer is “D.” The history and physical examination are most consistent with ankylosing spondylitis, a seronegative (RF negative) spondyloarthropathy. Ankylosing spondylitis is the most common form of spondyloarthropathy and is thought to have a prevalence of 1% in Caucasian populations. Historically, there is a 5:1 male-to-female ratio (but this may also be because ankylosing spondylitis is less recognized in women). Studies based on radiographic appearance and human leukocyte antigen (HLA) B27 typing show a much lower male:female ratio. In addition to the historical features mentioned in the answer to the previous question, there is often a family history of ankylosing spondylitis in patients ultimately diagnosed with the disease.

“A” is incorrect. Reactive arthritis occurs in reaction to an infection (*Chlamydia* urethritis, GI infection, etc.), and presents with mono- or oligoarthritis, usually of the joints in the leg. Note that chronic GI disease (e.g., Crohn, ulcerative colitis, celiac disease) may be associated with arthritis, but this is not considered “reactive arthritis.” This patient’s age makes osteoarthritis and degenerative disc disease less likely, so “B” and “C” are wrong. Also, he has no neurologic findings that you might expect with disc prolapse. Malignancy is associated with constitutional symptoms (fever and weight loss), neurologic involvement, and steadily worsening pain that is not relieved by activity—none of which are present in this case. Physical examination findings of spondyloarthropathies are listed in Table 11-8.

HELPFUL TIP:

The FABER (Flexion, Abduction, External Rotation) test, also known as the “figure 4” test, is performed by having the patient lie supine, passively flexing the knee to 90 degrees, resting the patient’s foot on the contralateral thigh just above the knee, and applying pressure laterally and downward on the ipsilateral knee.

TABLE 11-8 PHYSICAL FINDINGS IN THE SPONDYLOARTHROPATHIES

- Limited range of motion in the axial spine
- Peripheral arthritis
- Tenderness at the sacroiliac joints
- Enthesopathy (pain at tendon site insertion, particularly the Achilles tendon and plantar fascia synovitis)
- Extra-articular symptoms (anterior uveitis in 30–40%, psoriasis, inflammatory bowel disease)

When viewed from above, the patient’s legs take on the “figure 4” appearance. The pelvis should be stabilized by the examiner. A positive test occurs if ipsilateral hip or sacroiliac (SI) joint pain is reproduced. It is nonspecific and can be positive in many diseases of the SI joint and hip.

Question 11.11.3 Time for some tests! Which of the following is the best initial test to confirm the diagnosis of ankylosing spondylitis?

- A) ANA
- B) Lumbar spine radiographs
- C) HLA-B27
- D) ESR
- E) Sacroiliac joint radiographs

Answer 11.11.3 The correct answer is “E.” The hallmark of ankylosing spondylitis is sacroiliitis on pelvic radiographs. Although there are no universally accepted criteria for diagnosing spondyloarthropathies, x-ray evidence of sacroiliitis in the setting of a consistent clinical picture is sufficient to diagnose ankylosing spondylitis. Unfortunately, in early ankylosing spondylitis, x-rays are often inconclusive. MRI is more sensitive for detecting early sacroiliitis, but the cost is higher and may not be necessary when plain x-ray images are strongly supportive of sacroiliitis. The rest of the answers are incorrect. Ankylosing spondylitis is not associated with a positive ANA. Lumbar spine x-rays may be useful in ruling out other conditions and do show some changes in ankylosing spondylitis but may miss early disease. HLA-B27, a class I HLA gene, is present in about 90% of white patients and 50% to 80% of non-white patients with ankylosing spondylitis and is generally associated with spondyloarthropathies. However, HLA-B27 is not specific. It is present in many normal individuals as well and is of very little diagnostic value (although it does have a good negative predictive value). ESR is slightly elevated in most cases of spondyloarthropathy, but again it is not specific.

Lumbar spine x-rays show squaring of the vertebral bodies. Pelvic x-rays identify mild symmetric sacroiliitis. You are now confident of the diagnosis of ankylosing spondylitis.

Question 11.11.4 Which of the following management plans is best for this patient?

- A) Aspirin 650 mg by mouth four times daily (or Zorprin or other extended-release aspirin twice daily) and physical therapy referral
- B) Naproxen 500 mg twice daily and physical therapy referral
- C) Orthopedic referral for early surgical consideration
- D) Prednisone 40 mg daily and fitting for a back brace
- E) Naproxen 500 mg twice daily and fitting for a back brace

Answer 11.11.4 The correct answer is “B.” NSAIDs are the mainstay of medical therapy for active phases of spondyloarthropathy. Patients generally experience significant relief from NSAIDs, and any additional benefit from systemic

corticosteroids is questionable. Sulfasalazine is a second-line drug. Interestingly, aspirin tends to be less effective in these patients; thus, “A” is incorrect. The management of ankylosing spondylitis should also include an exercise regimen designed specifically for the patient, and physical therapy may play a key role. The use of braces is not helpful and may actually exacerbate the patient’s symptoms. Orthopedic surgery only becomes necessary in cases of advanced ankylosing spondylitis when kyphosis or peripheral joint symptoms become severe.

After 3 months of physical therapy and NSAIDs, your patient returns. He has noticed minimal benefit, and now you find limitation of his neck range of motion.

Question 11.11.5 What is the most appropriate next step in the evaluation and management of this patient?

- A) Discontinue naproxen and switch to indomethacin 50 mg three times daily
- B) Begin methotrexate 15 mg per week and folic acid 1 mg daily
- C) Begin prednisone 60 mg daily
- D) Order MRI of the cervical spine
- E) Continue naproxen and refer to rheumatology

Answer 11.11.5 The correct answer is “E.” The patient is losing range of motion despite NSAID therapy. Referral to a rheumatologist to consider anti-TNF therapy (e.g., infliximab, adalimumab, or etanercept) is the best next step. Anti-TNF agents can halt disease progression and often improve range of motion in early disease *but are not considered first-line agents*. “A” is incorrect. Switching NSAIDs may provide some minor additional benefit but is unlikely to arrest disease progression. “B” is incorrect. Methotrexate may be beneficial for the peripheral arthritis of spondyloarthropathies but not for the axial skeleton disease. “C” is incorrect since systemic corticosteroids have no value in treating spondyloarthropathies. Local corticosteroid injections are often beneficial for enthesopathy and peripheral arthritis. “D” is incorrect. MRI of the cervical spine will show inflammatory changes of the spine but will not change your management.

The patient fails to keep his rheumatology appointment and returns to you 1 year later. He is taking over-the-counter naproxen. His neck is very stiff, with even less range of motion. He relates that he has been having crampy abdominal pain, and loose stools with bloody mucus. He is having dyspnea with mild exertion. On examination, his neck range of motion is worse, and back flexion is limited with straightening of his lumbar lordosis.

Question 11.11.6 What is the next most appropriate step in the evaluation and management of this patient?

- A) Discontinue naproxen
- B) Check CBC with differential and iron panel
- C) Consult gastroenterology for EGD and colonoscopy
- D) Consult rheumatology and tell patient he must keep his appointment
- E) All of the above

Answer 11.11.6 The correct answer is “E.” The patient could have enteropathic arthritis in association with inflammatory bowel disease. He could also have chronic GI blood loss from an NSAID-induced ulcer. For this reason and because NSAIDs can exacerbate inflammatory bowel disease, the naproxen must be discontinued (“A”). A CBC and iron panel may reveal iron deficiency anemia, which would explain the patient’s dyspnea on exertion. Subspecialty evaluations by a gastroenterologist and rheumatologist are indicated both to confirm the diagnosis and to help with long-term disease management. Anti-TNF agents—like infliximab and adalimumab—but not etanercept—are beneficial for both the spondyloarthropathy (in this case, ankylosing spondylitis) and associated inflammatory bowel disease in enteropathic arthritis.

HELPFUL TIP:

The most common spondyloarthropathies are ankylosing spondylitis, psoriatic arthritis, enteropathic arthritis, and reactive arthritis. These are pathogenically similar diseases that may be difficult to differentiate in early stages, but lack of differentiation does not generally affect therapy.

HELPFUL TIP:

Enteropathic arthritis occurs frequently in patients with inflammatory bowel disease, and has features in common with ankylosing spondylitis, including inflammatory back pain and sacroiliitis. However, a reactive spondyloarthropathy may also occur after a GI infection such as *Salmonella*, *Yersinia*, *Shigella*, or *Campylobacter* and other infections such as chlamydia. Finally, other illnesses such as celiac disease may cause a reactive spondyloarthropathy.

► Objectives: Did you learn to ...

- Recognize clinical manifestations of spondyloarthropathies, particularly ankylosing spondylitis?
- Name some of the different types of spondyloarthropathies?
- Develop an appropriate evaluation for the patient presenting with inflammatory back pain?
- Appropriately manage a patient with ankylosing spondylitis?

QUICK QUIZ: SPONDYLOARTHROPATHIES

Which of the following is NOT a characteristic of reactive arthritis?

- A) Conjunctivitis
- B) Keratoderma blenorrhagicum
- C) HLA-B8
- D) Urethritis
- E) Arthritis

The correct answer is “C.” Reactive arthritis (formerly Reiter syndrome) is associated with HLA-B27 and not HLA-B8 (which is found in sclerosing cholangitis). All of the other choices are seen with reactive arthritis, including keratoderma blenorrhagicum, which is a rash found especially on the soles of patients with reactive arthritis. The urethritis is generally due to *Chlamydia trachomatis*.

HELPFUL TIP:

The onset of reactive arthritis is less insidious than that of ankylosing spondylitis, with some patients presenting with an acute illness that includes fever, acute joint swelling, and rash (keratoderma blenorrhagicum). Generally, reactive arthritis resolves within 12 months. Antibiotics are not effective as a treatment of reactive arthritis (although may be indicated for the underlying infection).

▶ CASE 11.12

A 52-year-old female presents to your office for an initial visit and complains of mild pain and weakness in her hips and thighs. The symptoms have been present for months. About 2 years ago another doctor diagnosed her with psoriasis because of a rash on her hands and elbows, which has since resolved. Otherwise, she reports being relatively healthy and taking no medications. She is a smoker. She has had no recent health screening. On physical examination, her vitals are normal. She has considerable difficulty getting out of her chair. Her strength is symmetrically diminished in the quadriceps and hip flexors. The rest of the examination is unremarkable.

Question 11.12.1 Which of the following diagnostic tests do you order first?

- A) Muscle biopsy
- B) Electromyography (EMG)
- C) TSH
- D) ANA
- E) Troponin-T

Answer 11.12.1 The correct answer is “C.” Hypothyroidism (along with many other diseases—see below) can cause a proximal muscle weakness and is very common in middle-aged females. A muscle biopsy or EMG study is premature without first evaluating for myopathy with serum enzyme levels (CK, aldolase). “D,” an ANA, is not likely to be helpful. Autoimmune diseases such as polymyositis and dermatomyositis cause myopathy, but ANA is not specific for diagnosing these diseases. Finally, although CK-MB may be elevated in patients with myopathy, troponin-T (“E”) is an enzyme relatively specific to cardiac muscle and should be normal.

You order TSH and CBC, which are both within normal limits. ESR, CK, and AST are elevated. You proceed to order that EMG which demonstrates abnormalities of the paraspinal

muscles. Your patient returns to discuss her test results and complains that her psoriasis is back. There are violaceous plaques on her knuckles and elbows and around her eyes.

Question 11.12.2 You recommend the following management plan for the disease:

- A) Ultraviolet light therapy
- B) Topical corticosteroids
- C) Oral corticosteroids
- D) Topical emollients
- E) Acetaminophen

Answer 11.12.2 The correct answer is “C.” This patient now has findings that support a diagnosis of dermatomyositis. To diagnose idiopathic inflammatory myopathy, such as dermatomyositis or polymyositis, certain criteria must be present (see Table 11-9). This patient has three of these criteria plus skin changes consistent with dermatomyositis. Violaceous plaques on the knuckles are commonly called Gottron papules. Similar lesions are often observed over pressure points (e.g., elbows). Because dermatomyositis is a systemic condition, treatment should likewise be systemic. Local topical therapies do not treat the disease, and oral corticosteroids are typically the first-line agents. Hydroxychloroquine is helpful when the rash does not respond to corticosteroids. Addition of immunosuppressive drugs, such as methotrexate or azathioprine, may be indicated.

Question 11.12.3 You diagnose dermatomyositis. Which of the following tests and exams should now be ordered?

- A) Pap and pelvic examination, CA-125, and pelvic ultrasound
- B) Screening mammogram
- C) Chest radiograph
- D) Fecal occult blood screening
- E) All of the above

Answer 11.12.3 The correct answer is “E.” Patients with adult-onset dermatomyositis have a sixfold increased risk of developing cancer. Therefore, upon diagnosing dermatomyositis, a thorough history and physical examination must be performed. All patients should undergo age-appropriate cancer screening tests (e.g., Pap smear, fecal occult blood testing, and mammography in this patient). Also, other tests generally recommended include CBC, metabolic profile, liver function tests, urinalysis, and chest x-ray—especially important in smokers. Since the patient is over age 50, colonoscopy is indicated. The cancers most commonly associated with dermatomyositis include

TABLE 11-9 DIAGNOSTIC FEATURES OF POLYMYOSITIS AND DERMATOMYOSITIS

- Elevated muscle enzymes (CPK and aldolase)
- Symmetrical proximal muscle weakness
- Abnormal EMG
- Consistent findings on muscle biopsy

Note: Skin findings must be present in order to diagnose dermatomyositis.

ovarian and gastric cancers and lymphoma. Therefore, it is reasonable to consider CA-125 and pelvic ultrasound.

HELPFUL TIP:

The association of dermatomyositis with GI malignancy is particularly strong. You may consider endoscopies and an alpha-fetoprotein (for gastric cancer). Some authorities also suggest CT of the abdomen and pelvis to rule out malignancy.

HELPFUL TIP:

Other causes of proximal muscle weakness include alcohol use, muscular dystrophy, medications (e.g., penicillamine and HMG-CoA reductase inhibitors), Cushing syndrome, viral infections, hypothyroidism, and diabetes mellitus. The list goes on, including myasthenia gravis and Eaton–Lambert syndrome.

► Objectives: Did you learn to ...

- Recognize symptoms and signs of dermatomyositis and polymyositis?
- Describe how inflammatory myopathies are evaluated and diagnosed?
- Appreciate the relationship between malignancy and inflammatory myopathy?

QUICK QUIZ: ARTHRITIS AND JOINT INVOLVEMENT

Compared with RA, osteoarthritis has a greater predilection for which of the following joints?

- A) MCPs
- B) DIPs
- C) Knees
- D) Wrists

The correct answer is “B.” Osteoarthritis tends to affect the DIP and PIP joints in the hand, sparing the MCP joints, whereas RA affects the MCPs and spares the DIPs. Both disease processes may involve the knees and wrists.

Clinical Pearls

- Aspirate a monoarthritis and send synovial fluid for cell count with differential, Gram stain, culture and crystal analysis for evaluating and ruling out a septic joint. Remember that those with crystalline arthritis may also have a septic joint.
- Begin supplementation with calcium and vitamin D for osteoporosis prevention with initiation of corticosteroids in the treatment of rheumatologic disease.

- Do not delay initiation of high-dose corticosteroids for treatment of giant cell arteritis while awaiting a temporal artery biopsy.
- Do not rely upon serum uric acid levels to diagnose or refute a gout attack.
- Do not routinely order “rheumatology panels.” Order appropriate rheumatologic tests based on clinical evaluation and specific disease under consideration.
- Do not routinely screen for Lyme disease for chronic musculoskeletal pain. Repeat after us: “There is no such thing as chronic Lyme disease responsive to antibiotics. Once the patient is appropriately treated, additional courses of antibiotics are worthless.”
- Do not use opioid pain medications in treating chronic pain related to fibromyalgia as they tend to worsen central sensitization and increase fibromyalgia pain over time.
- Ensure that women of child-bearing age on methotrexate have reliable contraception.
- Prescribe a trial of DMARDs (disease modifying anti-rheumatic drugs) as first-line therapy in rheumatoid arthritis.
- Use the lowest and minimum effective prednisone dose for acute symptomatic relief of inflammatory arthritis.

Orthopedics and Sports Medicine

12

Britt L. Marcussen, Tameem A. Shoukhi, and Mark A. Graber

General note: On the test if you have a choice between acetaminophen and an NSAID for an acute injury or noninflammatory arthritis, acetaminophen will always be the right choice. Most acute injuries are not inflammatory, and acetaminophen is a lot safer without gastropathy or platelet inhibition. If you do use an NSAID, naproxen is the safest from a cardiovascular standpoint but carries the same gastrointestinal risks as other NSAIDs. With that said, in 2012 the FDA recommended that the maximum daily dose of acetaminophen in otherwise healthy adults be reduced from 4,000 to 3,000 mg/day. In addition, the number needed to treat and get a 50% reduction in pain is 4.6 for 650 mg of acetaminophen compared to 1.7 for 600 mg of ibuprofen! So... well there is a quandary for you!

▶ CASE 12.1

A 5-year-old boy presents with acute onset of left anterior thigh and hip pain that began 2 days ago with no known prior trauma. He reports that it initially “loosened-up” after he had been out of bed for a few hours but has become worse again by afternoon. His pain is exacerbated by weight bearing and active or passive range of motion (ROM). His mother notes that he had a cold 7 to 10 days ago, but has been asymptomatic until he complained of thigh pain two nights ago. She also notes that he has had a low-grade fever. He has no other significant constitutional symptoms and appears to be in some pain, but otherwise he appears well.

Question 12.1.1 Based on the information obtained thus far, which of the following is the most likely diagnosis?

- A) Osteomyelitis
- B) Rheumatic fever
- C) Slipped capital femoral epiphysis (SCFE)
- D) Legg–Calve–Perthes disease (LCPD)
- E) Transient (toxic) synovitis

Answer 12.1.1 The correct answer is “E.” This presentation is classic for transient (toxic) synovitis. This is the

most common cause of hip pain in children aged 3 to 10 years, with peak occurrence in ages 5 to 6 years. It is more commonly seen in boys (male:female ratio of 2–3:1) and is often preceded by a viral respiratory infection, although numerous studies have failed to demonstrate a specific viral or bacterial agent. Physical examination reveals a limp or refusal to walk and complaint of pain over the groin and/or proximal thigh. There is pain with ROM testing, especially during abduction. Most children will be afebrile with a temperature of $\leq 38^{\circ}\text{C}$.

Question 12.1.2 Appropriate diagnostic workup might include which of the following?

- A) Joint aspiration
- B) Plain film radiographs
- C) Inflammatory markers including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
- D) CBC with differential
- E) All of the above

Answer 12.1.2 The correct answer is “E.” All of the above may be appropriate as transient synovitis is a diagnosis of exclusion. Patients with mild symptoms may be observed without further investigation. However, if the pain is significant, ROM is significantly impaired, or if the temperature is $>37.5^{\circ}\text{C}$, further diagnostic workup is indicated. Laboratory findings consistent with transient synovitis include: clear joint fluid aspirate, normal CBC, and a mildly increased ESR. Blood cultures, antistreptolysin O (ASO) titer, bone scan, and MRI may also be of benefit to rule out other possibilities (e.g., septic arthritis, rheumatic fever, and SCFE). *It is of extreme importance to differentiate transient synovitis from septic arthritis. Unfortunately, there is no combination of physical findings and laboratory tests short of joint fluid that will definitively rule out septic arthritis.* There are published clinical decision tools, but these are generally based on observational data and often have conflicting results. It requires clinical judgment; decide which patients you are worried enough about that you want to commit them to hip joint aspiration.

**HELPFUL TIP:**

Septic arthritis is an orthopedic emergency and commonly presents with an elevated temperature, general malaise, and inability to bear weight—often with pain, spasm, and guarding. Generally, you will also see an elevated white blood cell (WBC >12K), CRP (>20), and ESR, **although neither these or fever (>38.5) is a good enough indicator to rule out a septic joint by their normality or absence.** Joint fluid will have numerous WBCs (classic teaching is >50,000 WBC/mm³; however, counts lower than this do not rule out septic arthritis); 50,000 WBC/mm³ is only 62% sensitive with 25,000 WBC/mm³ still only 77% sensitive. Blood cultures are positive in 30% of patients. Remember Lyme arthropathy Chikungunya in your differential diagnosis in the proper geographic location!

Question 12.1.3 What is the most appropriate treatment for this patient with transient synovitis?

- A) Open fixation
- B) Immobilization
- C) Antibiotics
- D) Surgical decompression
- E) Ibuprofen and rest

Answer 12.1.3 The correct answer is “E.” Conservative treatment is warranted: the appropriate initial treatment is rest, weight bearing as tolerated, and observation. Transient synovitis generally responds well to oral NSAIDs. Home care is acceptable; however, admission is indicated if the diagnosis is equivocal or if significant pain management is required. For septic arthritis, prompt administration of an intravenous (IV) antibiotic—directed at the most likely infecting pathogen (*Staphylococcus aureus*, Group A and B *Strep* [more common in infants], *Hemophilus influenza*, and rarely *Salmonella* and *N. gonorrhea*) and altered as necessary based on culture results—is indicated. Surgical irrigation of the joint is often necessary and early orthopedic consultation is needed.

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of transient synovitis?
- Differentiate transient synovitis from septic arthritis?
- Treat a patient with transient synovitis?

► **CASE 12.2**

A 6-year-old white male is brought into clinic by his parents because he is complaining of pain in his hip and anterior thigh. He is walking much less than usual since the pain began about 4 weeks ago. You order a plain radiograph, which shows mild sclerosis with some increased density of the femoral head. An MRI is ordered (which is denied three times by the insurance company, but eventually obtained after 4 hours on hold), which shows osteonecrosis of the femoral head.

Question 12.2.1 What is the most likely diagnosis in this patient?

- A) Osteomyelitis
- B) Septic arthritis
- C) SCFE (slipped capital femoral epiphysis)
- D) LCPD (Legg–Calve–Perthes disease)
- E) Sickle cell anemia

Answer 12.2.1 The correct answer is “D.” LCPD is idiopathic osteonecrosis of the femoral head. It is unilateral in 90% of cases, and the typical age range is 4 to 8 years, but patients may be as young as 2 years and as old as 12 years. “A” is a possibility, although there should be evidence of osteomyelitis on MRI. “B” is discussed in the previous case. “C,” SCFE, classically occurs in obese children (male predominance) who are 10 to 16 years old (see more below). “E,” sickle cell anemia, can cause osteonecrosis of the femoral head also, but the disease is rare in white populations. LCPD is less common in black populations.

Question 12.2.2 Which of the following factors best predicts a poor outcome for patients with LCPD?

- A) Later age at onset of illness
- B) Findings of subchondral fractures or fragmentation
- C) Early appropriate treatment
- D) Severity of pain and in ability to bear weight
- E) Bilateral involvement

Answer 12.2.2 The correct answer is “A.” Compared to older children, younger children generally have a longer time for remodeling to occur via molding of the femoral head within the acetabulum; and therefore, younger children have less flattening of the femoral head.

Question 12.2.3 Which of the following is the best initial treatment for this patient with LCPD?

- A) Joint replacement
- B) Osteotomy
- C) Rest and physical therapy
- D) Opioids
- E) Corticosteroid injection of the hip joint

Answer 12.2.3 The correct answer is “C.” The initial treatment for a patient with LCPD typically includes rest, activity restriction, and physical therapy. The objectives are to increase ROM in the hip and to reduce the risk of significant deformity. In general, patients should be seen by an orthopedic specialist. The likelihood of a good outcome with nonoperative treatment is significantly higher in younger patients, less than 8 years of age. “A” is incorrect because joint replacement is not an option. “B” is incorrect. While osteotomy may be used, it is typically reserved for older children and patients who are not progressing well with conservative therapy. “D” and “E” are not appropriate interventions in this patient with mild pain and no joint inflammation.

LCPD is difficult to treat largely because of the long duration of treatment and activity restrictions required. Periods of rest

with activity restriction, physical therapy, and surgical intervention may be indicated over **1 to 2 years of treatment** and observation. Even with the best of care, prognosis is fair with need for total hip replacement reaching approximately 50% by middle age due to severe degenerative arthritis.

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of LCPD?
- Manage a patient with LCPD?

► CASE 12.3

A 15-year-old female cross-country runner presents to your clinic with the chief complaint of bilateral knee pain. She describes a gradual increase in her symptoms during the first 3 weeks of the season. She wants to run varsity this year and has done extra running and hill training after practice each day. She describes anterior knee pain in the patellar region with little or no swelling, but complains of crepitus and pain exacerbated by running, squatting, stair climbing, and prolonged sitting with the knee bent.

Question 12.3.1 The most likely diagnosis for the condition described is:

- A) Osgood–Schlatter disease
- B) Chondromalacia patellae
- C) Patellofemoral pain syndrome (PFPS)
- D) Femoral stress fracture
- E) Jogger's joints

Answer 12.3.1 The correct answer is “C.” PFPS is a common overuse syndrome seen more frequently in runners and female athletes (thus the moniker “runner’s knee”). This condition is due to forces across the knee that lead to biomechanical overload of the patellofemoral joint and other anterior knee structures. Maltracking and malalignment of the patellofemoral joint can contribute to this overload, as can training errors, core weakness, and muscle imbalance. “A,” Osgood–Schlatter disease, is also related to overuse but is two to three times more common in males, particularly in athletes engaging in repetitive jumping. The pain of Osgood–Schlatter is generally well localized to the tibial tubercle. Radiographic evidence of fragmentation of the epiphysis or heterotrophic ossification anterior to the tubercle may be seen, but is not necessary for diagnosis. “B,” chondromalacia patella, is softening of the articular cartilage of the patella as seen on arthroscopy and may be a result of long-term patellofemoral dysfunction. This is a surgical diagnosis and the term should be avoided clinically. Femoral stress fracture (“D”) would be unlikely to present bilaterally. “E” is not a real thing but has nice alliteration.

Question 12.3.2 What is the preferred treatment for this female runner?

- A) Arthroscopic debridement
- B) Decreased activity level along with quadriceps and hip strengthening exercises

- C) Evaluation for “Female Athlete Triad”
- D) Casting or immobilization
- E) Corticosteroid injection

Answer 12.3.2 The correct answer is “B.” The most effective treatment modality is a combined physical therapy regimen consisting of strength training of the hip abductors and quadriceps, as well as quadriceps stretching. Quadriceps strengthening is usually initiated by resisted straight leg raises (SLRs) to minimize patellofemoral compressive forces. NSAIDs, cross-training, and core strengthening may also be of benefit. Adjunctive trials of therapeutic modalities such as orthotics and taping may be considered, but should not be used in isolation. Recalcitrant cases and patients with recurrent dislocation/subluxation should be referred to your friendly neighborhood orthopedic surgeon for consideration of surgical intervention. “A,” “D,” and “E” are all unnecessarily invasive for PFPS. As for “C,” while it would be good to explore her general health in more detail, screening for the female athlete triad will not treat her current problem.

Three months later, the same patient presents complaining of unilateral right knee pain over the medial knee joint. Again, this pain is exacerbated by knee flexion and she notes popping and snapping when she stands from sitting. She notes that the pain is worse after prolonged sitting or going up or downstairs. Your examination shows a tender band of tissue about 1 cm medial to the patella.

Question 12.3.3 The most likely diagnosis is:

- A) Osteosarcoma
- B) Medial collateral ligament (MCL) strain
- C) Plica syndrome
- D) Recalcitrant PFPS
- E) Meniscal tear

Answer 12.3.3 The correct answer is “C.” This is the typical presentation of plica syndrome. Plicae are synovial remnants that did not resorb properly during development. They can be irritated, usually chronically or subacutely, especially in sports that require repeated flexion of the knee (e.g., rowing, cycling, running, etc.). Typical symptoms include popping or snapping sensation with knee flexion; there may also be knee locking and catching as well as having the knee “give.” Treatment includes rest, ice, quadriceps strengthening, and NSAIDs. If conservative management fails, steroid injection or arthroscopy may alleviate the symptoms.

HELPFUL TIP:

The plica should be palpable. A medial/inferior plica is the most common (between the patella and the medial joint line). It can also occur laterally and either above or below the midpole of the patella. Adolescents and young adults are more frequently affected than patients of other ages.

► **Objectives: Did you learn to ...**

- Identify and manage PFPS?
- Recognize plica syndrome?

► **CASE 12.4**

A mother brings her 18-month-old son in for a well-child check. Her only new concern today is that he seems to walk “bow-legged.” He has been somewhat pigeon-toed since he could pull himself up and cruise along walls and furniture at home. On examination, you find the child’s feet to be pointing inward. The foot is flexible and looks normal. The patellae are in a neutral position facing directly forward.

Question 12.4.1 What is the most likely diagnosis in this patient?

- A) Cerebral palsy
- B) Excessive femoral retroversion
- C) Forefoot varus
- D) Internal tibial torsion
- E) Bilateral developmental dysplasia of the hip (DDH)

Answer 12.4.1 The correct answer is “D.” This represents a case of intoeing (pigeon-toeing), which has several causes, and internal tibial torsion is frequently the culprit. Internal tibial torsion is characterized by a flexible, normal foot, with the patellae in a neutral position. The condition can be diagnosed by examining the child on his knees (feet dangling) or prone with knees flexed. Normally, there should be approximately 30 degrees of external rotation of the feet in this position. With internal tibial torsion, the toes will be pointing inward. In addition, when the child is sitting with legs dangling over a table, the lateral malleolus will be anterior to the medial malleolus, which is the opposite of what is normally observed. Finally, the hips must be normal in order to confirm this diagnosis. “A” is incorrect because you would expect other findings in a patient with cerebral palsy. “B” is incorrect. In fact, femoral retroversion is synonymous with “out-toeing,” which is the opposite of intoeing (of course!). Excessive **femoral anteversion** can be a cause of intoeing. “C” is incorrect because the foot examination does not show varus deformity. Finally, “E” is incorrect, although bilateral DDH can be quite difficult to diagnose if not caught early in the newborn period. With DDH, one would expect external rotation of the leg rather than intoeing.

Question 12.4.2 What is the treatment of choice for this child?

- A) Referral for bilateral osteotomy
- B) Shoe modification and bracing (The Forest Gump Treatment Plan)
- C) Physical therapy referral
- D) Serial casting
- E) Reassurance and watchful waiting

Answer 12.4.2 The correct answer is “E.” Spontaneous resolution is the norm for most intoeing and out-toeing deformities. Most will spontaneously correct by age 6. Children continuing to have difficulty with persistent trips and falls or grossly unsightly gait beyond this time may benefit from a rotational osteotomy. Children with neuromotor disorders and cerebral palsy are more likely to require surgical intervention.

HELPFUL TIP:

Another cause of intoeing is femoral torsion. Femoral torsion is diagnosed by placing the patient prone with the hips in neutral and knees flexed to 90 degrees. Feet are rotated away from midline to measure internal rotation (anteversion). For external rotation (retroversion), place one hand on the buttocks and move one leg through midline until the pelvis begins to tilt. Typically, normal external rotation is 45 degrees, and normal internal rotation is 35 degrees. Rotation greater than this is considered excessive if it is accompanied by a limited ROM in the opposite direction. **In addition, when a patient with femoral torsion is seated with legs dangling, the patellae will not face forward (they face inward for intoeing from femoral torsion and outward for out-toeing from femoral torsion).**

► **Objective: Did you learn to ...**

- Evaluate and manage intoeing and out-toeing in children?

► **CASE 12.5**

A 13-year-old male presents to the clinic with his mother for difficulty walking. He is unsure of when the problem first began, but has noticed it getting worse over the last week. It has forced him to stop playing sports. He reports a dull pain in the left hip but denies trauma. On examination, you find an obese male in no distress. There is loss of internal rotation, abduction, and flexion at the left hip joint. When his hip is flexed to 90 degrees, this loss of ROM is more pronounced.

Question 12.5.1 What is the most likely diagnosis in this case?

- A) Osteoarthritis
- B) Septic arthritis
- C) SCFE
- D) LCPD
- E) Juvenile idiopathic arthritis

Answer 12.5.1 The correct answer is “C.” SCFE occurs most commonly in active, overweight, adolescent males. Shear forces across the relatively weak physis cause displacement. **Slippage is generally gradual but may occur acutely.** Mean age at presentation is 12 for females (range 10–14) and 13 for males (range 11–16). Endocrinopathies, such as hypothyroidism and osteodystrophy, should be considered in those presenting atypically or outside the typical age range. Watch for development

of a similar process in the contralateral hip over time, which has been reported anywhere from 20% to 80% of the time.

Question 12.5.2 Which of the following is the first study you order to confirm the diagnosis?

- A) AP and frog-leg lateral radiographs of the hip
- B) CT scan of the hip/pelvis
- C) MRI of the hip/pelvis
- D) ESR
- E) None; physical examination is sufficient

Answer 12.5.2 The correct answer is “A.” Radiographs of the hip should demonstrate displacement of the femoral head, which can then be classified as mild, moderate, or severe. “B” and “C” are incorrect because the radiograph is diagnostic in most cases. “D” is incorrect since SCFE is not an inflammatory condition. “E” is incorrect. Imaging should be obtained in order to confirm the diagnosis and rate the severity. MRI may be able to diagnose an early SCFE when radiographs are negative and you should have a low threshold for pulling the MRI trigger, given the consequences of missing this one!

Question 12.5.3 The treatment of choice for this patient is:

- A) Antibiotics
- B) Immobilization
- C) Physical therapy
- D) Surgical decompression
- E) Surgical fixation

Answer 12.5.3 The correct answer is “E.” The goals of treatment of SCFE are to prevent further slippage, promote closure of the physis, and to minimize the risk of osteonecrosis or chondrolysis. These aims are best accomplished through referral to an orthopedic surgeon and, ultimately, surgical fixation. “B” and “C” are incorrect because they delay definitive therapy and will not produce the desired result. “A” and “D” are incorrect because SCFE is not an infectious process.

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of a child with SCFE?
- Treat a patient with SCFE?

► CASE 12.6

A worried mother presents with her 4-year-old son for evaluation of lower extremity pain. She reports the boy has complained of some vague bilateral leg pains over the past several weeks after vigorous physical activities. She became alarmed after he had awakened the past two nights crying in pain. The boy reports the pain is hardly noticeable during the day. Recently, the pain has been in the bilateral distal thighs; however, his mother notes times of unilateral pain. The boy and his mother both deny constitutional symptoms now or over the past several weeks. Examination reveals an afebrile, well-developed male in no distress. The musculoskeletal examination is normal.

Question 12.6.1 The most likely diagnosis for the condition described here is?

- A) Ewing sarcoma
- B) Growing pain
- C) Kohler disease
- D) Leukemia
- E) Osteochondritis dissecans

Answer 12.6.1 The correct answer is “B.” “Growing pain” is a diagnosis of exclusion, although history and physical examination usually suffice for excluding more serious diagnoses. It is a condition of unknown etiology, but is thought by some to be a result of overuse/overactivity on an immature musculoskeletal system. It is most frequently seen in otherwise healthy, active children aged 2 to 5, with some older children affected as well. Pain is commonly bilateral and localized to the calf, but may be felt at the ankle, knee, or thigh. Pain is more common in the evening and often causes awakening at night. Less commonly, patients have pain during the day after vigorous activities. Presentation with constitutional symptoms should lead to further evaluation with imaging and lab tests.

Question 12.6.2 Which of the following should you entertain when a patient presents with typical growing pain?

- A) Osteomyelitis
- B) Malignancy
- C) Juvenile idiopathic arthritis
- D) All of the above
- E) None of the above

Answer 12.6.2 The correct answer is “D.” It is important to consider other potential causes of what would otherwise appear to be growing pain. Although you may not find it necessary to perform any laboratory or radiologic studies, you should at least keep these and other diagnoses in mind when taking your history and performing your examination. Remember, growing pain is a diagnosis of exclusion.

HELPFUL TIP:

Severe or persistent pain during the day is **not** “growing pain.” By definition, “growing pain” occurs primarily at night and is better during the day.

Question 12.6.3 Treatment for growing pain includes:

- A) Reassurance, rest, and short-term use of NSAIDs
- B) Amputation
- C) Chemotherapy and radiation
- D) Casting and bracing followed by physical therapy
- E) Staging of the disease is required prior to initiation of therapy

Answer 12.6.3 The correct answer is “A.” OK, so this was just a fun one. Do not do anything drastic for a benign condition! Those of you who chose “B,” amputation, will find themselves

in one of Dante's circles (or in court—which is worse?) ... and clearly need a coffee break.

The same boy returns with his mother years later. He is now 12 years old; the mother has noticed that one shoulder seems to be higher than the other (truncal asymmetry).

Question 12.6.4 Which of the following methods is the most sensitive for detecting scoliosis?

- A) Observe the patient from the front with a loose-fitting shirt on; measure the difference in shoulder height
- B) Observe the patient from behind, with shirt off, while he bends forward at the waist; look for elevation of the ribs or paravertebral muscle mass on one side
- C) Observe the patient from the front, with shirt off, while he bends forward at the waist; look for elevation of the ribs or paravertebral muscle mass on one side
- D) Observe the patient from the side, with shirt off, while he bends forward at the waist; look for elevation of the ribs or paravertebral muscle mass on one side

Answer 12.6.4 The correct answer is "B," which is known as the "forward bending test." This test is more sensitive than the other methods described. The forward bending test is accomplished by having the patient bend at the waist with feet together and hands hanging free. Observe the patient from behind and note any elevation of the ribs or paravertebral muscle mass on one side. The elevation should be measured in degrees (inclinometers are available), and an inclination of 5 degrees or more should be evaluated further. Options "A," "C," and "D" are **not** accepted methods of screening for scoliosis.

HELPFUL TIP:

Until 2018, routine screening for scoliosis was a recommendation "D" by the US Preventative Services Task Force (not recommended). In January 2018, USPSTF released an updated recommendation of "I" (insufficient evidence to assess balance of risks and benefits). For screening of otherwise healthy adolescents, it is reasonable to skip it, but scoliosis evaluation may be appropriate in patients who have noticed pain or some other abnormality.

HELPFUL TIP:

Scoliosis is a lateral curvature of the spine, usually accompanied by rotation and generally occurring in the thoracic or lumbar areas. It can occur with excessive kyphosis (posteriorly convex curvature) or lordosis (anteriorly convex curvature).

On forward bending test, you find slight elevation of the left paravertebral muscles mass, which you estimate to be 7 degrees. The remainder of the examination is normal.

You decide to obtain radiographs that show 12 degrees of angulation (Cobb angle).

Question 12.6.5 This patient's scoliosis is most likely:

- A) Congenital
- B) Idiopathic
- C) Related to a tumor
- D) Secondary to infection
- E) Secondary to demonic possession

Answer 12.6.5 The correct answer is "B." Most scoliosis that develops during adolescence is idiopathic. When there is no pain, fever, weight loss, or other warning signs (e.g., neurologic symptoms), the curvature is unlikely to be due to tumor or infection. "A," congenital scoliosis, typically presents earlier in life. Infection, malignancy, and demons are not known to cause scoliosis.

Question 12.6.6 The most appropriate initial management plan for this patient includes:

- A) Bracing
- B) Observation
- C) Physical therapy
- D) Surgery
- E) Any of the above are equally appropriate initial management plans

Answer 12.6.6 The correct answer is "B." In an otherwise healthy patient with a curvature measured at <25 degrees, observation is appropriate. "C" is incorrect because physical therapy and exercise regimens do not seem to limit the progression of scoliosis. "A" and "D" are incorrect because bracing and surgery are typically not warranted for this degree of scoliosis. Repeat examination and possibly repeat radiographs are warranted, but if the scoliosis remains stable and mild, the patient is not likely to experience any significant progression of disease with aging.

HELPFUL TIP:

Bracing for scoliosis should be limited to those with idiopathic scoliosis and greater than 30 degrees of angulation. Bracing is only effective if the child is still growing and <1 year past menarche if female. You should not go for this one alone...get help!

The mother returns now with her 2-year-old daughter who is refusing to move her right arm. Earlier today she threw a tantrum at the store when her father refused to buy her the new "princess toy" (advertising hits them young). Dad was holding on to her arm when she flopped to the floor. She immediately began crying and refusing to move her right arm. In the office, she is well but holds her right arm adducted, flexed, and pronated. (The princess toy is in the other hand. Guilt is a powerful weapon.) Despite every trick you know, you can't get her to move that arm. You inspect and palpate the

entire extremity and clavicle and find no crepitus, swelling, or tenderness.

Question 12.6.7 What is your next diagnostic step?

- A) Obtain an x-ray of the elbow
- B) Actively supinate the forearm and flex the elbow while applying pressure over the radial head
- C) Actively twist the forearm at the elbow 360 degrees
- D) Consult orthopedics
- E) Perform a skeletal survey, mostly to bide time

Answer 12.6.7 The correct answer is “B.” This child has a “nursemaid’s elbow” that is due to subluxation of the annular ligament rather than subluxation or dislocation of the radial head. It occurs in toddlers due to traction via pulling on a pronated and extended arm. Symptoms are immediate and care is sought due to the child’s refusal to move the arm. The diagnosis is clinical. Manual reduction may be done via supination/flexion or hyperpronation. Sedation is not needed. A palpable click may be felt. The child usually regains immediate movement of the arm and relief of discomfort. Immobilization is not needed, but parents should be told that recurrent subluxations may occur and therefore pulling on the arm should be avoided. “A” would be correct if there was concern for a fracture based on findings of swelling, history of trauma, or focal tenderness. “C” is impossible: Can you really rotate a joint 360 degrees? “D” is incorrect as any primary-care provider may manage this. “E” is unnecessary as a nursemaid elbow is not a marker of abuse, although traumatic injuries in children should always make one consider abuse.

HELPFUL TIP:

Reducing a nursemaid’s elbow is gratifying. The patient with nursemaid’s elbow should be using the arm normally within minutes. If the child still refuses to use the extremity after adequate observation, reconsider your diagnosis and whether the reduction was successful. Note that many will spontaneously reduce while radiographs are being done (therapeutic x-ray?). Both flexion and supination and extension and pronation have been used to reduce nursemaid’s elbow.

HELPFUL TIP:

When dealing with pediatric orthopedics, always remember that child abuse is in the differential diagnosis. Be sure that the reported mechanism of the injury is consistent with the findings on examination and radiograph.

After successful reduction, you see the same 2-year-old child a month later presenting to your clinic with the parents who state that the child has been crying and has refused to walk since tripping over a toy a couple of hours ago. You look at

the child and find no signs of abuse. The injured area is represented by the lower leg image in Figure 12-1.

Question 12.6.8 Your approach at this point is to:

- A) Consult Child Welfare since this is almost always abuse
- B) Consult orthopedics for casting and further treatment
- C) No treatment necessary for this particular fracture in a 2-year-old
- D) Obtain an MRI

Answer 12.6.8 The correct answer is “B.” This is a typical “toddler’s fracture” that consists of a spiral fracture of the tibia usually from insignificant rotational trauma (e.g., running and falling with a twisting motion). There should not be an associated fibular fracture. “A” is incorrect because this type of fracture is not usually from abuse. A midshaft fracture would more likely be from abuse. “C” is incorrect because this fracture needs to be treated. For a quick summary of fracture terminology, see Table 12-1, and keep these in mind—we’ll use them later.

► **Objectives: Did you learn to ...**

- Consider a broader differential diagnosis in a patient presenting with typical “growing pain?”
- Initiate conservative treatment for a patient with growing pain?
- Screen a patient for scoliosis?
- Develop an approach to the adolescent with scoliosis?
- Recognize the clinical presentation and treatment of a “nursemaid’s elbow” (radial head subluxation)?
- Recognize a toddler’s fracture (tibial spiral fracture)?

FIGURE 12-1. Toddler’s Fracture.

TABLE 12-1 TERMINOLOGY FOR DESCRIBING A FRACTURE

Avulsion fracture:	Fragment of bone pulled from its normal position by a muscular contraction or resistance of a ligament
Closed fracture:	A fracture that does not communicate with the external environment (i.e., not through the skin)
Comminuted fracture:	Consisting of three or more fragments
Greenstick fracture:	Incomplete, angulated fracture of a long bone, particularly in children
Open fracture:	Fracture that communicates with the external environment
Torus (Buckle) fracture:	Described as a buckle fracture or compression of the bone without cortical disruption; seen especially in the distal forearms of children

► CASE 12.7

A mother presents to your clinic with her 10-month-old son. She is concerned that he has been very irritable since she arrived home from work, particularly when his legs are touched. She states that he has been crying “nonstop” since she arrived home. He was well when she left for work this morning, leaving the patient under the care of her boyfriend, Tony “the Hustler” O’Neil. The patient’s mother denies any fevers, vomiting, diarrhea, or cough. On examination, he is generally fussy, worsening with palpation of his left leg, particularly around his knee. You also note five bruises on his chest and back. The remainder of the examination is unremarkable. You obtain the following radiograph of his left knee (Fig. 12-2).

Question 12.7.1 Which of the following mechanisms is most likely responsible for the fracture seen on x-ray (marked with the helpful arrow sign)?

- A) A low-energy fall (fall off a low couch)
- B) A high-energy fall (fall out of a second-story window)
- C) A low-energy rotational force (tripping causing the foot to twist inward)
- D) A high-energy tension or shearing force (a violent twisting of the leg)
- E) Any of the above could result in the injury

Answer 12.7.1 The correct answer is “D,” a high-energy tension or shearing force. The above radiograph depicts a metaphyseal corner fracture that is highly specific for nonaccidental trauma (that’s the nice way to say “child abuse”). These fractures are typically caused by shaking of the child with flailing of the extremities or with forceful yanking or twisting of the arm or leg. The incidence of these fractures decreases substantially as children grow beyond 1 year of age.

Question 12.7.2 In which of the following patients is a skeletal survey indicated for concern of nonaccidental trauma?

- A) A 2-month-old male with multiple bruises but no other localizing injuries
- B) A 2-year-old female with an intracranial injury on brain CT
- C) A 6-month-old male with a known metaphyseal corner fracture

**FIGURE 12-2.** From Case 12.2.

- D) An 18-month-old female with burns consistent with nonaccidental trauma
- E) A skeletal survey is indicated for all the above patients

Answer 12.7.2 The answer is “E,” all of the above. The American Academy of Pediatrics consensus guidelines on the radiographic evaluation of child abuse state that a skeletal survey should be obtained for all children younger than 2 years of age who may have experienced maltreatment. Skeletal surveys should also be considered for children between the ages of 2 and 5 depending on the clinical scenario. The following images are generally included in a skeletal survey: humeri, forearms, lower legs, hands, feet, skull, cervical spine, thorax (including oblique views), lumbar spine, and pelvis.

Question 12.7.3 Which of the following fractures is considered highly specific for nonaccidental trauma?

- A) Posterior rib fractures
- B) Clavicle fractures
- C) Distal radius fractures
- D) Spiral fractures of the tibia
- E) Supracondylar fractures

Answer 12.7.3 The correct answer is “A,” posterior rib fractures. In addition, the following fractures have moderate to high specificity for nonaccidental trauma: metaphyseal fractures, multiple fractures (especially if bilateral), fractures of different ages, epiphyseal separations, vertebral body fractures, digital fractures, scapular fractures, sternal fractures, and complex skull fractures.

► Objectives: Did you learn to ...

- Recognize a metaphyseal corner fracture and what implications this fracture has?
- Know the indications to perform a skeletal survey when suspecting nonaccidental trauma and what images are included?
- Understand which fractures are specific for nonaccidental trauma?

QUICK QUIZ: THE BURNIN' HIP O' FIRE

A 35-year-old obese female with a large pannus presents with a burning pain in anterior-lateral thigh. It started when she bought a new wide belt (ornate with skulls and Harley-Davidson logos) and started wearing hip hugger pants in order to display her tasteful sacral tattoo (... and society thanks her). The pain seems worse on days when she wears the belt and seems better on days when she hangs out *au naturel* at home.

The most likely diagnosis is:

- A) Meralgia paresthetica
- B) Trochanteric bursitis
- C) Tropical pyomyositis
- D) Ruptured plantaris muscle
- E) Polymyositis

The correct answer is "A." Meralgia paresthetica is described as a burning pain in the anterior-lateral thigh and is caused by compression of the lateral femoral cutaneous nerve. It is most common in those who wear tight jeans or wide belts and who are obese. Treatment is to relieve the inciting cause. Tricyclic antidepressants or other medication for neuropathy may also be helpful. "B," trochanteric bursitis, occurs when there is inflammation of the bursa over the greater trochanter of the femur. Patients complain of pain in the lateral hip and outer thigh. There is point tenderness over the greater trochanter. Treatment is physical therapy for core strengthening and a steroid injection of the bursa. "C," tropical pyomyositis, is a deep infection of a single muscle group that is often caused by *Staphylococcus aureus* and is generally in the muscles of the lower extremities. It is increasingly recognized in the United States. Predisposing factors in temperate climates include immunosuppression (especially HIV), malnutrition, IV drugs use, etc. In the tropics patients usually have a normal immune system. "D," a ruptured plantaris muscle, occurs in the calf and is not related to the thigh. It is often caused by planting of the foot forcefully (such as in tennis or basketball) and patients may report a "pop" followed by calf/gastrocnemius pain. "E," polymyositis, would cause bilateral pain and weakness in the proximal legs, but the pain would not be burning in nature.

CASE 12.8

A concerned father presents to your clinic with a 1-month-old daughter. He is worried that his daughter appears to be pigeon-toed, and his mother-in-law is sure (as most mothers-in-law are) that the child will need immediate surgery for correction. Your examination reveals a pleasant, well-developed 1-month-old female with moderate medial deviation of the forefoot bilaterally. A line bisecting the heel passes through the fourth toe on each foot. The lateral borders of the feet are convex; the heels are in a normal neutral position. The feet are flexible and the deformity can be passively corrected to the midline.

Question 12.8.1 This description is best characterized as?

- A) Clubfoot
- B) Internal tibial torsion
- C) Flexible flatfoot
- D) Excessive femoral anteversion
- E) Metatarsus adductus

Answer 12.8.1 The correct answer is "E." The above is a classic description of the foot shape of metatarsus adductus. In the normal foot, a line bisecting the heel would pass through the second and the third toe webspace. In those with metatarsus adductus, it passes more laterally depending on the severity. In those with the most severe deformity, a line bisecting the heel would pass through the fourth and the fifth toe webspace. In addition to the heels remaining in a neutral position—indicating that the problem is isolated to the shape of the foot and **not** to an internal rotation of the tibia—the forefoot is flexible and easily straightened into normal position.

Question 12.8.2 The most appropriate treatment for the above case would be?

- A) Surgical reconstruction
- B) Serial casting
- C) Physical therapy referral for stretching and exercise
- D) Watchful waiting and reassurance
- E) Orthopedic outflare shoes

Answer 12.8.2 The correct answer is "D." Spontaneous correction occurs in most children. The mother-in-law can begin a regimen of gentle foot stretching. It will give her something to do but does not change the outcome. Care should be taken to avoid keeping the child in the prone position with the feet in an inward position—which the parents should be doing anyway ("back to sleep" for SIDS prevention). **If the deformity is severe and inflexible, serial casting and/or surgical intervention may be indicated.** A rigid metatarsus adductus in a child >3 months or a residual problem in a child with a flexible metatarsus adductus >6 months is an indication for pediatric orthopedic referral.

HELPFUL TIP:

Clubfoot (talipes equinovarus) is observed at birth. Patients are more often males (2:1 male:female ratio) and present with the following findings: calcaneus seems to be drawn inward and upward, moderate forefoot adduction, and the foot can be placed in a neutral position by passive manipulation. These patients can be treated successfully with early referral for serial casting and manipulation, typically via the Ponseti method, which we are obligated to promote since Dr. Ignacio Ponseti developed it at the University of Iowa. Actually, it really is an extremely important advance in clubfoot treatment and is now the standard of care used around the world.

► **Objectives: Did you learn to ...**

- Identify a patient with metatarsus adductus?
- Discuss treatment approaches to metatarsus adductus?

► **CASE 12.9**

A 5-year-old girl who has recently recovered from chicken pox (“Thank you, anti-vaccine parents!”) presents with her mother for evaluation of left leg pain and refusal to walk. The mother reports that she has complained of worsening pain over the last 4 to 5 days. She started to limp noticeably yesterday and refused to walk this morning. Also, the mother reports general malaise and subjective fever. The patient complains of pain over the distal thigh and knee. The mother has not seen any swelling of the knee, and the patient denies trauma.

Examination reveals a pleasant 5-year-old female who appears uncomfortable, but nontoxic and in no acute distress. Her temperature is 38.5°C. The left distal thigh (not the joint) is painful to palpation, and slightly warm. The knee joint has no effusion and the ROM is full with only mild discomfort on knee motion. There is no hip joint involvement.

Question 12.9.1 What is the most common bacterial pathogen associated with this patient’s condition?

- A) Group A *Streptococcus*
- B) Group B *Streptococcus*
- C) *Haemophilus influenzae*
- D) *S. aureus*
- E) None of the above; this is not an infection

Answer 12.9.1 The correct answer is “D.” The acute nature of the symptoms, presence of fever, and minimal involvement of the joint makes osteomyelitis the most likely diagnosis. In addition, osteomyelitis is associated with chicken pox in children. There is clearly an increase in the prevalence of MRSA as a pathogen in osteomyelitis (two-thirds of cases in a recent review). Thus, it is wise to choose an antibiotic with MRSA coverage.

**HELPFUL TIP:**

Pseudomonas aeruginosa is commonly associated with osteomyelitis in the setting of a plantar puncture wound through a tennis shoe.

Allow us to digress.

Question 12.9.2 The most common organism causing osteomyelitis in patients with sickle cell disease is:

- A) *Neisseria gonorrhoeae* (Gonococcus)
- B) Polymicrobial
- C) *Salmonella* species
- D) *S. aureus*
- E) *Streptococcus* species

Answer 12.9.2 The correct answer is “C.” *Staphylococcus* is responsible for the majority of bone infections in the general population. *Salmonella* species are responsible for up to 85% of bone and joint infections in patients with a history of sickle cell disease, with *E. coli* being another important player.

**HELPFUL TIP:**

Most cases of childhood osteomyelitis are the result of hematogenous spread rather than by direct contamination of the bone (as opposed to our middle-aged or elderly diabetic foot ulcer patients).

Question 12.9.3 Identification of the pathogen in a case of osteomyelitis is most commonly made by:

- A) ASO titer
- B) Blood culture
- C) Joint aspiration, culture, and Gram stain
- D) Pathology report following open biopsy
- E) Witchcraft

Answer 12.9.3 The correct answer is “B.” A blood culture will reveal the offending organism in 40% to 50% of cases. However, empiric treatment is often the rule, and antibiotics are selected based on most likely pathogens expected in a given clinical scenario. Joint aspiration is not typically indicated unless there is strong evidence of joint involvement. It can take weeks for changes to be seen on plain film radiographs. Therefore, MRI is the imaging modality of choice. CT or bone scan can also be used if MRI is not available or contraindicated. If changes are identified and a neoplastic process is ruled out, aspiration at the site of periosteal elevation and bony destruction should be considered if a pathogen has not yet been identified by blood culture. “A,” an ASO titer, would not be helpful here since this test is for *Streptococcus pyogenes* infection. An ASO titer would be helpful if looking for rheumatic fever. “D,” surgical biopsy, may be required if blood cultures do not reveal a pathogen and the patient is not responding appropriately to empiric antibiotics.

**HELPFUL TIP:**

Treatment of osteomyelitis requires 4 to 6 weeks of antibiotics. Surgical debridement is usually (if not always) required as well. Several acute phase reactants can be useful in these cases including CRP and ESR. CRP rises rapidly and normalizes with successful treatment. ESR will decline steadily over 2 to 3 weeks with treatment.

► **Objectives: Did you learn to ...**

- Diagnose osteomyelitis in a child?
- Identify common pathogens involved in osteomyelitis?

► CASE 12.10

A 45-year-old female with a history of rheumatoid arthritis, on chronic low-dose prednisone, presents to your clinic with 2 days of right knee pain. The patient reports that her knee has been swollen and painful to touch, and she now is having difficulty bearing weight due to the pain. She has had previous knee pain, but nothing this severe. She denies any trauma, fevers, chills, knee surgery, illegal drug use, or risky sexual behavior. On examination, she is well appearing, afebrile, and has a moderate right knee effusion with limited ROM. There is no overlying erythema, but the knee feels warm to touch.

Question 12.10.1 Which of the following diagnostics is the most valuable to rule in or rule out the diagnosis with the highest potential morbidity?

- A) Plain films of the affected knee
- B) WBC count
- C) ESR
- D) Arthrocentesis
- E) MRI

Answer 12.10.1 The correct answer is “D.” The most concerning diagnosis with the highest potential morbidity in this patient is septic arthritis. Her history of rheumatoid arthritis as well as long-term steroid use put her at high risk. In a patient in whom you are concerned about septic arthritis, the most important piece of diagnostic data that you can obtain comes from synovial fluid analysis. While plain radiographs, a WBC count, an ESR, and CRP may be obtained (your friendly neighborhood orthopedic surgeon will surely want to know them), they are neither sensitive nor specific enough to rule in or rule out septic arthritis in a high-risk patient.

Question 12.10.2 Which of the following signs or symptoms has sufficient sensitivity to rule out septic arthritis if *absent*?

- A) Joint edema or effusion
- B) Fever
- C) Sweats
- D) Significantly restricted ROM
- E) None of the listed signs or symptoms has sufficient sensitivity to rule out septic arthritis, if absent

Answer 12.10.2 The correct answer is “E.” Unfortunately, there are no clinical signs or symptoms that have sufficient sensitivity to rule out septic arthritis. Signs and symptoms should raise clinical suspicion; however, the only definitive diagnostic modality is arthrocentesis.

You effortlessly obtain 10 mL of cloudy synovial fluid that is sent to the lab for Gram stain, culture, cell count with differential, and crystal analysis. The Gram stain is

TABLE 12-2 SENSITIVITY AND SPECIFICITY OF SYNOVIAL FLUID ANALYSIS IN SEPTIC ARTHRITIS

Synovial Fluid WBC Count	Sensitivity (%)	Specificity (%)
>100,000/mm ³	30	>99
>50,000/mm ³	62	92
>25,000/mm ³	77	73

negative with cultures pending. The synovial WBC count is 51,000/μL with >90% polymorphonuclear cells. The crystal analysis shows calcium pyrophosphate crystals. You obtain a peripheral WBC count that is 11,000/μL and an ESR is 55 mm/hr.

Question 12.10.3 What is the most appropriate next course of action based on these findings?

- A) Prescribe high-dose prednisone for a flair of her rheumatoid arthritis
- B) Start IV antibiotics and obtain emergent orthopedic consultation
- C) Treat her for pseudogout
- D) Recommend rest, ice, compression, and a prescription for oxycodone

Answer 12.10.3 The correct answer is “B.” Various cutoffs for synovial WBC counts have been proposed, ranging from >25,000/μL to >100,000/μL in native joints, with sensitivities ranging from 30% to 77% (Table 12-2). Cutoffs are much lower in patients with prosthetic joints. A prosthetic joint with WBC count of >1,700/μL may be up to 94% sensitive for septic arthritis. When the percentage of polymorphonuclear cells is >90%, this significantly increases the likelihood of septic arthritis. Don’t let the calcium pyrophosphate crystals dissuade you from suspecting septic arthritis as both gout and pseudogout can coexist with septic arthritis up to 25% of the time (*J Rheumatol.* 2012;39:157).

► Objectives: Did you learn to ...

- Recognize the clinical presentation of septic arthritis?
- Understand the limitations of using signs and symptoms to rule out septic arthritis?
- Describe the appropriate workup for a patient with suspected septic arthritis?

QUICK QUIZ: MY BIG FAT GREEK KNEE PAIN

A 55-year-old obese female comes to your office complaining of knee pain when she walks. She had an MRI at an urgent care center, which showed some meniscal damage. She is tender inferiorly and medial to the patella on the proximal tibia (but not on the joint line).

Which of the following is true?

- A) Washing out her knee by arthroscopy will help to relieve her symptoms
- B) The finding of a meniscal injury on MRI correlates well with symptoms of pain
- C) Based on its location, pes anserine bursitis is the likely cause of her pain
- D) Baklava is Dr. Wilbur's favorite food

The correct answer is "C." The pes anserine ("goose's foot") bursa is located on the medial, proximal aspect of the tibia and is where the tendons of the sartorius, gracilis, and semitendinosus attach. It often becomes inflamed causing significant and chronic knee pain. Conservative therapy with rest, ice, NSAIDs, and stretching may be tried initially. However, these often fail, and most patients experience significant improvement with corticosteroid injections. "A" is incorrect. Several studies have found that washing out the knee and trimming the cartilage is of no benefit in either meniscal injury or osteoarthritis. "B" is also incorrect. MRI of the knee is not particularly useful for determining whether a meniscal injury is the source of pain. Similar to herniated disks, many asymptomatic patients have meniscal injuries on MRI, limiting our ability to assign symptoms to an MRI finding. This is especially true in the elderly with arthritis where >90% will have meniscal damage. As to "D," it obviously does not relate to the case. We call that "test taking skill." If you chose "D," woe is with you.

QUICK QUIZ: ORTHOPEDIC INFECTIONS

The most common organism causing septic arthritis in the teenage years is:

- A) *N. gonorrhoeae*
- B) Polymicrobial
- C) *Salmonella* species
- D) *S. aureus*
- E) *Streptococcus* species

The correct answer is "A." Gonococcus is the most common organism isolated from the joints of sexually active, teenage individuals.

▶ CASE 12.11

A 28-year-old male presents to your clinic for evaluation of lower-back pain (LBP). Yesterday morning he first noticed the discomfort, manifesting as stiffness and soreness in the lower back. The day before had been spent running a floor polisher. He describes his pain as sharp in nature and 8/10 in intensity. He denies radiation of the pain, sensory changes, and constitutional symptoms. He is concerned after consulting Dr. Google that this may be an injury to a disk and that he may be permanently

disabled due to his extreme pain. In fact, he helpfully printed the disability forms and hands them to you to complete.

Question 12.11.1 Which of the following signs or symptoms would be "red flags" indicating the need for early imaging and/or referral?

- A) Pain radiating down one or both legs into the posterior thigh
- B) Severe pain, prompting the patient to request narcotics
- C) Pain greater with active lumbar extension than with forward flexion
- D) New-onset erectile dysfunction with back pain
- E) Pain worse with bending over

Answer 12.11.1 The correct answer is "D." The onset of erectile dysfunction is suggestive of neurologic involvement and warrants further investigation. None of the other options are suggestive of significant disease requiring immediate intervention ("A" certainly could represent disk disease; however, this does not require immediate intervention). Of note, spontaneous erections without sexual stimulation can also be a sign of neurologic involvement.

Question 12.11.2 Early imaging should be obtained in all of the following presentations of LBP EXCEPT:

- A) Neurologic symptoms such as bowel or bladder dysfunction and impotence
- B) History of fever, night sweats, and weight loss
- C) History of cancer
- D) Trauma
- E) Age > 50 years

Answer 12.11.2 The correct answer is "E." Patients over the age of 50 should have early imaging. See Table 12-3 for other criteria that should prompt early imaging.

TABLE 12-3 CRITERIA SUGGESTING THE NEED FOR EARLY IMAGING FOR BACK PAIN

Bowel or bladder dysfunction
New onset of erectile dysfunction
Fevers or night sweats (suggestive of infection or malignancy)
Unplanned weight loss
Night pain
Personal history of cancer
Saddle anesthesia
History of recent trauma (e.g., fall or direct blow, NOT twisting or lifting)
Age >50 or <18 years
Patient with current or recent use of steroids
Any suspicion of an infectious or neoplastic cause for low-back pain
Pain for >6 weeks

**HELPFUL TIP:**

Several of the indicators listed in Table 12-3 are associated with cauda equina syndrome. Cauda equina syndrome is the product of an acute reduction in the volume of the spinal canal which can lead to compression and paralysis of multiple nerve roots in the S-1 to S-5 area resulting in urinary retention, saddle anesthesia, and lower extremity weakness. It is often caused by central disk herniations, epidural abscesses and hematomas, fractures, and other trauma. Incomplete syndromes are common; the patient may not have all of the clinical findings above. Cauda equina syndrome is an *orthopedic emergency*. An MRI and surgical consultation should be sought without delay.

**HELPFUL TIP:**

Patients who **do not** have films done initially for mild back pain from twisting, etc. actually have better outcomes than those who do. When we order imaging studies, we “medicalize” the illness, causing the patient to expect a longer recovery and the need for intervention in order to get better. Don’t do films unless they have one of the red flag symptoms above.

Upon physical examination, you note the vital signs are normal. Straight leg raise (SLR) testing on the right leg at 55 degrees reproduces the patient’s pain in the lower back and a painful “tightness” in the posterior thigh. He complains of the same discomfort on the left at 30 degrees.

Question 12.11.3 Based on these findings, which of the following statements is true?

- A) This is a positive SLR test bilaterally and is specific for disk herniation
- B) This is a positive SLR test on the left and is specific for disk herniation
- C) This is a positive SLR test on the right and is specific for disk herniation
- D) This is a negative SLR test bilaterally

Answer 12.11.3 The correct answer is “D.” The SLR test can be performed in several ways, which are listed here.

- **Seated active:** with the patient seated on the examination table, the patient dorsiflexes the foot and extends the knee.
- **Seated passive:** with the patient seated on the examination table, the examiner passively extends the knee, and radicular symptoms will be exacerbated with passive ankle dorsiflexion.
- **Lying passive:** with the patient in a supine position, the examiner holds the knee in full extension and passively flexes the hip, and radicular symptoms will be exacerbated with passive ankle dorsiflexion.

In all cases, the test is positive when radicular symptoms occur (e.g., pain and paresthesias down the leg below the level of the knee—not back or thigh pain from muscle stretching) between 25 and 75 degrees of hip flexion while lying or with knee extension while seated. The symptoms will be exacerbated with active or passive ankle dorsiflexion. However, SLR is neither sensitive nor specific for disk disease. “Crossover” pain with radicular symptoms in the leg not lifted is very specific for disk disease but is not very sensitive.

Even though SLR is negative, you continue your neurologic examination. You note symmetric patellar reflexes, diminished Achilles reflex on the right, and symmetric strength in the legs except for decreased strength with right foot plantar flexion. You also note decrease in gross sensation to light touch over the right lateral foot.

Question 12.11.4 Which of the following nerve roots is most likely compromised?

- A) L3
- B) L4
- C) L5
- D) S1
- E) S2–S4

Answer 12.11.4 The correct answer is “D.” A summary of nerve root innervation is given in Table 12-4.

TABLE 12-4 EXAMINATION FINDINGS OF LUMBAR AND SACRAL SPINAL NERVE ROOTS

Nerve Root	Reflex	Motor	Sensory	Test
L2–L3	None	Quadriceps	Anterior thigh	Knee extension
L4	Patella	Tibialis anterior (foot dorsiflexion, inversion)	Medial lower leg and foot	Walk on heels
L5	Medial hamstring (difficult to assess)	Extensor hallucis longus (dorsiflexion of big toe)	Dorsal foot	Hold up great toe
S1	Achilles	Peroneus longus and brevis (ankle eversion) and plantar flexion of foot	Lateral foot	Walk on toes
S2–S4	Anal wink	Intrinsic foot muscles, anal sphincter tone	Perianal	

Question 12.11.5 Appropriate initial treatment for this patient's acute back pain should include which of the following?

- A) Strict bed rest
- B) Pain control
- C) Corset or lumbar belt
- D) Referral for epidural steroid injection or endoscopic disk resection
- E) A and B

Answer 12.11.5 The correct answer is "B." In acute mechanical back pain (no longer than 6 weeks), regardless of the method of treatment, 40% are better within 1 week, 60% to 85% in 3 weeks, and 90% in 2 months. Negative prognostic factors include more than three episodes of back pain, gradual onset of symptoms, and prolonged absence from work. *Bed rest does not contribute to a return of function and may worsen outcomes.* Early mobilization of the patient is best for allowing him to continue activities as tolerated. Acetaminophen can be used for pain control and may have fewer side effects than do the NSAIDs. (However ... see NNT in the first paragraph of this chapter!) Chiropractic care may be useful (but not for the neck where it may result in carotid or vertebrobasilar vessel dissection). Data on acupuncture are mixed.

HELPFUL TIP:

For LBP, early mobilization and walking is important. Epidural steroid injections, while intuitively appealing for disk disease, have been shown to be of no long-term (and little short-term) benefit (*J Bone Joint Surg.* 2012;94:1353–1358; *BMJ.* 2015;350:h1748).

For **spinal stenosis**, surgery has not been shown to be particularly better than conservative, nonsurgical treatment (*Ann Intern Med.* 2015;162:465). Steroids have also not been shown to be of any benefit in spinal stenosis. Gabapentin and other anticonvulsants are not helpful for back pain (*CMAJ.* 2018; Jul 3).

You prescribe your pain medication of choice (as long as it's not an opioid) and recommend rehabilitation exercises.

Question 12.11.6 Which of the following has been shown to be effective at reducing the recurrence of back injury in the workplace?

- A) Back support belts
- B) "Back School" that teaches proper lifting techniques, stretches, etc.
- C) Increasing physical fitness and muscle tone
- D) A and C
- E) B and C

Answer 12.11.6 The correct answer is "C." The only thing that has been unequivocally shown to reduce further back injuries is improving the overall fitness of the patient and their muscle tone. Of special note, back support belts, long worn in industry,

have equivocal data with most studies being negative. "Back School" also does not seem to help.

HELPFUL TIP:

Physical therapy modalities such as application of heat, cold, ultrasound, and muscle stimulation may have short-term benefit. Rehabilitation exercises focusing on trunk extensors, abdominal muscles, and aerobic conditioning promote early mobilization, which is critical in treating acute back pain. **The specific exercise does not matter as much as the mobilization.** Sham therapy works as well as specific exercises as long as the patient is mobile.

► **Objectives: Did you learn to ...**

- Generate a differential diagnosis and understand the etiology of lumbar spine pain?
- Evaluate and treat acute LBP?
- Recognize warning signs of LBP?

QUICK QUIZ: BACK PAIN

Spondylolysis commonly occurs in which part of the spine?

- A) Cervical spine lateral processes
- B) Thoracic spine pars interarticularis
- C) Thoracic spine lateral processes
- D) Lumbar spine pars interarticularis

The correct answer is "D." Spondylolysis is characterized by pars interarticularis stress fractures and most commonly occurs in the lumbar region.

QUICK QUIZ: MORE BACK PAIN

Anterior slippage of one vertebra on another is called:

- A) Spondylolysis
- B) Spondylolisthesis
- C) Spondylitis
- D) Spondyloarthropathy
- E) Scheuermann disease

The correct answer is "B." Slippage of one vertebra on another is called spondylolisthesis. "A," spondylolysis, is discussed above. Spondylolysis can lead to spondylolisthesis. Spondyloarthropathy is a nonspecific term referring to inflammation of the spine and encompasses such diseases as ankylosing spondylitis, Reiter disease, enteropathic arthritis, etc. Spondylitis is a more specific term for the same thing (e.g., ankylosing spondylitis). "E," Scheuermann disease, is a benign process causing kyphosis by compression of the vertebrae (at least 5 degrees of wedging in three consecutive

vertebrae). The cause is unknown but it tends to present in adolescence.

QUICK QUIZ: EVEN MORE BACK PAIN

Spondylolisthesis is graded based on the degree of slipping of one vertebra on the other. Which of the following patients would need surgical consultation?

- A) Grade one (<25% slip) with no symptoms in an early teen (12–14)
- B) Grade 2 (25–50% slip) with no symptoms in an early teen (12–14)
- C) Grade 3 (50–100% slip) with mild pain in a 20-year-old college gymnast
- D) When slippage is 10% to 15% with no symptoms in a patient >60 years old
- E) When slippage is 25% with no symptoms in a patient >60 years old

The correct answer is “C.” Spondylolisthesis can be a problem in the late teens and twenties, especially in athletes. Patients often become symptomatic when there is 25% slippage or greater. Mild degrees of slip can be treated conservatively, although surgical treatment threshold varies considerably among orthopedic surgeons. Predisposing factors for spondylolisthesis include recurrent lumbar hyperextension (gymnasts, football players, etc.), although many patients do not have an identifiable cause. Any adolescent athlete who presents with back pain that is made worse by hyperextension should raise your suspicion and spondylolisthesis. Older patients who are asymptomatic do not need to be considered for surgical treatment unless the slip is grade 4 (100% or greater).

QUICK QUIZ: BACK PAIN IN CHILDREN

A 4-year-old boy presents to your office accompanied by his mother who says he has a limp and LBP. This has been getting progressively worse over the past 2 weeks. When the patient sits, he sits in a “tripod” position supporting his weight on his hands. Vitals are normal without a fever and a CBC is normal.

This history is most consistent with:

- A) Discitis
- B) Occult fracture
- C) Growing pains
- D) Juvenile idiopathic arthritis
- E) Mechanical low-back strain

The correct answer is “A.” This history is most consistent with discitis. Discitis is an inflammatory process of the disk usually found in children age infancy to 3 years but may occur at any age. The etiology is usually *Staphylococcus* (low-grade infection, 60%) but there may be sterile inflammation. Fever is usually absent in discitis (seen in only 25%), and blood cultures are sterile.

The white count is usually normal, although ESR is elevated in 90%. Treatment is not standardized, but most experts would include anti-staphylococcal antibiotics. “B,” occult fracture, is unlikely in a child this age. “C,” growing pains, does not present with back pain (see the discussion of growing pains earlier in this chapter). Juvenile idiopathic (previously rheumatoid) arthritis presents with small joint involvement as opposed to back pain.

CASE 12.12

A 24-year-old male presents to the clinic 2 days after a collision during a softball game in which he fell on his outstretched right hand (“But I made the play!” he exclaims). He reports he could not continue playing and that his pain has not improved. He has some general edema around the right wrist, poor grip strength secondary to pain, point tenderness over the radial aspect of the wrist (“snuff box tenderness”), and decreased ROM. There is no obvious deformity, and he is neurovascularly intact.

Question 12.12.1 Of the following, what would be the most likely diagnosis for this patient?

- A) Colles fracture
- B) Scaphoid fracture
- C) Smith fracture
- D) Extensor carpi radialis strain
- E) Scapholunate sprain

Answer 12.12.1 The correct answer is “B.” Although all of these could be in the differential diagnosis, “B” is the most likely based on mechanism of injury and clinical findings. The scaphoid spans both the proximal and distal carpal row. In this position, it is quite vulnerable to high-impact injuries, such as a fall on an out-stretched hand, and is the most commonly fractured carpal bone. The absence of deformity makes a Colles or Smith fracture (“A” and “C”) less likely. Further, a sprain or a strain (options “D” and “E”) are less likely, given the bony point tenderness, decreased range of motion, and overall nonimprovement with conservative measures.

HELPFUL TIP:

Palpating for snuffbox tenderness with the wrist in slight ulnar deviation increases the sensitivity of the physical examination. An additional physical examination finding consistent with a scaphoid injury is pain at the scaphoid with axial loading of the thumb.

Plain film radiographs, including AP and lateral of the hand and wrist as well as scaphoid views, are negative for fracture.

Question 12.12.2 What is the most appropriate next step for this patient?

- A) Short-arm thumb spica cast with follow-up in 10 to 14 days
- B) NSAIDs, ice, compression, and elevation followed by physical therapy

- C) MRI or CT to rule out an occult fracture
- D) Orthopedic referral
- E) Return to play within the week

Answer 12.12.2 The correct answer is “A.” Scaphoid fractures are often occult acutely and usually will be evident on plain films after 10 to 14 days due to bony resorption along the fracture line. If repeat films are negative but suspicion remains high, an MRI or CT should be considered.

HELPFUL TIP:

Although not the standard of care, early MRI or CT (neither is definitively superior to the other) to evaluate for occult scaphoid fractures may allow patients to return to full activity sooner than would be possible if they were splinted for 10 to 14 days. This may be cost-effective for certain patients (i.e., concert violinists or the Iowa Hawkeyes’ starting quarterback). Both MRI and CT are better at excluding fractures than they are at confirming them (they can be ruled out, but not necessarily ruled in). It should be noted that **splinting** does not eliminate motion at the scaphoid; thus, there can be shear forces across the fracture line making avascular necrosis more likely...so, if you are worried they will be better off **casted** or in the MRI machine.

Repeat wrist radiographs including scaphoid views 2 weeks post injury indicate a nondisplaced fracture of the proximal pole of the scaphoid.

Question 12.12.3 You recommend which of the following treatment plans?

- A) Wrist and thumb spica splint and physical therapy because good blood supply at the proximal pole allows fast healing
- B) Thumb spica cast for 6 weeks then repeat x-rays
- C) Short-arm cast excluding the thumb for 4 to 6 weeks
- D) Orthopedics referral for open reduction/internal fixation
- E) B or D

Answer 12.12.3 The correct answer is “E.” It is clear that a spica cast with the thumb included is important; whether a short- or long-arm cast is optimal is still a matter of debate. Open fixation is another option. Generally, an orthopedic surgeon should oversee treatment of scaphoid fractures since the complication rate is high. A proximal pole fracture has high risk for nonunion and avascular necrosis (90%). **The blood supply to the scaphoid is through the distal pole, putting the proximal pole at high risk for complications.** Evidence of healing may not be well visualized on plain films, and a CT or MRI may be needed to confirm the degree of healing. The closer the fracture line is to the proximal pole, the lower the threshold for orthopedic referral.

HELPFUL TIP:

Healing time for a distal pole scaphoid fracture is 6 to 8 weeks, for middle third or waist fractures 8 to 12 weeks, and proximal pole fractures can take 12 to 24 weeks.

► Objectives: Did you learn to ...

- Recognize a patient at risk for scaphoid fracture?
- Manage a patient with a scaphoid fracture?

QUICK QUIZ: HAND INJURIES

A patient presents after “jamming” his index finger while playing basketball. He has mild swelling at the DIP joint. At rest, his DIP is flexed. He has full ROM of all joints except he cannot extend at the DIP.

What is the appropriate treatment and follow-up?

- A) RICE therapy, PRN follow-up
- B) A full extension splint of the DIP joint worn at all times with orthopedic follow-up in 1 to 2 weeks
- C) A removable aluminum splint to be worn for comfort, follow-up in clinic in 1 month
- D) Ibuprofen and return to full activities, PRN follow-up

The correct answer is “B.” The patient has suffered an injury to his extensor tendon mechanism, known as a “mallet finger.” X-rays are indicated to evaluate for a bony fracture/avulsion. The initial treatment is an extension splint at the DIP joint, and follow-up with an orthopedic surgeon as surgical correction is sometimes required. The splint must be worn at all times. See Figure 12-3 for the anatomy of a mallet finger.

HELPFUL TIP:

Surgical indication for a Mallet finger include: volar subluxation, >30% of the articular surface involved, >2 mm gap of the avulsed bone, chronic injury >12 weeks. An extensor lag of 10 degrees or less can be tolerated unless you are a professional pianist. If greater than 10 degrees, it increases the chance of a swan neck deformity down the road.

FIGURE 12-3. Mallet Finger.

**QUICK QUIZ: FRACTURES****A Colles fracture consists of:**

- A) Fractures of the midshaft of the radius and ulna
- B) Fractures of the head of radius and ulna that is displaced dorsally and is angulated
- C) Fractures of the head of the radius and ulna that are displaced ventrally and is angulated
- D) Fracture of the distal radius at the metaphysis, dorsally displaced and often angulated

The correct answer is "D." OK, some of you may have chosen "B." However, the head of the radius is at the *elbow* and not at the wrist. A Colles fracture is a fracture of the distal radius at the metaphysis, which is displaced dorsally and often angulated. It is the most common wrist fracture in adults. The ulnar styloid is often involved, and there may be intra-articular involvement as well.

**HELPFUL TIP:**

Finkelstein's test can be painful regardless of tendonitis so check both sides when doing your exam or you will get fooled.

**QUICK QUIZ: ANGER MANAGEMENT ISSUES**

A 19-year-old male was mad at his computer and decided to punch the wall. "He fought the wall and the wall won." Radiographs demonstrate a fifth metacarpal fracture with some angulation.

What is the maximal acceptable angulation and rotation for a boxer fracture, fourth or fifth metacarpal, to maintain full hand function?

- A) 10 degrees of dorsal angulation and 10 degrees of rotation
- B) 30 degrees of dorsal angulation and 5 degrees of rotation
- C) 40 degrees of dorsal angulation and 0 degrees of rotation
- D) 90 degrees of dorsal angulation and 0 degrees of rotation

The correct answer is "C." Any degree of rotation, or >40 degrees of dorsal angulation, may result in significant functional deficits. Reduction should be attempted if angulation is >10 degrees. Patients should be advised that with angulations >10 to 15 degrees, there will likely be a loss of metacarpophalangeal (MCP) prominence, although there should be no loss of function. If this is unacceptable to the patient, referral is recommended.

**HELPFUL TIP:**

Any "scissoring" or crossing of the patient's fingers while they clench their fist should raise your suspicion for a rotational deformity.

**HELPFUL TIP:**

If you can't beat your computer at chess, don't get frustrated; try changing sports. We are sure you can beat your computer at mixed martial arts.

CASE 12.13

The next patient in the ED is an 18-year-old high school football player. He was playing in a football game this evening when he was tackled from the side and landed directly on the lateral aspect of his right shoulder. He states that he can actively move his arm, but is limited by pain on the top of his shoulder. He has also noticed a small painful bump on top of the right shoulder and is concerned that he "broke his collarbone."

Question 12.13.1 Based on the mechanism of injury and patient history, the most likely injury would be?

- A) Acromioclavicular (AC) sprain
- B) Biceps tendon rupture
- C) Glenohumeral dislocation
- D) Rotator cuff tear
- E) Scapula fracture

Answer 12.13.1 The correct answer is "A." Although any of these injuries may be present, an AC sprain is the most likely based on the history and the way the patient fell. A thorough examination should be able to further distinguish between these injuries. "B" is not likely, given the mechanism of injury. The deformity associated with biceps tendon rupture (a defect in tendon with pain and deformity in the muscle belly representing the contracted, detached muscle) would be on the upper arm or at the elbow, not on the "top" of the shoulder. "C" is incorrect. The deformity and loss of ROM of a glenohumeral dislocation (shoulder dislocation) is usually obvious. The mechanism of injury is typically a forced abduction and external rotation. "D" is less likely. A rotator cuff tear will present with pain more laterally over the subacromial space and should not have an associated deformity. The ROM is generally markedly limited by pain. "E" is unlikely. Scapula fractures are uncommon and are usually the result of high velocity blunt trauma such as a blow from a baseball bat or motorcycle accident. Plain film radiographs should be obtained to rule out a clavicle fracture, especially when any deformity is present.

Question 12.13.2 Your patient is worried that he broke his "collarbone." If he did sustain a nondisplaced clavicle fracture, which of the following would be appropriate treatment?

- A) Rest, ice, and NSAIDs for pain control
- B) A sling for comfort only
- C) A figure-of-eight splint
- D) A and B
- E) Any of the above is an equally valid treatment

Answer 12.13.2 The correct answer is “D.” While the traditional teaching has been that a figure-of-eight splint is required, it adds nothing to the treatment of a clavicle fracture. Pain control and using a sling works just as well. Additionally, figure-of-eight splints often increase a patient’s pain and can cause a brachial plexus injury. Thus, a sling is preferable. Complete immobilization is not necessary for nondisplaced clavicle fractures—keep the patient moving.

Question 12.13.3 The proper treatment for a clavicle fracture that is minimally displaced is:

- A) Closed reduction and then a sling
- B) Open reduction and immobilization
- C) Open reduction and **early** mobilization
- D) A sling
- E) Clavicular disarticulation

Answer 12.13.3 The correct answer is “D.” The ends of a displaced clavicle fracture need not be 100% approximated for healing to occur and for function to return. Thus, reduction is generally not necessary.

HELPFUL TIP:

The paradigm of the treatment of clavicle fractures is shifting. More patients are getting surgical intervention (an internal fixation), especially athletes when a quick return to sport is desired. This decision depends on the degree of displacement and the occupation of the patient (Surgeons? Yes. Car Salesmen? Not so much). Greater degrees of fracture displacement and bayoneting have higher rates of fracture nonunion. Thus, discussion with an orthopedist is appropriate for patients with displaced clavicle fractures.

You send the patient for x-rays. AP radiographs show *slight* widening of the AC joint on the injured side. The examination and radiograph confirm your suspicion of an AC injury.

Question 12.13.4 For *this* patient with an AC sprain, you offer:

- A) Sling for comfort, ice, and NSAIDs or analgesics for pain control
- B) Referral for open fixation
- C) Figure-of-eight strap for 4 to 6 weeks
- D) Corticosteroid injection followed by physical therapy
- E) Manual reduction, then sling-and-swath immobilization for 6 to 8 weeks

Answer 12.13.4 The correct answer is “A.” Conservative management is appropriate for low-grade AC joint sprains. AC sprains are graded I to VI. Grades I to III are generally treated conservatively, while grades IV–VI may need to be treated surgically. Signs of high-grade (IV–VI) AC sprains include posterior or inferior displacement of the clavicle and widening of 100% or more of the coracoclavicular space. Just like with clavicle fractures, figure-of-eight straps have largely fallen out of favor for treatment of AC joint injuries. Corticosteroid injections are

not the treatment of choice for acute AC joint injuries. An injection may be considered as an adjunct treatment for degenerative arthritis of the AC joint at some distant point in the future. Sling-and-swath immobilization is not indicated.

► **Objectives: Did you learn to ...**

- Differentiate between causes of shoulder injuries?
- Treat a clavicular fracture?
- Manage AC injuries?

► **CASE 12.14**

A 65-year-old male presents with left shoulder pain and weakness, which started 2 weeks ago after he put a new roof on his house. He does not recall a specific injury. The pain is worse with reaching for and lifting objects as well as with overhead activities. Nighttime pain is present. He describes himself active and healthy, and he only takes acetaminophen when needed for shoulder pain. You suspect that he may have rotator cuff tendinopathy.

Question 12.14.1 If this is the case, what do you expect to find on examination?

- A) Tenderness to palpation of the greater tuberosity of the humerus
- B) Limited active ROM
- C) Normal passive ROM
- D) Shoulder shrug with attempted abduction (such as with a frozen shoulder)
- E) Any of the above

Answer 12.14.1 The correct answer is “E.” Ok, so this might fit under the category of “trick question,” but the shoulder examination can be normal in a patient with a rotator cuff tear or tendinopathy, or it can include any of the elements listed in “A” through “D.” Notably, normal PASSIVE ROM (“C”) does not rule out rotator cuff pathology.

Question 12.14.2 Which of the following muscles is NOT a part of the rotator cuff?

- A) Supraspinatus
- B) Infraspinatus
- C) Subscapularis
- D) Teres major
- E) Teres minor

Answer 12.14.2 The correct answer is “D.” The rotator cuff consists of the other four muscles listed and functions to rotate the arm and stabilize the humeral head.

Question 12.14.3 Which of the following muscles is the most commonly torn in the rotator cuff?

- A) Supraspinatus
- B) Infraspinatus
- C) Subscapularis
- D) Teres minor

Answer 12.14.3 The correct answer is “A.” The supraspinatus is generally the point of origin for most tears.

HELPFUL TIP:

Full-thickness tears of the rotator cuff are uncommon in individuals below the age of 40, unless associated with trauma. Asymptomatic rotator cuff tears are very common in those over the age of 60 and are not always the pain generator—in other words—order MRIs judiciously in this population!

Based on your history and physical examination, you diagnose a rotator cuff tendinosis.

Question 12.14.4 Appropriate initial management of this 65-year-old male should be:

- A) Acetaminophen and physical therapy
- B) Oral corticosteroids and physical therapy
- C) Subacromial injection with corticosteroid and physical therapy
- D) Surgical repair and physical therapy
- E) Figure-of-eight strap

Answer 12.14.4 The correct answer is “A.” For initial management in an individual >60 years of age, acetaminophen and physical therapy for 6 weeks is the best answer. If the patient has no improvement or inadequate response, a corticosteroid injection may be used judiciously. Injection likely will result in at least short-term pain relief, but there is no good evidence that it helps long term. In addition, it is thought to weaken the tendon and may accelerate extension of a tear, if present. Patients with significant symptoms or failed therapy should be considered for MRI, orthopedic referral, and surgical management. Patients under the age of 60 with acute traumatic tears should be considered for surgery, with best results within 6 weeks of injury.

HELPFUL TIP:

The old adage about corticosteroids causing weakening of the tendon has recently been questioned. It is now thought that the steroid injection provides enough relief of the pain that the patient will start using the extremity in ways he or she had not done before. This leads to tendon rupture from the additional load. However, the point remains that steroid injections may be associated with, but not causative of, tendon rupture.

Your patient is successful in rehabilitating his left shoulder, but then he returns 2 years later with right shoulder problems. The right shoulder has become progressively stiff and painful, and his ROM is now significantly limited in

all directions. Your examination is consistent with “frozen shoulder” or adhesive capsulitis.

Question 12.14.5 Adhesive capsulitis is most commonly associated with which of the following?

- A) Diabetes
- B) Hyperthyroidism
- C) Spondyloarthritis
- D) Nondominant arm
- E) Male gender

Answer 12.14.5 The correct answer is “A.” Adhesive capsulitis has no clear predilection as to gender, race, arm dominance, or occupation. It is characterized by loss of ROM of the shoulder in all directions, with loss of both passive and active motion. It has a high incidence in patients with diabetes and tends to be more recalcitrant in those patients, of whom up to 50% will have bilateral involvement—although not necessarily concomitantly. Adhesive capsulitis is not typically related to trauma, but it can be associated with disuse due to pain, osteoarthritis, sling use, etc. Other conditions that are associated with adhesive capsulitis include hypothyroidism and Parkinson disease.

HELPFUL TIP:

Adhesive capsulitis is considered to be idiopathic and separate from posttraumatic or postoperative joint stiffness or adhesions.

Question 12.14.6 What initial treatment do you recommend for this patient with adhesive capsulitis?

- A) Arthroscopic debridement
- B) Oral corticosteroids
- C) NSAIDs and a sling for comfort
- D) Extended progressive physical therapy
- E) Mobilization under anesthesia

Answer 12.14.6 The correct answer is “D.” A progressive stretching program with heat and NSAIDs or acetaminophen to improve comfort is the most appropriate early treatment. A corticosteroid injection of the glenohumeral joint (under ultrasound guidance or fluoroscopy) may be beneficial but should be used cautiously in diabetic patients. Oral steroids have no greater benefit than NSAIDs. “C” is incorrect because a sling will contribute to further immobilization and worsening of the problem. Mobilization or capsular release under anesthesia may be a last resort in adhesive capsulitis.

HELPFUL TIP:

The typical clinical course for adhesive capsulitis evolves over 1 to 2 years with an initial “painful” phase followed by a “freezing” phase characterized by continued pain and worsening stiffness followed by a slow “thawing” phase with decreasing pain and increasing ROM.

► **Objectives: Did you learn to ...**

- Define the muscles of the rotator cuff?
- Identify, evaluate, and treat a rotator cuff injury?
- Recognize the presentation, associations, and treatment of adhesive capsulitis?

► **CASE 12.15**

A 58-year-old male presents after sudden onset of right upper arm pain. He was working in the yard, cutting and pulling out some bushes, when he heard a “snap” and felt the pain. He has a history of rotator cuff tendinosis and osteoarthritis.

Question 12.15.1 You should look for all of the following on physical examination EXCEPT:

- A) A positive elevated arm stress test (“Roos” test)
- B) A palpable biceps muscle defect
- C) Normal grip strength
- D) An asymmetric bulge in the affected arm

Answer 12.15.1 The correct answer is “A.” The elevated arm stress test is used to evaluate a patient for thoracic outlet syndrome. Have the patient abduct and externally rotate both shoulders, flex the elbows, pull their scapulae together, and repeatedly grip and relax the hands—for 3 minutes. The test is positive if neurological or vascular symptoms are reproduced. If you think to yourself, “Well, that might irritate my shoulder or arm,” you would be right to then suppose that this test has a high rate of false positives. In fact, the specificity for thoracic outlet syndrome is around 30%. And anyway, this patient’s presentation is not consistent with thoracic outlet syndrome. However, the history is consistent with biceps tendon rupture. “B” through “D” would be expected in a patient with biceps tendon rupture. Yes, there is usually normal grip strength. The injury is, of course, in the upper arm.

Question 12.15.2 Which portion of the biceps is most commonly involved in ruptures?

- A) Distal tendon
- B) Proximal short head tendon
- C) Proximal long head tendon
- D) Midmuscle belly
- E) Proximal short head belly

Answer 12.15.2 The correct answer is “C.” The long head is most commonly affected due to its position and risk for weakening secondary to rotator cuff tendinosis and shoulder impingement.

You decide this patient has a rupture of the long head of the biceps tendon.

Question 12.15.3 How is this injury treated initially?

- A) Immediate surgical repair
- B) Delayed surgical repair

- C) Immobilization for 4 to 6 weeks with sling
- D) NSAIDs and physical therapy
- E) Biceps muscle transplant, preferably from a retired NFL player

Answer 12.15.3 The correct answer is “D.” For most isolated proximal long or short head tears (with the exception of some young athletes and heavy laborers who would not tolerate the slight decrease in strength), treatment is conservative. Analgesics and physical therapy typically suffice. Surgical repair may be indicated if conservative therapy fails. Of note, you should discuss with patients the cosmetic deformity that will be permanent when these injuries are unrepaired versus scarring associated with surgery. Generally, there is approximately a 20% loss of elbow flexion and supination strength with an isolated proximal tear.

HELPFUL TIP:

Although proximal biceps tendon ruptures are treated conservatively, distal ruptures should be referred for early surgical repair, as the continuity of the entire muscle is lost and function at the elbow joint is significantly impaired with a 30% to 40% loss of strength across the elbow joint.

► **Objectives: Did you learn to ...**

- Identify the clinical presentation of biceps tendon rupture?
- Manage a patient with biceps tendon rupture?

► **CASE 12.16**

A 25-year-old male presents to you with a history of a soccer injury. Someone evidently fell on his right foot while trying to steal the ball. The patient rapidly and forcefully twisted around the fixed foot. Since then he has had significant pain and swelling of the foot. His x-ray is shown in Figure 12-4.

Question 12.16.1 Which of the following is true regarding this radiograph?

- A) It shows a step-off between the base of the second metatarsal and the middle cuneiform
- B) It shows midfoot boney instability
- C) It may require weight-bearing films to identify this injury
- D) The abnormality is named after a French gynecologist
- E) All of the above are true

Answer 12.16.1 The correct answer is “E,” all of the above. This is a Lisfranc injury, which occurs as a result of ligamentous rupture between the metatarsals and the tarsal bones (the space between the metatarsals and the tarsal bones is known as the Lisfranc joint). Look for a widened space between the first and second and/or second and third metatarsals. There may also

FIGURE 12-4. X-ray for Case 12.16.

be a step-off between the second metatarsal and middle cuneiform. These injuries may be difficult to identify, but obtaining weight-bearing films or stress views may help. Significant foot pain should be a tip off. See Figure 12-5 for further explanation. And, yes indeed, Dr. Lisfranc was a surgeon and gynecologist in Napoleon's army! Why did Napoleon need a gynecologist on campaign with him? That is a matter of debate.

Question 12.16.2 Appropriate treatment for this type of injury should include:

- A) Weight bearing as tolerated in a post-op or hard-soled shoe
- B) Rest, ice, compression, elevation, NSAIDs, and activity as tolerated. Will heal well and can be treated like a midfoot sprain
- C) Orthopedic referral for open reduction/internal fixation (ORIF)
- D) Walking boot that can be removed for several weight-bearing hours a day
- E) Early 19th century French legionnaire's boot

Answer 12.16.2 The correct answer is "C." This injury/dislocation will lead to significant long-term pain and mid-foot instability if not recognized and treated appropriately. Any significant displacement (>2 mm) should be referred for surgical consideration. These are generally complex injuries prone to poor outcomes and should be managed by an orthopedic consultant.

► **Objectives: Did you learn to ...**

- Identify a Lisfranc injury?
- Manage a patient with a Lisfranc injury?

► **CASE 12.17**

An 18-year-old female gymnast lands her dismount from the balance beam awkwardly. She reports the knee buckling, hearing a pop, and experiencing immediate right knee pain. She presents to your office 45 minutes after the injury. She is able to bear some weight on the leg but reports it is already swollen and feels "loose." On examination, there is a knee effusion present.

Question 12.17.1 Based on the information above, the most likely isolated injury experienced by this athlete is:

- A) Medial meniscus tear
- B) MCL sprain
- C) Distal quadriceps/patellar tendon rupture
- D) Anterior cruciate ligament (ACL) rupture
- E) Distal femur fracture

Answer 12.17.1 The correct answer is "D." Did the patient or someone else hear a pop? If yes, suspect ACL tear (80%), meniscal injury (15%), and rarely a fracture. When did you notice swelling? If 0 to 12 hours after the injury, suspect ACL tear, fracture, or patellar dislocation/subluxation; if 12 to 24 hours, suspect meniscal injury. If there is hemarthrosis on aspiration, suspect ACL injury (>75%), patellar subluxation, or intra-articular fracture. A history of, "My knee gives way; buckles; feels loose; or comes apart," may be secondary to patellar subluxation/dislocation, ACL deficiency, or arthritis. Medial and lateral collateral ligament injuries do not typically present with significant effusion and typically feel stable with forward ambulation but are painful with side-to-side movements.

FIGURE 12-5. Case 12.16. Annotated Lisfranc Injury.

Muscle or tendon rupture may cause buckling, but will not typically cause effusion and will generally have an obvious deformity and inability to bear weight.

Question 12.17.2 Of the following, which is the best test to confirm the diagnosis of an ACL injury?

- A) Plain film radiographs
- B) McMurray test
- C) Lachman test
- D) Anterior drawer test

Answer 12.17.2 The correct answer is "C." In the hands of an experienced clinician, the Lachman test is the most sensitive test for ACL insufficiency (sensitivity 80–95%). The anterior drawer sign is negative in about 50% of acute ACL tears, and often is negative subacutely. McMurray test is used to evaluate for a meniscal tear. Plain films should be obtained for all patients with acute knee injury with effusion or suspected ACL tear. A Second fracture (small avulsion of the lateral tibial plateau) is an x-ray finding associated with ACL tears. Although an MRI may be considered a gold standard test, its sensitivity has been reported as 97% when compared against arthroscopy findings and is positive in only 82% in cases of complete rupture. An orthopedic consult is generally indicated if ACL injury is suspected, and obtaining one is less expensive than MRI.

HELPFUL TIP:

The Lachman test is performed with the knee flexed at 20 to 30 degrees with the patient in a supine position. The examiner then attempts to anteriorly displace the tibia on the femur while stabilizing the femur. Always remember to check the contralateral side. Some patients have naturally lax ligaments.

You feel that this patient is very appropriate for radiographic evaluation, and you obtain x-rays of the knee.

Question 12.17.3 Which of the following is NOT one of the criteria of the Ottawa knee rules predicting the need for knee radiographs?

- A) Age <18
- B) Pain isolated to the patella
- C) Tenderness at the head of the fibula
- D) Inability to flex the knee 90 degrees
- E) Inability to bear weight for four steps

Answer 12.17.3 The correct answer is "A." The age criterion for the Ottawa knee rules is age >55 years. All of the other options are correct. If **any** of these criteria are present (including a patient >55 years of age), a radiograph should

be obtained. These rules have been validated and are 97% sensitive for fracture. The Pittsburgh rules, which are reportedly 99% sensitive, have only two criteria: (1) age <12 years or age >50 and (2) inability to bear weight in the clinic or ED. Of the two, the Ottawa rules are the more commonly accepted.

The x-ray shows no fracture. You prescribe a knee immobilizer, rest, ice, NSAIDs, and refer the patient to an orthopedic surgeon. The patient returns 2 days later with marked effusion and pain. To help relieve the pain, you perform an arthrocentesis and 90 mL of bloody aspirate is obtained. As per your clinic's standard protocol, the joint fluid is sent for analysis. The analysis returns with the only abnormalities being blood and fat droplets.

Question 12.17.4 Based on the effusion, you suspect what diagnosis?

- A) Complete ACL rupture
- B) Meniscal tear
- C) ACL and PCL tear
- D) Intra-articular fracture
- E) Patellar subluxation

Answer 12.17.4 The correct answer is "D." Fat from bone marrow may be seen even with a small intra-articular fracture. Consider CT or MRI if fracture is not noted on plain film. If a fracture is still not demonstrated, consider referral for orthopedic consultation.

HELPFUL TIP:

There is no need to refer for an ACL injury acutely (though they still should be referred). In fact, outcomes are the same regardless of whether the ACL is repaired or not (*BMJ*. 2013;346:f232). So, waiting a couple of days or a week for an orthopedic appointment is OK; give them crutches (partial weight bearing) and a hinged brace for comfort and stability. Of course you get an unhinged parent who demand a referral NOW.

► Objectives: Did you learn to ...

- Generate a differential diagnosis for knee pain in an athlete?
- Diagnose ACL injury?
- Determine when knee radiographs are appropriate?

QUICK QUIZ: KNEE PAIN

The best clinical test for determining the presence of a meniscal injury is:

- A) Posterior sag test
- B) Apley test
- C) McMurray test
- D) Pivot shift test
- E) Thessaly test

The correct answer is "E." The best meniscus test is the Thessaly test with a diagnostic accuracy in the range of 61% to 96% compared to McMurray at 56% to 84%. It is performed standing with the knee bent 20 to 30 degrees. Then with the heel planted and fixed, the patient "does the twist." Pain (or a locking or clicking sensation) localizing to the joint line is considered a positive test. The McMurray test is done by flexing the knee and then extending the knee while performing internal and external rotation of the tibia/fibula. Keep one hand on the knee. The test is positive when the examiner feels a pop during the maneuver or when there is significant pain during internal or external rotation. The Apley test is done with the patient in a prone position. Move the knee to 90 degrees of flexion. Put downward pressure on the tibia/fibula while internally and externally rotating the lower leg. Pain suggests a meniscal tear. Pain should be relieved by distracting the joint. The posterior sag test is used to detect PCL injury, while the pivot shift test is used to detect ACL injury.

► CASE 12.18

A 24-year-old female presents to the clinic 24 hours after slipping on a patch of ice outside her home. She reports feeling a "pop" and immediate pain on the lateral aspect of the ankle. She reports significant swelling in the first few hours with pain and inability to bear weight initially, but now she is able to walk with a significant limp. She reports no significant past injuries to the foot or ankle. On examination, you note edema/effusion over the lateral ankle, some ecchymosis, tenderness, but no laxity on anterior drawer and inversion stress. There is no bony tenderness on palpation of the foot and ankle, but there is tenderness anterolaterally in the soft tissue.

Question 12.18.1 The most likely injury this patient has suffered is?

- A) Fracture of the distal tibia
- B) Fracture of the distal fibula
- C) Sprain of the lateral ligament complex
- D) Sprain of the medial ligament complex
- E) Syndesmosis sprain

Answer 12.18.1 The correct answer is "C." A sprain is most likely because there is no bony tenderness. And, since she is tender laterally, the lateral ligament complex is most likely sprained.

Question 12.18.2 In this case, the most likely structure injured would be the:

- A) Anterior talofibular ligament
- B) Distal fibula
- C) Distal tibia
- D) Deltoid ligament
- E) Achilles tendon

Answer 12.18.2 The correct answer is "A." This is a sprain of the anterior talofibular ligament. This is the first ligament

injured with an inversion ankle sprain. It is followed by the calcaneofibular ligament if enough force is involved. “E,” Achilles tendon injury (specifically rupture), is of special note. First, this injury presents as pain in the Achilles tendon area. With a complete Achilles tendon tear, the patient will have marked weakness of plantar flexion. A diagnostic test (Thompson test) is to squeeze the posterior calf, with the patient lying supine on the bed and the feet dangling off. In response, the foot should plantar flex. If this does not occur, consider Achilles rupture. Operative and nonoperative treatments can be used.

**HELPFUL TIP:**

The Ottawa criteria reliably predict who needs an ankle radiograph and who does not. This has been validated in ages 5 to 55. The Ottawa foot and ankle criteria are listed in Figure 12-6.

Question 12.18.3 Which of the following is the most appropriate management of this patient’s sprained ankle?

- A) Cast for 4 weeks followed by physical therapy
- B) Crutches, non-weight-bearing for 2 weeks, and then progressive physical therapy
- C) Rest, ice, elevation, and early mobilization using external support, crutches, or cane if needed; progress to activity as tolerated
- D) Refer for orthopedic consultation

- E) Immobilization with short-leg walking cast, heat for comfort, analgesics or NSAIDs, and progress to activities as tolerated

Answer 12.18.3 The correct answer is “C.” Treatment for most sprains includes an external supportive brace, ice application, and elevation; early mobilization is critical and will hasten recovery. NSAIDs or acetaminophen should be used for pain control. The patient should be allowed partial weight bearing as tolerated with crutches or a cane. Patients with recurrent problems of instability should be referred to an orthopedist for evaluation.

**HELPFUL TIP:**

Early mobilization and weight bearing reduces the time of disability for ankle sprains. Rest and nonweight bearing should be minimized. Allow the patient to advance activities as tolerated.

► **Objectives: Did you learn to ...**

- Identify a patient with an ankle sprain?
- Differentiate ankle sprain from fracture based on history and examination?
- Use the Ottawa ankle rules to determine when to obtain an ankle radiograph?
- Manage a patient with an ankle sprain?

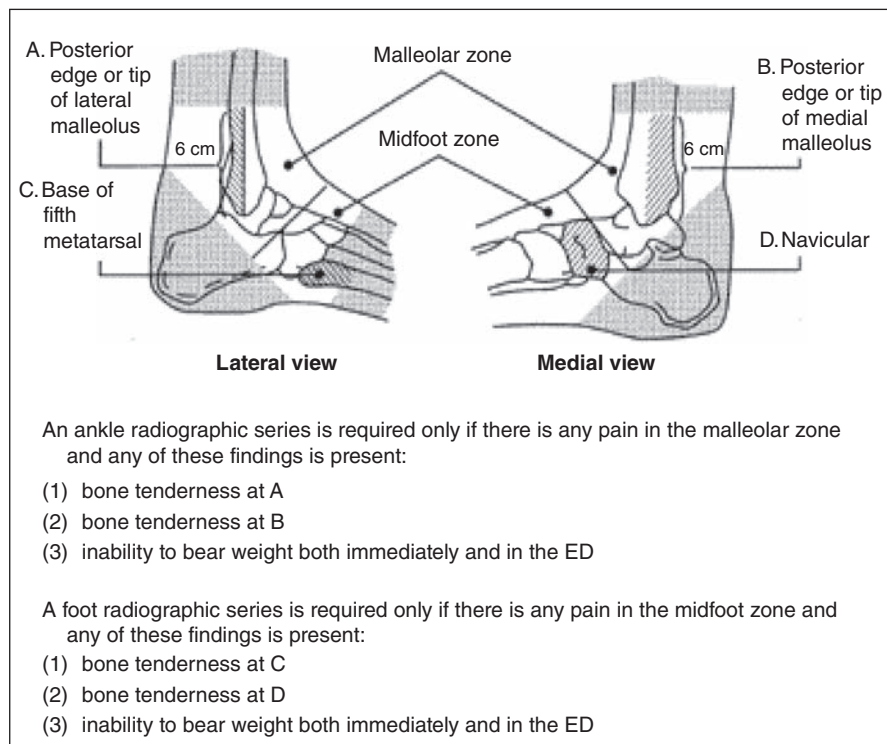

FIGURE 12-6. Ottawa Foot and Ankle Rules.

► CASE 12.19

A 27-year-old male presents to your clinic following an inversion-type injury to the foot and ankle. He cannot bear weight on the foot on presentation. He complains of pain and swelling laterally on the foot and ankle. There is some soft-tissue swelling but no obvious deformity. There is tenderness over the lateral ankle ligaments as well as over the base of the fifth metatarsal. AP and lateral films of the foot and ankle are obtained and reveal a nondisplaced fracture at the base of the fifth metatarsal. The radiograph is available for your review in Figure 12-7.

Question 12.19.1 What is the name of this fracture?

- A) Jones fracture
- B) Maisonneuve fracture
- C) Colles fracture
- D) Avulsion fracture of tuberosity, base fifth metatarsal

Answer 12.19.1 The correct answer is “D.” This is an avulsion fracture of the base of the fifth metatarsal that may result from an inversion ankle injury. Classically, this has been thought to occur due to an attempt at dynamic stabilization by the peroneus brevis, causing an **avulsion of the proximal portion of the metatarsal base**, but may also be due to avulsion of the lateral band of the plantar fascia. A **Jones fracture** is a transverse fracture of the proximal fifth metatarsal at the metaphyseal–diaphyseal junction and

FIGURE 12-7. Fracture of the 5th Metatarsal.

typically extends into the inter-metatarsal facet (see Fig. 12-8). Jones fractures have a high incidence of nonunion because they occur in a watershed area of blood supply. A Maisonneuve fracture is a fracture of the proximal one-third of the fibula associated with an external rotation injury of the ankle. A Colles fracture is a fracture of the distal radius (not involving the joint) with dorsal angulation of the distal fracture fragment.

HELPFUL TIP:

An unfused apophysis in children and adolescents may be confused with a fifth metatarsal avulsion injury. Tuberosity avulsion fractures are transverse, while the unfused apophysis is oriented vertically along the long axis of the metatarsal.

Question 12.19.2 Appropriate treatment for the fracture described above would be:

- A) A hard-soled postoperative shoe bearing weight as tolerated
- B) Nonweight-bearing short-leg cast for 6 to 8 weeks
- C) Operative internal fixation
- D) Walking boot with crutches for 6 to 8 weeks
- E) None of the above

FIGURE 12-8. Fractures of the 5th Metatarsal.

Answer 12.19.2 The correct answer is “A.” Nondisplaced tuberosity fractures generally heal well with conservative measures. These may be managed with a postoperative shoe with weight bearing as tolerated. A walking boot may be needed initially if there is significant pain present preventing ambulation in a hard-soled shoe; however, ankle immobilization is generally not needed for these avulsion fractures to heal. For a fracture with a displaced fragment >3 mm, orthopedic referral should be considered. Fractures to the metaphyseal–diaphyseal junction (**Jones fractures**) result from a vertical load placed on the lateral foot, such as an inversion injury or a stress injury. Jones fractures may potentially be managed with 6 to 8 weeks in a nonweight-bearing short-leg cast if nondisplaced; however, many require surgical intervention. **Jones fractures should be referred due to the high incidence of nonunion.**

HELPFUL TIP:

Stress fractures of the forefoot are common in competitive and recreational athletes, especially after a sudden increase in activity, intensity, duration, frequency, or a change in surface type. They may be occult on plain films acutely, but some subtle periosteal change may be evident on close examination in the area of maximal tenderness. If plain films are negative but suspicion remains high, treat as if a fracture is present. You may consider an MRI or repeat plain films and re-examination in 10 to 14 days. The same treatment considerations apply to metatarsal stress fractures as to any other nondisplaced forefoot fracture.

HELPFUL TIP:

Be alert for midfoot tenderness over the navicular. All navicular fractures, including stress fractures, should be referred to an orthopedist due to potential for avascular necrosis.

► Objectives: Did you learn to ...

- Evaluate foot injuries?
- Describe fifth metatarsal fractures?
- Manage straightforward metatarsal fractures and identify which fractures should be referred?

► CASE 12.20

A 40-year-old female factory worker presents with progressively worsening heel pain. She has pain when she first gets out of bed in the morning. The pain tends to subside after 20 to 45 minutes, but is worsened by standing on the concrete floor of the factory where she works. She has a history of diabetes and hyperlipidemia. On examination, you find an obese female with a normal stance and gait. She

has exquisite tenderness to palpation just distal to the heel on the underside of the foot. Pain is exacerbated by extension of the toes.

Question 12.20.1 Which of the following is the most likely diagnosis?

- A) Tarsal tunnel syndrome
- B) Achilles tendon rupture
- C) Charcot foot
- D) Plantar fasciitis
- E) Plantar fascia rupture

Answer 12.20.1 The correct answer is “D.” Plantar fasciitis, the most common cause of heel pain in adults, is a degenerative condition of the origin of the plantar fascia. “A” is incorrect. Tarsal tunnel syndrome is due to posterior tibial nerve entrapment and presents with diffuse pain at the medial ankle and arch of the foot. Paresthesias and dysesthesias often occur as well. “B,” Achilles tendon rupture, is incorrect because the pain should be sudden, stabbing, and located in the calf (not the plantar aspect of the heel). “C” is also incorrect. Charcot foot does occur in diabetics, but it is actually the result of neuropathy and so generally does not present with pain. Instead, Charcot foot presents as an inflammatory condition (e.g., warmth, erythema, and edema) and progresses to joint instability and severe foot deformities. Finally, “E” is incorrect because plantar fascia rupture should have a sudden onset and is often related to trauma.

Question 12.20.2 Which of the following is true of plantar fasciitis?

- A) It more commonly occurs in individuals with pes cavus
- B) It is more common in women
- C) It is commonly an acute injury
- D) Radiographic identification of a “heel spur” or osteophyte is pathognomonic

Answer 12.20.2 The correct answer is “B.” Plantar fasciitis is not associated with any particular foot type. It is nearly twice as common in women as men. It is also more common in overweight individuals. A rupture of the plantar fascia may occur acutely. Spurring may be seen in up to 50% of patients with plantar fasciitis but is present in 20% of age-matched asymptomatic adults. Thus, the finding of a spur is not diagnostic.

Question 12.20.3 Appropriate initial treatment for this patient’s plantar fasciitis should include:

- A) A heel cup or silicon pad
- B) Achilles stretching
- C) Ice or heat
- D) NSAIDs
- E) All of the above

Answer 12.20.3 The correct answer is “E,” all of the above. Other initial treatments to consider include night splints to maintain ankle dorsiflexion and stretch the Achilles tendon and

plantar fascia. Physical therapy modalities such as ultrasound may be helpful as well. Advanced treatments, such as corticosteroid injections, may be considered after failure of initial conservative therapy. However, injections are not without risk, including plantar fascia rupture, loss of the fat pads of the feet causing significant pain and disability, and infection.

HELPFUL TIP:

Not all heel pain is plantar fasciitis. Remember these others: tarsal tunnel syndrome (described above), painful heel pad syndrome (pain located over the heel secondary to breakdown of fibrous septae from overuse and which may take up to 6 months to heal), and piezogenic papules (pain over medial/inferior aspect of heel, tender papules noted when patient standing).

► Objectives: Did you learn to ...

- Diagnose plantar fasciitis and consider other causes of heel and foot pain?
- Describe the natural history of and treatments for plantar fasciitis?

QUICK QUIZ: HAND INJURIES

A “gamekeeper’s thumb” would likely be seen as the result of which of the following injuries?

- A) Fall on an outstretched hand
- B) Crush injury, for example, between two pieces of machinery
- C) Fall by a skier using a ski pole
- D) Excessive electronic gaming (e.g., Nintendo and Xbox)
- E) Fall from a mountain bike

The correct answer is “C.” A gamekeeper’s thumb is defined as an injury (partial or complete tear) of the ulnar collateral ligament of the first MCP joint. This injury can occur with a valgus force on the thumb, which may occur when falling with a ski pole. Plain films should be obtained to evaluate for fracture. Treatment is immobilization of the thumb, such as with a thumb spica splint. Displaced fractures and/or the presence of a Stener lesion (when a piece of the torn ulnar collateral ligament displaces superficially to the adductor pollicis aponeurosis, preventing healing of the ligament) will require surgical referral. “Gamer’s thumb,” “D,” is a repetitive use syndrome caused by playing (appropriately enough) video games. It is an overuse syndrome often presenting with swelling at the base of the thumb.

QUICK QUIZ: ELBOW FRACTURE

The most specific finding on radiograph for a radial head fracture is:

- A) Anterior fat pad sign
- B) Posterior fat pad sign

- C) Trousseau sign
- D) Medial fat pad sign

The correct answer is “B.” The posterior fat pad sign, which indicates an effusion in the joint, is the most **specific** of the findings for a radial head fracture. An **anterior** fat pad sign is the most sensitive. Figure 12-9 demonstrates both the anterior and posterior fat pad signs. There is no medial fat pad sign, and Trousseau sign is related to hypocalcemia and is carpal spasm with arterial occlusion (as with a blood pressure cuff).

QUICK QUIZ: RADIAL HEAD FRACTURE

The proper treatment of a nondisplaced, fractured radial head is:

- A) Internal fixation
- B) Sling with early mobilization
- C) Short-arm cast
- D) Long-arm cast

The correct answer is “B.” For a nondisplaced radial head fracture, the treatment is simply a sling for comfort and early mobilization. Mobilization is especially important to avoid a stiff elbow. Orthopedic referral should be considered if there is any sense of a mechanical block to the elbow motion.

FIGURE 12-9. Fat Pad Signs in the Elbow.

QUICK QUIZ: PEDIATRIC FRACTURES

The most common elbow fracture in the pediatric population with a positive “fat pad sign” but no obvious fracture on x-ray is:

- A) Radial head fracture
- B) Supracondylar fracture
- C) Medial condyle fracture
- D) Lateral condyle fracture
- E) Olecranon fracture

The correct answer is “B.” Although in adults the most common occult elbow fracture is of the radial head, in the pediatric population it is a supracondylar fracture. These may be significantly displaced, but if nondisplaced they can be very subtle and the only sign of a fracture may be a displaced posterior (or anterior) fat pad.

QUICK QUIZ: HIP PAIN

A 76-year-old female nursing home resident is brought to clinic after rolling out of bed last night. She is normally able to ambulate independently, but today cannot bear weight due to pain in her hip. She has significant hip tenderness and pain with any movement of her leg. She is unable to perform a SLR secondary to pain. Plain x-rays of her pelvis and hip are read as osteopenia with no obvious fracture.

What is the most appropriate next step?

- A) Conservative treatment with acetaminophen and bed rest until able to ambulate
- B) Admission for observation
- C) Hip MRI
- D) Physical therapy
- E) Fentanyl patch

The correct answer is “C.” The patient may have an occult hip fracture. Rates of occult hip fractures range from 2% to 10% of all hip fractures. To miss the diagnosis of a hip fracture may lead to displacement of the fracture and a worse outcome. Both CT and MRI can be used to evaluate for occult fracture, but most studies indicate that MRI has a greater sensitivity.

▶ CASE 12.21

A 45-year-old female hospital clerk presents with bilateral aching pain in the forearms and thenar eminences. The pain is made worse with driving and typing. She also has intermittent numbness over the same areas. She tried to ignore the symptoms, but today she dropped her coffee mug on her computer keyboard and became alarmed at her loss

of strength. She has hypothyroidism and is obese, but she reports that her health is otherwise good.

Question 12.21.1 Based on the history alone, which of the following is the most likely diagnosis?

- A) Carpal tunnel syndrome
- B) Osteoarthritis
- C) Ulnar neuropathy
- D) Diabetic neuropathy
- E) Stroke

Answer 12.21.1 The correct answer is “A.” Carpal tunnel syndrome is due to median nerve entrapment in the carpal tunnel of the wrist. Typical symptoms include numbness, paresthesias, and pain at the palmar/radial aspect of the hand, quintessentially the thenar eminence. In more severe or long-lasting cases, you may see atrophy of the thenar eminence. Patients may also develop weakness of thumb opposition. Osteoarthritis of the wrists does not usually cause nerve symptoms, but can cause spondylosis and nerve root impingement on occasion. Ulnar neuropathy involves the ulnar aspect of the hand, especially the fourth and fifth fingers, rather than the radial aspect, which is involved with carpal tunnel syndrome. Diabetic neuropathy typically presents in the feet since they are innervated by the longest nerves in the body. *Note:* This could represent cervical disk disease as well, especially given that it is bilateral.

Phalen sign is positive (placing the wrists in a flexed position causes aching and numbness in the median nerve distribution).

Question 12.21.2 What is the best next step in the continuing evaluation and management of this patient?

- A) Nerve conduction studies
- B) Radiograph of the wrist
- C) MRI of the cervical spine
- D) Orthopedic referral
- E) Initiation of treatment

Answer 12.21.2 The correct answer is “E.” In a clear-cut case of carpal tunnel syndrome, there is no need for further studies. If the diagnosis is in doubt, electromyogram and nerve conduction studies (EMG-NCS) may be of benefit. If the ROM in the wrist is limited, x-rays may be helpful. At this point in time, MRI and orthopedic referral are not likely to add much.

Question 12.21.3 Which of the following IS NOT associated with carpal tunnel syndrome?

- A) Hypothyroidism
- B) Diabetes mellitus
- C) Amyloidosis
- D) Polycythemia vera
- E) Rheumatoid arthritis

Answer 12.21.3 The correct answer is “D.” All of the above are associated with carpal tunnel syndrome except for polycythemia

vera. Polycythemia vera can cause erythromelalgia which is a burning pain of the hands and feet associated with erythema, pallor, or cyanosis. It responds to aspirin. Other conditions associated with carpal tunnel syndrome include pregnancy, menopause, obesity, acromegaly, and end-stage renal disease. The point here is that patients with carpal tunnel syndrome should have a systemic cause ruled out, either clinically or with labs.

Question 12.21.4 What is the most appropriate initial treatment?

- A) Thumb spica splint
- B) Steroid injection
- C) NSAIDs and neutral position wrist splints
- D) Short-arm casts
- E) Bilateral figure-of-eight splints

Answer 12.21.4 The correct answer is “C.” Conservative therapy should be initiated first, unless there is some compelling reason for more aggressive therapy (e.g., severe weakness of the hands and loss of function). Most patients respond well to NSAIDs and the use of neutral position splints. The traditional cock-up splints are not as effective as neutral position splints. The splints should be worn at night. The patient may wear the splints during the day, too, but should take them off for several hours per day to avoid disuse muscle atrophy. “A” is incorrect since a thumb spica is not needed. “B,” steroid injection, might be tried if initial conservative measures fail. However, the benefit is generally limited to 1 month. “D” is just wrong—don’t cast patients with carpal tunnel syndrome! “E” is a terrible idea as well since a bilateral figure-of-eight splint is basically a straight jacket.

HELPFUL TIP:

Oral and injectable steroids have been used for carpal tunnel with limited success. Unfortunately, most modalities (NSAIDs, splints, steroids, etc.) are no better than placebo in randomized trials.

HELPFUL TIP:

Phalen and Tinel signs are crude tools at best. Tinel sign, which is a painful sensation of the fingers induced by percussion of the median nerve at the level of the carpal tunnel, may be positive, but is only 50% sensitive (flip a coin) and 54% specific. Phalen sign, keeping both wrists in a palmar-flexed position, may reproduce symptoms. Sensitivity varies from 10% to 88% depending on study; its specificity is 80%.

► **Objectives: Did you learn to ...**

- Diagnose carpal tunnel syndrome and consider other causes of wrist pain?
- Manage a patient with carpal tunnel syndrome?

QUICK QUIZ: CASTING

A few days ago, your partner placed a cast on the arm of a 20-year-old male for a distal radial fracture. He calls your office today, when your partner has gone fishing (darn her, anyway). The patient is complaining of increasing pain and numbness of his fingers in the casted arm.

Which course of action is most appropriate?

- A) Have the patient follow up tomorrow, when your partner is back in the office
- B) Send the patient to the emergency room for compressive Doppler examination of the arm to rule out venous thrombosis
- C) Ask the patient to come to clinic to have the cast replaced
- D) Tell the patient that these are expected symptoms and advise him to take some aspirin
- E) Recommend that he have his cast signed by as many friends as possible to take his mind of these clearly psychosomatic symptoms

The correct answer is “C.” This patient has symptoms that are most likely due to an improperly fitted cast. The problem here could be vascular compromise, nerve compression, or a compartment syndrome. He should be seen without delay to evaluate for these, and the cast should be adjusted or replaced. The cast can be bivalved or have a window cut into it, then be observed for improvement in symptoms if the cast does not need to be completely removed to rule out the pathology noted above.

► **CASE 12.22**

A 30-year-old new mom presents to your office with back pain, pubic pain, fatigue, sore nipples, and fatigue, saying, “This mom stuff is rough!” However, what she really wants to address is her wrist pain. She has pain with lifting her daughter, doing the laundry (which never stops, by the way), carrying the car seat, and breastfeeding. Pain is at the base of the thumb and radiates up the arm. On exam, you can feel crepitus as she flexes and extends the thumb. Pain is exacerbated by ulnar deviation of the wrist when she is gripping her thumb (positive Finkelstein test).

Question 12.22.1 What is the most likely diagnosis?

- A) Triangular fibrocartilage complex (TFCC) injury/tear
- B) Extensor carpi ulnaris tendinitis
- C) Intersection syndrome
- D) De Quervain’s tenosynovitis

Answer 12.22.1 The correct answer is “D.” De Quervain’s is a tendinosis of the abductor pollicis longus (APL) and/or extensor pollicis brevis (EPB) that often present in the setting of wrist overuse (although it can occur out of the blue). It is more common in women and during the postpartum period. Feeling crepitus over the tendons makes the diagnosis in this case but is not

required finding. A positive Finkelstein's test is the classic physical exam finding (have the patient grip their own thumb and ulnar deviate, which will cause exquisite pain). "A," a triangular fibrocartilage complex (TFCC) tear usually occurs in the setting of a fall on an outstretched hand (FOOSH) injury and presents similar to a meniscus tear of the knee with painful clicking and catching *on the ulnar side of the wrist*. For TFCC tears, the tenderness is distal to the ulnar styloid. Extensor carpi ulnaris (ECU) tendinitis ("B") causes pain on the ulnar side of the wrist and the tendon can be palpated on the dorsal aspect of the ulnar wrist. ECU pain is often caused by repetitive motion (tennis, squash). The patient will have worsening of the pain with resisted supination and will be tender over the tendon. "C," intersection syndrome can present similarly to de Quervain, but the pain is several centimeters proximal to the wrist joint and not at the base of the thumb. The pain is on the dorsal side of the forearm.

Question 12.22.2 How would you initially treat this patient's de Quervain's tenosynovitis?

- A) Steroid injection in the area of the tendon
- B) Thumb spica splint
- C) Give up the infant for adoption, thus removing stress on the tendons
- D) NSAIDs as needed
- E) A, B, and D

Answer 12.22.2 The correct answer is "E." Treatment is immobilization in a thumb spica, NSAIDs for pain, and injectable steroids. Be realistic—splinting and NSAIDs often have a low success rate in patients with moderate-to-severe pain. Some practitioners use injectable steroids as first-line. Surgery can be done in recalcitrant cases.

HELPFUL TIP:

For wrist pain, it helps to know where it hurts.

- Diffuse pain at the dorsal aspect: think of osteoarthritis (OA)
- Ulnar side pain: ECU tendinitis, chronic TFCC injury
- Radial side pain: OA of the wrist or base of the thumb, de Quervain's tenosynovitis, intersection syndrome

► **Objectives: Did you learn to ...**

- Diagnose de Quervain's tenosynovitis and consider other causes of wrist pain?
- Manage a patient with de Quervain's tenosynovitis?

QUICK QUIZ: AN ULTRA PAIN IN THE FOOT

A 30-year-old ultra-marathon runner presents to your office after an unusually long training block of 200 miles in the last week... that's a lot of books on tape! She complains of pain in the distal right foot. Pain is diffuse over the second and third metatarsal heads and does not radiate. On exam, she has a large, firm callus under the second metatarsal head. There is

no swelling or redness over the joint. Pain is not reproduced with lateral compression over the distal metatarsal region. Her gait is normal and her arches are well supported. The second digit has a bit of a hammertoe deformity. Her x-rays are normal.

Based on the presentation, which of the following is true about her diagnosis?

- A) This is most consistent with a Morton's neuroma and a corticosteroid injection might help
- B) This is a stress fracture and she should cancel her registration for her upcoming event the "Death on Two Legs Ultramarathon"
- C) She suffers from mania, and you should start lithium
- D) This is metatarsalgia, and the treatment is conservative including RICE and a metatarsal pad/lift to take the pressure off the area

The correct answer is "D." In this case her callus (indicating increased load and friction) and her hammertoe (which further drives the metatarsal head down) are contributing to the biomechanical overload of the area and pain. Metatarsalgia is not just a running injury but can present in many patients and is considered an overuse injury. Patients with metatarsalgia are generally tender over the metatarsal head and may complain that they feel as though they are walking on a stone or rock. The treatment is, as noted in answer "D," a metatarsal lift or pad. Changing shoes may also help. Occasionally, in severe cases, boot immobilization and/or crutches will be needed to cool things off. "A," Morton's neuroma, typically presents with neuropathic pain that radiates into the toes. The squeeze test done by lateral compression across the metatarsals can reproduce the pain associated with Morton's neuroma. Stress fracture is also a possibility in this patient, given her mileage, and can be hard to differentiate from metatarsalgia. If you are concerned and need an answer right away, start with an x-ray, but you may need an MRI as x-rays miss a lot of these.

QUICK QUIZ: EXERCISE PRESCRIPTION

Which of the following is true regarding current exercise recommendations for general health and disease prevention?

- A) Patients should get at least 30 minutes of moderate intensity exercise five or more times per week
- B) As an alternative to moderate intensity exercise, patients can get 20 minutes of high-intensity exercise three to four times per week
- C) For older adults, 2 to 3 days per week of resistance training is recommended
- D) For kids age 6 years and older, AAP recommends 60 minutes of moderate-to-vigorous activity daily
- E) All of the above are true

The correct answer is "E." This is an important topic as obesity and inactivity rates have skyrocketed. Obesity is currently the fourth leading cause of death in the United States. More than 56%

of adults do not meet the recommended amount of exercise, and 36% of adults do no exercise at all. This costs our healthcare system over \$300 per person per year and over \$100 billion dollars annually. When suggesting exercise, recommend a warm-up period and a cool-down period. Remember the mnemonic “FITT”:

Frequency: at least 3 days per week to start and build up from there

Intensity: moderate to intense effort (but remember to build up to this ... nobody will keep it up if you start them doing wind sprints on the first day)

Time: ideally 30 minutes or more five times per week, but this can be broken up in other ways, and the target of 150 minutes per week works better for some patients

Type: involve major muscle groups (walking, core training, weights, bicycling, etc.)

Moderate exercise is defined as 50% to 70% of your maximum heart rate, such as a brisk walk. Shorter bouts of more intense exercise have the same benefit as longer slower regimens. Patients can break exercise into shorter blocks throughout the day if that works better (e.g., walking rapidly for 10 minutes three times per day). Contrary to popular belief, resistance training also has cardiovascular benefit (*Mayo Clinic Proc.* 2017;92:1214–1222).

HELPFUL TIP:

So, what's your excuse? Take a study break and get out there. Exercise is good for your brain! Also, it has been shown that inactive and overweight doctors are less likely to prescribe exercise.

Clinical Pearls

- Do not let the presence of calcium pyrophosphate crystals or uric acid dissuade you from suspecting septic arthritis as both gout and pseudogout commonly coexist with septic arthritis.
- Do not routinely order plain films for low-back pain unless trauma, abnormal physical examination findings, or “red flag” symptoms are present.
- Do not routinely screen for scoliosis in asymptomatic adolescents.
- Maintain a high suspicion for a scaphoid fracture if there is trauma with snuffbox tenderness present.
- To achieve faster recovery, recommend early mobilization for low-back pain and ankle sprains.
- Maintain a high degree of suspicion for the orthopedic emergencies of septic arthritis and cauda equina syndrome.
- Avoid knee arthroscopy as initial therapy for meniscal tears.
- Do not prescribe opioids for chronic musculoskeletal pain as first-line therapy. Opioids should only be used as a last resort—if at all—and monitored closely.
- Use the Ottawa Ankle, Knee, or Foot Criteria to determine whether plain films are needed for evaluation of ankle, knee, or foot injuries.

Pediatrics

Guru V. Bhoojhwon and Patrick J. McCarthy

► CASE 13.1

A 6-year-old male presents to your office with his mom. He has been soiling his underwear frequently and it is causing stress at home and school. His parents are frustrated and think he is old enough to know better. At school, he is being teased and being called “stinky pants.” He reports feeling embarrassed. Mom asks you if there is something medically wrong with him.

Question 13.1.1 What percentage of chronic encopresis is functional (meaning no underlying medical or organic cause)?

- A) 10%
- B) 25%
- C) 50%
- D) 75%
- E) 90%

Answer 13.1.1 The correct answer is “E.” Ninety percent of chronic encopresis is functional. Functional encopresis is the repeated involuntary passage of stool into underwear in a child who is 4 years of age or older and at a developmental level appropriate for toilet training in the absence of an underlying medical cause. The most common reason is retentive constipation with overflow incontinence. Frequently, the child has an associated psychological problem. Boys are affected more often than girls. Children with this disorder withhold feces voluntarily thereby avoiding defecating. As stool stays in the colon, more water is absorbed, creating harder stool that is more difficult to pass. This leads to a self-perpetuating cycle. The excess stool stretches the rectum with eventual loss of sensation to defecate. Liquid stool may leak around the impacted mass, which parents often mistake as diarrhea. In some, a triggering event, such as passage of a painful stool leading to fear of stooling, forced toilet training before the child is ready, or sexual abuse, may have occurred. Often, children will dislike using public toilets, leading to voluntary holding, inciting the functional constipation cycle. A common theme is parental misunderstanding of the

problem, thinking it is due to an undiagnosed medical condition, attention-seeking behavior, or child laziness.

HELPFUL TIP:

Some definitions ... **Non-retentive encopresis** is the *voluntary* stooling of one's pants. Once a medical cause has been ruled out, this is purely a behavioral or psychiatric problem. **Primary encopresis** is when stool continence has never been achieved. **Secondary encopresis** occurs when accidents began after a period of successful toilet training.

Question 13.1.2 Which of the following conditions is(are) associated with encopresis?

- A) Urinary tract infections
- B) Enuresis
- C) Social isolation
- D) Attention-deficit hyperactivity disorder (ADHD)
- E) All of the above

Answer 13.1.2 The correct answer is “E.” Encopresis is an independent risk factor for urinary tract infections. Feces in the underwear allows for close contact with the urethra and introduction of bacteria. Chronic contracting of pelvic floor muscles to withhold stool may lead to dysfunctional voiding and urinary stasis. Enuresis occurs in up to 40% of patients with chronic constipation. A mass of stool in the rectum can compress the bladder leading to uncontrolled voiding. The chronic odor of feces makes socialization rough and teasing frequent. ADHD frequently is associated with functional constipation and encopresis due to other stimuli diverting the child's attention from the urge to defecate.

HELPFUL TIP:

Encopresis or daytime enuresis should prompt you to rule out a spinal cord lesion with a detailed examination and further imaging, such as an MRI, if indicated by examination.

Question 13.1.3 Which of the following is(are) medical (organic) cause(s) of constipation?

- A) Hypothyroidism
- B) Hypercalcemia
- C) Cystic fibrosis
- D) Lead poisoning
- E) All of the above

Answer 13.1.3 The correct answer is “E.” All of the above can cause constipation and fecal incontinence. Organic causes account for only 5% to 10% of encopresis cases and can be anatomical (anteriorly displaced anus), neurological (Hirschsprung disease), immunologic (celiac disease), or iatrogenic (medications such as narcotics or anticholinergics). The first step in evaluating a child with encopresis is to rule out an underlying medical condition starting with a good history and physical examination. Do not forget to ask about timing of meconium passage in the past medical history, as delayed meconium passage may suggest cystic fibrosis or Hirschsprung disease. Rectal examination is useful to evaluate rectal sphincter tone and assess for fecal impaction. Look at the back for signs of an occult spina bifida such as sacral dimple or hair tuft. Lack of anal wink, cremasteric reflex, or deep tendon reflexes is suggestive of a neurologic cause. Often a painful fissure may initiate a vicious cycle of pain with stooling, leading to the withholding of stool, and leading to even more painful defecation, etc.

**HELPFUL TIP:**

Fecal impaction is a clinical diagnosis made by feeling a hard stool mass on rectal examination. It is not made by abdominal x-ray. Though guidelines do not recommend the routine use of digital rectal exams in diagnostic evaluation of functional constipation, if a fecal impaction is suspected, a rectal examination must be done. Yes ... a rectal examination on a child. No one's happy about it, but it can be performed comfortably with lubrication and proper positioning (i.e. knee-chest positioning).

**HELPFUL TIP:**

Abuse may be a triggering event for constipation and encopresis. If abuse is suspected, contact child protective services.

Question 13.1.4 All of the following are useful in the treatment of functional encopresis EXCEPT:

- A) Polyethylene glycol (PEG) 3350 (MiraLAX®)
- B) Oral sodium phosphate solution (OsmoPrep)
- C) Mineral oil
- D) Lactulose
- E) Milk of magnesia

Answer 13.1.4 The correct answer is “B.” In 2008, the FDA placed a black box warning on oral sodium phosphate solutions

due to risk of acute kidney injury from deposition of calcium phosphate crystals. As a result, oral non-phosphate-containing medications are frequently used. Treatment begins with disimpaction with enemas or with an oral medication such as PEG 3350 (MiraLAX®) or mineral oil. Many treatment guidelines prefer disimpaction using oral PEG 3350 (MiraLAX®) solutions over enemas or manual disimpaction. **Use of high-dose PEG 3350 (1.5 g/kg/day) or enemas for 6 consecutive days were equally effective in treating fecal impaction.** Manual disimpaction may be effective, but often requires general anesthesia in order to be tolerated. PEG 3350 (MiraLAX®) is generally preferred over enemas, given the widely accepted oral route of administration.

Treatment should be individualized. After disimpaction, patients require maintenance therapy (combination of medical, behavioral, dietary, and counseling). Evidence suggests that PEG 3350 (MiraLAX®) is most effective for maintenance therapy, though lactulose, milk of magnesia, or mineral oil may also be used. PEG 3350 (MiraLAX®) 0.2 to 0.8 g/kg/day should be initiated and incrementally increased until the patient is having regular, soft bowel movements. The normal recommended daily allowance of fiber and fluid intake should be encouraged. Behaviorally, the child should sit on the toilet with active pushing after each meal to make use of the gastrocolic reflex. Even if the child does not stool, they are learning to use the toilet and training their bowels. Use of a footstool may improve Valsalva maneuvers (kinda like the McRobert's maneuver!). A sticker chart can give visual reinforcement. Families need to understand that there is no quick fix and relapse is common (about 50%). It takes months for the rectum to return to normal size and sensation. But it may comfort readers to know that one of your editors witnessed a 19-cm colonic distention return to normal after aggressive use of PEG 3350; so, it happens. Patients who fail to improve after 6 months of compliant treatment should be referred to a pediatric gastroenterologist.

**HELPFUL TIP:**

Remember never to use mineral oil enterally in any child who is at risk of aspiration. It can cause a chemical pneumonitis.

► Objectives: Did you learn to ...

- Describe encopresis, including its presentation, diagnosis, and causes?
- Differentiate between organic and nonorganic causes of encopresis?
- Medically manage constipation and encopresis?

**QUICK QUIZ: NEONATAL POLYCYTHEMIA**

Causes of neonatal polycythemia (central venous hematocrit of 65% or greater) in the immediate postpartum period include all of the following EXCEPT:

- A) Delayed umbilical cord clamping
- B) Twin-twin transfusion

- C) Congenital adrenal hyperplasia
- D) Maternal diabetes
- E) Sepsis

The correct answer is “E.” Neonatal polycythemia can be caused by all of the above except for sepsis. Other causes include chronic intrauterine hypoxia (e.g., mother is a heavy smoker), intrauterine growth restriction, maternal hypertension, congenital hypothyroidism, and chromosomal abnormalities (e.g., trisomy 21, 18, and 13).

QUICK QUIZ: MORE ON NEONATAL POLYCYTHEMIA

Patients with neonatal polycythemia are at risk for hyperviscosity syndrome including respiratory distress, hypoxia, cyanosis, hyperbilirubinemia, and hypoglycemia. Heart failure, stroke, renal vein thrombosis, and necrotizing enterocolitis may also occur.

The best treatment for these patients is:

- A) Phlebotomy
- B) Exchange transfusion with normal RBCs
- C) Exchange transfusion using D5W
- D) Exchange transfusion using normal saline
- E) Aspirin

The correct answer is “D.” Partial exchange transfusion using normal saline is the treatment of choice. “A” is incorrect since phlebotomy alone will reduce overall circulating volume and may exacerbate the problem. “B” is incorrect. If you chose this, back home for you! What is the point of taking out cells and then putting more in? “C” is incorrect because large amounts of D5W can cause fluid shifts, electrolyte abnormalities, cerebral edema, and hemolysis. Isotonic solution, such as normal saline, would be appropriate. Of note, patients with a hematocrit of 65% to 70% can be observed if they are asymptomatic. Samples obtained via heel-stick may have a falsely elevated hematocrit and should be confirmed with a venous draw. There is no one-to-one predictable relationship between hematocrit and blood viscosity. Also of note, there is no evidence that long-term outcomes are improved in *asymptomatic* patients with partial exchange transfusion versus observation.

▶ CASE 13.2

Amy, a 4-day-old infant, is brought to clinic because “she is yellow.” She was born at term to a 25-year-old woman. Maternal lab results are as follows: blood type A+, syphilis negative, rubella immune, group B streptococcus (GBS) negative. Amy has been breastfeeding every 3 to 5 hours. She has had one stool and three wet diapers per day. Her weight is 15% less than her birth weight. On your examination, you notice jaundice from the head to the thighs. Her

total bilirubin level is 21.6 mg/dL. The conjugated (direct) fraction is 0.4 mg/dL.

Question 13.2.1 Of the following, the infant most likely is experiencing:

- A) Breastfeeding failure jaundice
- B) Physiologic jaundice
- C) Biliary atresia; you must consult pediatric gastroenterology
- D) Alloimmune hemolysis due to ABO incompatibility

Answer 13.2.1 The correct answer is “A.” Amy most likely has breastfeeding failure jaundice (often referred to as “breastfeeding jaundice”). *This occurs within the first several days of birth* before the mother’s milk supply is adequate. This must be distinguished from **breast milk jaundice**, which **usually occurs later** without evidence of dehydration. One sign that Amy is not receiving adequate breast milk feedings—and that this is **breastfeeding failure jaundice** instead of breast milk jaundice—is the fact that she is 15% below birth weight, having fewer than six wet diapers per day and fewer than two to five stools a day. Remember that a well-hydrated infant of Amy’s age should generally lose no more than 10% of birth weight. You should try to evaluate the mother’s milk supply by asking about the mother’s feeling of engorgement, feeling of breast emptying with feeding, seeing milk on the infant’s lips and tongue immediately after feeding, and hearing the infants swallow with feedings. “B” is incorrect. Even though physiologic jaundice peaks at this age, the level of 21.6 mg/dL is higher than would be expected with physiologic jaundice (which should not be higher than 17 mg/dL in a term infant). “C” is incorrect because biliary atresia presents with **conjugated** hyperbilirubinemia (the liver can appropriately conjugate bilirubin, but there is obstruction to the outflow of the conjugated bilirubin—essentially an obstructive process). “D” is incorrect because ABO incompatibility is unlikely in a mother whose blood type is something other than O (who can make both anti-A and anti-B antibodies). In addition, Rh incompatibility is impossible due to the mother being Rh+. However, minor antigen incompatibility remains a possibility.

HELPFUL TIP:

Causes of an elevated direct (conjugated) bilirubin: infection (including congenital), metabolic abnormalities (cystic fibrosis, galactosemia, Dubin-Johnson and Rotor syndromes, glycogen storage disease, etc.), anatomic abnormalities (biliary atresia, etc.), and cholestasis (especially from total parental nutrition). Note that **conjugated bilirubin does not cause kernicterus**. To remember this, think about conjugated molecules being bigger and thus not able to cross the blood-brain barrier.

Causes of an elevated indirect (unconjugated) bilirubin: increased breakdown of RBCs (ABO/Rh incompatibility, cephalohematoma, thalassemias, etc.), prematurity, hypothyroidism. Basically, overwhelming the liver from RBC breakdown.

Question 13.2.2 Which of the following is NOT a risk factor for severe neonatal hyperbilirubinemia?

- A) Exclusive breastfeeding
- B) Gestational age ≥ 41 weeks
- C) Significant birth trauma
- D) Visible jaundice in first 24 hours of life
- E) East Asian race

Answer 13.2.2 The correct answer is “B.” Post-dates gestational age is not associated with jaundice. Rather, premature infants are at a greater risk of jaundice. “A” is true, and exclusively formula-fed infants are less likely to have severe hyperbilirubinemia (but this is not a reason to recommend bottle feeding). Cephalohematoma and large bruises result in increased bilirubin production from heme breakdown, so “C” is true. The earlier jaundice occurs, the higher the peak is likely to be, so “D” is also true. Other major risk factors for severe hyperbilirubinemia include: a sibling who required phototherapy, East Asian race, and blood group incompatibility.

**HELPFUL TIP:**

Infants with total serum bilirubin levels >5 mg/dL typically have visible jaundice. The jaundice usually starts at the head and progresses distally to the feet. It resolves in the opposite pattern with the distal extremities resolving first.

**HELPFUL TIP:**

Jaundice present in the first 24 hours of life is pathologic and usually due to hemolytic disease such as ABO incompatibility.

treatment. Adjunctive therapy with intravenous fluids is considered if weight loss exceeds 12% of birth weight. “D” is incorrect because the serum bilirubin level is above threshold for hospital admission and phototherapy. You should not recommend putting the baby in sunlight, as the ultraviolet radiation exposure is an unacceptable risk.

**HELPFUL TIP:**

The American Academy of Pediatrics (AAP) has established threshold values for hyperbilirubinemia treatment with phototherapy and exchange transfusion. Decisions regarding treatment vary depending on the infant’s risk, age (in hours after delivery), gestational age, and total bilirubin level. There are graphs, tables, and nomograms (such as the Bhutani curve) to assist with decision-making. A free decision-making tool is available online (<http://www.bilitool.org/>).

You admit Amy for further management. You confirm Amy’s current weight, which is indeed down 15% from birth weight. Children often lose weight after birth while effective feeding is being established.

Question 13.2.4 Beyond what point in time is it considered problematic if the patient has not returned to his or her birth weight?

- A) 5 days
- B) 7 days
- C) 10 days
- D) 14 days
- E) None of the above. Don’t worry, be happy.

Answer 13.2.4 The correct answer is “D.” Children should regain their birth weight by age 2 weeks. If they don’t, it isn’t always abnormal, however. Fourteen percent of infants resulting from vaginal deliveries and 24% of Cesarean babies will not regain their birthweight by 14 days (*Pediatrics* 2016 Dec; 138:e2016–2625). Nonetheless, a detailed feeding history and evaluation of breastfeeding adequacy (if breastfed) and assessment of health and social situation should be performed.

Amy does well under your care (and the bili lights) and returns at 2 months of age for her well-baby visit. Mom questions the need for immunizations, reasoning, “We never see these archaic diseases anymore—I mean, come on, I can’t even find a chicken pox party.” Plus, she’s read information on the Internet and has concerns about immunization safety. And wasn’t there a study about kids who suffered autism because of thimerosal in a vaccine? And another study that vaccines transformed children into space aliens? Unfortunately, Amy’s mother’s concerns are not unusual. Parents—and ill-informed politicians—often harbor misconceptions about vaccinations.

Amy’s CBC is unremarkable and blood type is A+.

Question 13.2.3 Which of the following is the most appropriate initial treatment for this patient (remember the conjugated [direct] fraction is 0.4 mg/dL)?

- A) Admission for exchange transfusion
- B) Admission for IV fluids alone to improve hydration
- C) Admission for phototherapy
- D) Discharge to home with recommendations for formula feeding, light exposure, and follow-up bilirubin tomorrow

Answer 13.2.3 The correct answer is “C.” Amy should be treated with intensive phototherapy, given her level of hyperbilirubinemia that exceeds the recommended threshold. “A” is incorrect because the infant does not meet exchange transfusion threshold. Even if mildly above exchange threshold, some providers may attempt intensive phototherapy first if the infant does not have signs of bilirubin encephalopathy. An exchange transfusion would follow if phototherapy failed to lower the bilirubin level or signs of acute bilirubin encephalopathy developed. “B” is incorrect since phototherapy is the definitive

Question 13.2.5 What is a common side effect that Amy might have after her immunizations at her 2-month visit?

- A) Fever to 104°F
- B) Autism
- C) Diabetes
- D) Erythema at the site of immunization
- E) Symptomatic shedding of virus in her stool

Answer 13.2.5 The correct answer is “D.” Vaccine side effects, such as **low-grade fevers** (not to 104°F as in “A”), induration and redness at the site, and fussiness are common. However, they are self-limited. “B” and “C” are incorrect. Autism and diabetes **have NOT** been linked to vaccines in **many large, well-designed studies**. “E” is incorrect because the DTaP, Hib, and IPV vaccines are inactivated. Thus, the virus or bacteria is killed and purified for a specific component. The hepatitis B vaccine is constructed with genetic engineering in a yeast cell. Thus, one would not shed virus in the stool. *The MMR, oral polio, oral rotavirus, and varicella vaccines are live attenuated vaccines.* With these immunizations, the virus has been weakened but can still replicate and be shed. In an immunocompetent host, this usually is not of clinical significance. Thus, “E” is incorrect. In patients who have an immunodeficient state (either innate or iatrogenic, such as immunosuppression or chemotherapy), care must be taken with provision of live vaccines, as they may cause illness in a susceptible host. When in doubt, consult the CDC website and ask a specialist before giving live vaccines! Also, oral polio vaccine is no longer used in the United States because the risk of disease from the vaccine is greater than the risk of disease from wild-type polio; IM polio vaccine only, please.

HELPFUL TIP:

The article “linking” MMR vaccine to autism was withdrawn by the authors (and *Lancet*) years ago, and the lead author (Andrew Wakefield) has lost his medical license because of fraudulent data. *He* turned out to be a space alien bent on world conquest by infecting the earth. Despite this there are continued misconstrued thoughts about vaccines.

Amy’s mother accepts your advice but still has concerns.

Question 13.2.6 What other factually correct information can you share with her about vaccines at her 2-month visit?

- A) Giving a child multiple vaccines at the same time weakens her immune system
- B) The fever and rash side effects of the MMR are from the measles component and usually occur 1 week after the vaccine is given
- C) If Amy receives her MMR at a 9-month visit (before she travels to visit Aunt Tilley who lives in an area where measles has re-surfaced due to lack of vaccination), her MMR immunization would be considered complete after this dose and another one at 5 years old

- D) If Amy had an acute otitis media and fevers of 100.4°F, we should delay her immunizations until she is afebrile
- E) Immunizations are not important, since these diseases are rare in the United States

Answer 13.2.6 The correct answer is “B.” The measles component can cause a fever and rash 5 to 10 days after the immunization. This occurs in 5% to 15% of infants. Up to 25% of adults have arthralgias after receiving the vaccine and up to 10% develop arthritis. The MMR dosing schedule includes two doses of MMR. However, the first must be **after 1 year** of age. It may be given sooner if the child is at risk (such as with travel or with a measles outbreak) but must be **repeated after the first birthday**. Thus, “C” is incorrect. Minor illnesses should not prevent vaccination. True contraindications include anaphylactic reactions to a vaccine or vaccine constituent, moderate-to-severe febrile illness, and encephalopathy within 7 days of DTaP. Live virus vaccines are contraindicated in immunocompromised patients.

HELPFUL TIP:

As a general rule, if a patient misses a vaccine, just start up where you left off. There is no need to increase the number of vaccines given. If you have questions, you may consult the CDC website on catch-up immunization recommendations (and can even create a personalized catch-up schedule). There is a *free* app for that: Search the iPhone app store for “CDC immunizations.” It is called “CDC Vaccine Schedule” (appropriately enough). There is also an Android version (same search words ... though why you would want to immunize Androids is beyond us).

Amy continues her scheduled well-child examinations. At one of those visits, she was babbling and crawling around the office. She poked her fingers at the outlets (which thankfully were covered) and used a pincer grasp to pick up a raisin off the floor—at least, it looked like a raisin (ew, gross!).

Question 13.2.7 These behaviors are appropriate for the development of a child at approximately age:

- A) 6 months
- B) 9 months
- C) 15 months
- D) 24 months

Answer 13.2.7 The correct answer is “B.” Take a moment to review the developmental milestones in Table 13-1. Children who are not meeting their milestones appropriately should be referred for developmental assessment and early intervention services. Note that premature infants’ developmental stage may correspond with their corrected gestational age instead of their chronological age.

TABLE 13-1 DEVELOPMENTAL MILESTONES

Age	Gross Motor	Visual Motor	Language	Social
1 mo	Raises head slightly from prone, makes crawling movements, lifts chin up	Has tight grasp, follows to midline	Alert to sound (e.g., by blinking, moving, startling)	Regards face
2 mo	Holds head in midline, lifts chest off table	No longer clenches fist tightly, follows object past midline	Smiles after being stroked or talked to	Recognizes parent
3 mo	Supports on forearms in prone, holds head up steadily	Holds hands open at rest, follows in circular fashion	Coos (produces long vowel sounds in musical fashion)	Reaches for familiar people or objects, anticipates feeding
4–5 mo	Rolls front to back and back to front, sits well when propped, supports on wrists, and shifts weight	Moves arms in unison to grasp, touches cube placed on table	Orients to voice; 5 mo: orients to bell (localized laterally), says “ahgoo,” razzes	Enjoys looking around environment
6 mo	Sits well unsupported, puts feet in mouth in supine position	Reaches with either hand, transfers, uses raking grasp	Babbles; 7 mo: orients to bell (localizes indirectly); 8 mo: “dada/ mama” indiscriminately	Recognizes strangers
9 mo	Creeps, crawls, cruises, pulls to stand, pivots when sitting	Uses pincer grasp, probes with forefinger, holds bottle, finger-feeds	Understands “no,” waves bye-bye; 10 mo: “dada/mama” discriminantly; 11 mo: one word other than “dada/ mama”	Starts to explore environment, plays pat-a-cake
12 mo	Walks alone	Throws objects, let’s go of toys, hand release, uses mature pincer grasp	Follows one-step command with gesture, uses 2 words other than “dada/mama”; 14 mo: uses 3 words	Imitates actions, comes when called, cooperates with dressing
15 mo	Creeps upstairs, walks backward	Builds tower of 2 blocks in imitation of examiner, scribbles in imitation	Follows one-step command without gesture, uses 4–6 words and immature jargon (runs several unintelligible words together)	Indicates some simple needs by pointing, hugs parents
18 mo	Runs, throws toy from standing without falling	Turns 2 or 3 pages at a time, fills spoon and feeds self	Knows 7–20 words, knows 1 body part, uses mature jargon (includes intelligible words in jargon)	Copies parent in tasks (e.g., sweeping, dusting), plays in company of other children
21 mo	Squats in play, goes up steps	Builds tower of 5 blocks, drinks well from cup	Points to 3 body parts, uses 2-word combinations, has 20 word vocabulary	Asks to have food and to go to toilet
24 mo	Walks up and down steps without help	Turns pages one at a time, removes shoes, pants, etc., imitates behavior of others	Uses 50 words, 2-word sentences, uses pronouns (I, you, me) inappropriately, points to 5 body parts, understands 2-step command	Parallel play
30 mo	Jumps with both feet off floor, throws ball overhand	Unbuttons, holds pencil in adult fashion, differentiates horizontal and vertical line	Uses pronouns (I, you, me) appropriately, understands concept of “one,” repeats 2 digits forward	Tells first and last names when asked, gets drink without help
3 yr	Pedals tricycle, can alternate feet when going up steps	Dresses and undresses partially, dries hands if reminded, draws a circle	Uses 3-word sentences, plurals, and past tense. Knows all pronouns. Minimum of 250 words, understands concept of “two”	Group play, shares toys, takes turns, plays well with others, knows full name, age, sex
4 yr	Hops, skips, alternates feet going downstairs	Buttons clothing fully, catches ball	Knows colors, says song or poem from memory, asks questions	Tells “tall tales,” plays cooperatively with a group of children
5 yr	Skips, alternating feet, jumps over low obstacles	Ties shoes, spreads with knife	Prints first name, asks what a word means	Plays competitive games, abides by rules, likes to help in household tasks

Amy continues her scheduled well-child examinations. However, at 14 months old, mom brings Amy for a sick visit because she turned blue. After taking a complete history and doing a complete physical examination, you appropriately diagnose breath-holding spells.

Question 13.2.8 Which of the following statements about breath-holding spells is true?

- A) The incidence of breath-holding spells for children between 6 months old and 6 years old is 50%
- B) If a color change occurs, it occurs after loss of consciousness
- C) Seizure-like activity may occur with breath-holding spells
- D) A child typically takes 60 to 90 minutes to return to her baseline after a breath-holding spell
- E) The evaluation should include an echocardiogram (ECG) and electroencephalogram (EEG)

Answer 13.2.8 The correct answer is “C.” A typical breath-holding spell begins with an inciting event (like Santa did not bring the right toy or mom refused to buy a Happy Meal). Breath-holding spells occur in up to 4% of children and 80% start before 18 months. The child begins to cry, holds his or her breath, turns blue, and (may) lose consciousness. After loss of consciousness, some rhythmic jerking of the extremities may occur. The loss of consciousness is brief, and the child returns quickly to normal activity (no post-ictal state). The differential diagnosis includes cardiac arrhythmias, seizures, and apnea. If the history is classic for breath-holding spells, no further evaluation is necessary. The treatment is parental reassurance. Parents should be encouraged to ignore the episodes and not to give in to the child’s requests in an attempt to avoid the spells. Iron supplementation may decrease the frequency of spells if anemia or iron deficiency is present.

HELPFUL TIP:

This type of spell in a child under 1 year of age may be referred to in the literature as a brief resolved unexplained event (BRUE). Until 2016, BRUEs were referred to as apparent life-threatening events (ALTEs). The term BRUE is nonspecific and is defined by what the parents observe: apnea, cyanosis, decreased responsiveness, etc. There is no relationship between a BRUE and sudden infant death syndrome (SIDS). The most common causes of a BRUE include lower respiratory tract infections, GERD, and seizure, though as many 50% occur without an identifiable cause. Additional causes include breath-holding spells, electrolyte abnormalities, cardiac dysrhythmias, metabolic diseases, and CNS problems. Always consider child abuse in your differential. A good history and physical examination are the most important evaluation tools. Diagnostic testing should be guided by history and physical examination findings. See Tieder JS, et al. *Pediatrics* 2016, for BRUE guidelines.

Question 13.2.9 Between 12 and 15 months of age, Amy should receive all of the following vaccines, as per Centers for Disease Control and Prevention (CDC) recommendations, EXCEPT:

- A) MMR
- B) Varicella
- C) Hepatitis A
- D) Rotavirus
- E) Influenza

Answer 13.2.9 The correct answer is “D.” Vaccination schedules and recommendations seem to represent quickly moving targets, so a regular review is required to keep up-to-date. At 12 to 15 months, the CDC recommends initial MMR, varicella, and hepatitis A vaccinations for all U.S. children. Influenza recommendations are updated annually and have become progressively more inclusive over time. The CDC recommends that all children ages 6 months through 18 years receive the influenza vaccine annually during the appropriate season. If the child is receiving her first year of influenza vaccination and is between 6 months and 8 years of age, she should receive two doses about 1 month apart to help boost immunity. Following this, the child may receive one dose of influenza vaccination annually. Of note, rotavirus vaccine should not be administered to children older than 32 weeks, and the first dose should not be given after 15 weeks.

Of course, the vaccine schedule is updated periodically but does not usually change drastically from year to year. For the most up-to-date version, go to the CDC website (<http://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html>) or use the app.

Amy’s breath-holding spells resolve by the time she is 3 years old, and she continues to grow and develop normally. Amy’s next issue comes when she is 5 years old and in your office for her pre-kindergarten physical.

Question 13.2.10 You notice a new murmur. Of the following, which suggests that this is a benign murmur?

- A) Murmur is grade II/VI
- B) Murmur has a thrill
- C) Murmur radiates to the apex
- D) Murmur is diastolic
- E) Murmur is holosystolic

Answer 13.2.10 The correct answer is “A.” Not all murmurs need to be referred to a cardiologist. There are features that can help differentiate pathologic from benign murmurs. A murmur that is diastolic, grades III to VI, pansystolic, or associated with cardiac symptoms is likely pathologic and requires further investigation. A benign murmur typically is systolic, soft (grades I–II, occasionally III), nonradiating, and short. A “benign” murmur is not a diagnosis of exclusion. You should try to decide about which innocent murmur it is. See Table 13-2.

On Amy’s examination, you hear a grade III/VI systolic murmur in the pulmonic area with wide, fixed splitting of the

TABLE 13-2 BENIGN CARDIAC MURMURS OF CHILDHOOD

Still murmur: A grade I–III murmur heard best in left middle sternal border or between left lower sternal border and apex. It is a “musical,” vibratory, or buzzing systolic ejection murmur, which is louder when the patient is supine, compared with when upright, and decreases in volume with a Valsalva maneuver. A Still murmur may get louder as blood flow increases with fever, exercise, or excitement.

Venous hum: A grade continuous I–III murmur heard best in the supraclavicular area. It should resolve when the patient is recumbent or with pressure over the jugular vein.

Pulmonic murmur: Heard as a grade I–III systolic ejection murmur in the first half of systole. It is generally best heard in the left upper sternal border.

Murmurs that change with respiration are generally, but not always, benign.

second heart sound. She is otherwise healthy without any cardiac symptoms.

Question 13.2.11 What is the appropriate next step in management of this issue?

- A) Family reassurance
- B) Endocarditis prophylaxis at the dental visit next week
- C) ECG and chest radiograph
- D) Limit physical activity
- E) Refer for immediate operative repair

Answer 13.2.11 The correct answer is “C.” Most likely, Amy has an ASD or atrial septal defect. The murmur is a systolic ejection murmur heard best at the upper left sternal border. The sound you hear is caused by increased flow across the pulmonic valve creating a relative stenosis (more volume needs to get through a relatively fixed outlet) and NOT from flow across the ASD. The increased flow across the pulmonic valve causes a wide, fixed split S2. There may be a mid-diastolic rumbling murmur at the lower left sternal border from increased flow across the tricuspid valve if the ASD is very large. The chest x-ray may demonstrate cardiomegaly with increased pulmonary vascular markings. The ECG can be normal or may show mild right ventricular hypertrophy, right axis deviation, and/or right bundle branch block with the characteristic rsR’ pattern in the right precordial leads. Children with an ASD do NOT need endocarditis prophylaxis (except for the first 6 months after their surgical repair) and rarely need to limit their physical activity. Most small ASDs will close spontaneously by age 4 years. Closure by one of a variety of methods is recommended for symptomatic and significant left-to-right shunts with right ventricular enlargement.

► **Objectives: Did you learn to ...**

- Describe the causes of neonatal hyperbilirubinemia?
- Manage an infant with breastfeeding failure jaundice?
- Identify risk factors for severe hyperbilirubinemia?
- Recommend vaccines for children in accordance with CDC guidelines?
- Identify vaccine misconceptions, list MMR side effects, and identify contraindications to immunization?

- Recognize stages of child development?
- Describe and manage breath-holding spells?
- Differentiate benign from pathologic cardiac murmurs in childhood?

QUICK QUIZ: JAUNDICE

The current recommendation for the treatment of breast milk jaundice (NOT breastfeeding failure jaundice as per the previous case) is:

- A) Continue to breastfeed
- B) Stop breastfeeding and change to a cow’s milk formula
- C) Stop breastfeeding and change to soy milk formula
- D) Stop breastfeeding and treat with rehydration solution (e.g., Pedialyte)

The correct answer is “A.” Patients with hyperbilirubinemia due to breast milk jaundice should continue to breastfeed. Breast milk jaundice begins on days 5 to 7 of life, peaks by 2 weeks of age, and usually resolves by 10 weeks of age; monitor to make sure that the jaundice remains unconjugated and there is no need to look for a second source. Bilirubin levels will gradually decline while breastfeeding is continued. If breastfeeding is discontinued, serum bilirubin levels decline rapidly. Kernicterus is rare. The etiology is unclear, but it is hypothesized that glucuronidase in breast milk may lead to de-conjugation and increased enterohepatic recirculation of bilirubin.

► **CASE 13.3**

A family has moved into the area and brings their 12-month-old girl in for a well-child examination. They bring her medical records with them. Her parents have no concerns, and she has been healthy. Her growth chart (Fig. 13-1) concerns you, however. Her length tracks along the 25th percentile. But her weight has gone gradually from around the 25th to 50th percentile at 0 to 6 months old down to the 10th percentile at 9 months old, and now is at the 5th percentile at 12 months.

Question 13.3.1 Which of the following most likely explains her pattern of growth?

- A) Normal variant
- B) Familial short stature
- C) Prenatal insult such as exposure to drugs or infection
- D) Hypothyroidism
- E) Inadequate nutrition

Answer 13.3.1 The correct answer is “E.” This patient’s pattern of growth is consistent with failure to thrive (FTT), now termed “weight faltering” or faltering growth (*Am Fam Physician*. 2016;94(4):299). The criteria for diagnosis of FTT include weight less than the third to fifth percentile (depending on the source) **or** a fall of weight of more than two major percentile lines in 6 months **or** weight less than 80% of ideal weight for age

FIGURE 13-1. Your patient's growth chart

and/or weight for height less than fifth percentile. The patient meets more than one of the criteria for FTT, so “A” is incorrect. In “B,” both height and weight would be affected. In this child, only the weight (and not the height) is affected. “C” is incorrect because a child with a prenatal insult tends to be smaller globally in both height and weight, and the weight percentile would not be expected to drop so dramatically from birth. “D” is unlikely because, in general, the endocrinological causes result in “stunting” where a child stops gaining height but continues to gain weight. Thus, “E” is the most likely cause of this patient’s FTT.

Taking more history, you discover that the patient eats mostly rice and fruit. She does not like meat. She is picky. She drinks about 12 oz of whole milk and 12 oz of apple juice each day. She is active and developmentally appropriate. Her review of systems is negative as is her past medical history.

Question 13.3.2 What is the LEAST appropriate way to proceed with evaluation and management of this patient?

- A) Allow the child to feed herself whenever she is hungry or thirsty. Parents should offer food and drink frequently throughout the day
- B) Obtain CBC, iron studies, and urinalysis
- C) Limit juice intake
- D) Consult a registered dietitian
- E) Prescribe a multivitamin

Answer 13.3.2 The correct answer (and least appropriate approach) is “A.” The goal of management of failure to thrive is to ensure appropriate caloric intake, identify treatable causes of failure to thrive, and look for effects of her malnutrition. Thus, a CBC, iron studies, electrolytes, bicarbonate, glucose, and urinalysis may be helpful to investigate possible iron deficiency, anemia, lead poisoning or renal tubular acidosis. Generally, however, extensive diagnostic workup is not needed until after a period of confirmed appropriate caloric provision. If the patient’s weight continued to falter, despite appropriate calories, more extensive workup is needed. Juice should be limited (due to its low nutritional value), meals scheduled, and caloric intake boosted. Although children should feed themselves, they take in more calories when given a set schedule for meals and snacks instead of being allowed to graze on food or drink throughout the day as in “A.” A registered dietitian can help educate the family on appropriate food choices for a toddler and ways to boost calories. A child with a restrictive eating pattern, especially poor in iron-containing foods (such as meats), may benefit from a multivitamin with iron.

HELPFUL TIP:

For infants with failure to thrive, increased caloric provision is often needed to “catch-up” and sustain growth. Encourage the parents to increase the caloric density of foods and drinks. In children older than 1 year, you may ask them to use whole milk rather than reduced fat milk, add butter to food, etc. In children under 1 year of age who are exclusively breastfed, evaluation of maternal milk supply and breastfeeding adequacy is needed. In

babies who are bottle-fed, fortification of breast milk or enrichment of formula (e.g., from standard 20 kcal/oz to 24 kcal/oz) may be needed. Most formulas can be used for this purpose, and recipes are readily available.

Your patient presents to the emergency department (ED) at 14 months old. Mom states that she has had several episodes of emesis over the last 48 hours and today began to have watery, foul-smelling diarrhea (as opposed to the yummy-smelling diarrhea to which we are so accustomed). Mom has lost track of number of episodes of emesis and diarrhea. She cannot tell if the child has had urine output because of the watery diarrhea. On your examination, the temperature is 102.5°F, heart rate 180 bpm, respiratory rate 50, blood pressure 80/50 mm Hg. Her weight is 8 kg. She has dry, cracked lips and dry skin. She lies in her mom’s arms and is not very interested in your examination. Her capillary refill is about 4 seconds with some mottling of the extremities.

Question 13.3.3 What is the most appropriate next step in the management of this patient’s condition?

- A) Evaluate for underlying bacterial infection with blood, urine, and stool cultures
- B) Admit to an inpatient unit and begin maintenance IV fluids
- C) Infuse 20 mL/kg of normal saline IV rapidly
- D) Begin oral rehydration with Pedialyte
- E) Infuse 10 mL/kg of D5/half-normal saline over 2 hours

Answer 13.3.3 The correct answer is “C.” This patient is severely dehydrated (estimated 15%) with signs of compromised tissue perfusion; therefore, she should have parenteral fluid resuscitation quickly with a 20 mL/kg isotonic fluid bolus. The bolus should be run over a few minutes and not administered with an infusion pump. Appropriate isotonic fluids include normal saline or lactated Ringer’s. Although she will likely need admission as suggested by “B,” she should be stabilized in the ED before transfer to the inpatient unit. Starting with maintenance fluids or a slow infusion, as suggested by “E,” is incorrect, as repletion of intravascular volume is needed immediately. Oral rehydration, as in “D,” is cost-effective in less severe dehydration, but is not recommended in the setting of compromised tissue perfusion. There are several tables published listing the clinical examination associated with various degrees of dehydration. See Table 13-3 for clues in determining the degree of dehydration.

HELPFUL TIP:

Dehydration is a clinical diagnosis, but laboratory findings can be helpful. The serum sodium classifies the dehydration as hypotonic, isotonic, or hypertonic. Metabolic acidosis is often present, and calculation of the anion gap may help determine the cause. Blood urea nitrogen and serum creatine concentrations can be helpful to assess for acute kidney injury but may be affected by other conditions.

TABLE 13-3 SIGNS AND SYMPTOMS OF DEHYDRATION^a

Mild (5% in an infant, 3% in a child): Normal skin turgor, moist lips, tears present, normal vital signs, consolable
Moderate (10% in an infant, 6% in a child): Dry skin and lips, skin tenting, slightly increased pulse, decreased urine output, normal capillary refill
Severe (15% in an infant, 9% in a child): Parched lips, sunken eyes, decreased or no urine output, cool skin, elevated pulse, prolonged capillary refill, lethargic or obtunded

^aBecause of the poor association of physical findings with a particular percent dehydration use the terms “mild,” “moderate” or “severe” is preferred over trying to assign a percent dehydration.

After completing the initial management, the patient is more interested in her surroundings. Her vital signs are pulse 160 bpm, respiratory rate 36, and blood pressure 80/50 mm Hg. Her lips are still dry, and she is irritable. The capillary refill is 2 to 3 seconds. She is more interactive with her mother.

Question 13.3.4 What further treatment is indicated for her dehydration?

- A) 80 mL/hr × 2 hours of D5-1/4-NS
- B) 33 mL/hr × 24 hours of D5-1/2-NS with 20-mEq KCl
- C) 50 mL/hr × 24 hours of D5-1/4-NS
- D) 20 mL/kg NS over 20 minutes
- E) 10 mL/kg D5-1/2-NS over 2 hours

Answer 13.3.4 The correct answer is “D.” After an initial bolus, the patient should be reassessed. This patient is still moderately dehydrated. Although she has responded to her initial bolus of normal saline, she still has abnormal vital signs as well as signs of dehydration on examination. Therefore, the normal saline bolus should be repeated. **Hypotonic solutions (e.g., 1/2 NS) or those containing glucose (D5) and/or potassium should NEVER be used as a bolus. Note the bold—we mean it!** Boluses of hypotonic solution can lead to hyponatremia, seizures, and cerebral edema. Boluses of potassium-containing solutions (especially in the setting of reduced urine output) can lead to life-threatening hyperkalemia. Potassium (if needed at all) should be withheld until the patient urinates and has better hydration status.

HELPFUL TIP:

Maintenance fluids can be used in patients with decreased oral intake to keep up with their daily water needs. Maintenance fluids can be calculated using the Holiday–Segar method: daily water needs for the first 10 kg of body weight is 100 mL/kg/day; water needs for the next 11 to 20 kg is 50 mL/kg/day; each additional kg over 20 kg is 20 mL/kg/day. You can also calculate the hourly fluid requirement by the “4, 2, 1” method. Children should get 4 mL/kg/hr for the first 10 kg body weight, 2 mL/kg/hr for the next 10 kg, and 1 mL/kg/hr for every kg over 20 kg. Assess for dehydration and/or a fluid deficit prior to starting maintenance fluids.

Fluid deficit (L) = usual weight (kg) – current weight (kg)

If a patient is dehydrated, utilize isotonic fluid boluses to correct this, then start your maintenance fluids! Remember, boluses “fill the tank” and maintenance fluids “keep it from running low.” You’ve gotta’ attain (euvoemia) before you can maintain! Also, replace ongoing losses from diarrhea, emesis, etc., if present.

HELPFUL (AND IMPORTANT) TIP:

Historically, hypotonic “peds” solutions (1/4 or 1/2 NS with 5% dextrose) had been used for maintenance fluids in children. In susceptible children, this can lead to hyponatremia, seizures, and cerebral edema. Fluids with a sodium content similar to that of plasma (135–145 mEq/L) should be used (*Lancet*. 2015;385(9974):1190–1197; 28). Recent literature suggests use of D5-NS (sodium content 154 mEq/L) or similar solutions are generally safer than hypotonic solutions when used as a maintenance fluid (*Cochrane Database Syst Rev*. 2014;12:CD009457; *Pediatrics*. 2014;133:105–113). Maintenance fluids in children should generally contain dextrose (5%) to maintain euglycemic and prevent catabolism. Care should be taken to prevent hyperglycemia in children with impaired glucose metabolism (e.g., metabolic syndrome, PCOS, diabetes mellitus).

The patient recovers well from her GI illness, but she returns a few months later to your clinic with a new illness. She has had temperatures of 103°F at home for 2 to 3 days. She has had no upper respiratory symptoms. Her oral intake has decreased, but she is maintaining good urine output. She has had no vomiting or diarrhea. Your examination reveals a febrile child who is slightly irritable. She is nontoxic and not dehydrated. Her oral cavity shows increased tonsil size with ulcers on her tongue and lips but not on the tonsillar pillars; *there are no other skin lesions*. Her anterior cervical lymph nodes are enlarged. The rest of her examination is noncontributory.

Question 13.3.5 What is the most likely diagnosis?

- A) Streptococcal pharyngitis
- B) Hand, foot, and mouth disease (HFMD)
- C) Herpetic gingivostomatitis
- D) Varicella
- E) Infectious mononucleosis

Answer 13.3.5 The correct answer is “C.” Primary oral herpes (herpetic gingivostomatitis) is associated with a relatively high fever and anteriorly placed ulcerations and vesicles (gums, tongue, and lips). Symptoms tend to start relatively abruptly with pain, salivation, refusal to eat, and fever. Herpes gingivostomatitis may recur during life in the form of “cold sores.” “B” is incorrect because the patient does not have hand and foot lesions, which are required for a diagnosis HFMD. Oral lesions

in HFMD often occur on the tongue and buccal mucosa. Like herpangina (see below), HFMD is caused by enteroviruses, most commonly coxsackieviruses. “D,” varicella, can occur in the oral pharynx, but would have lesions elsewhere in various stages and respiratory symptoms as well. Infectious mononucleosis is not associated with vesicular lesions or mucosal ulcerations.

HELPFUL TIP:

The poorly named “herpangina,” caused by enteroviruses (usually coxsackie A), is another consideration in the child with fever and mouth sores. Herpangina is associated with fewer vesicles and **ulcers located in the posterior oropharynx along the posterior soft palate and tonsillar pillars and fossa**. Headache, vomiting, and abdominal pain may be present as well. Note that this is a different clinical entity from hand, foot, and mouth disease despite the enteroviral cause.

Next, you see the patient’s sister who is age 10 and presenting for a school physical. Her mother is concerned because this patient has pubic hair, which her mother thinks is premature (and scary ... her baby can’t be growing up yet!). On your examination, she has enlarged areola and a small amount of breast tissue. She also has sparse, dark, but mostly straight pubic hair.

Question 13.3.6 This patient’s sexual maturity rating or Tanner stage is:

- A) 1
- B) 2
- C) 3
- D) 4
- E) 5

Answer 13.3.6 The correct answer is “B.” Breast buds and sparse, downy pubic hair put the patient in Tanner stage 2. Tanner stage 1 is prepubertal. Any sign of puberty moves a child from Tanner 1 to Tanner 2. Tanner stage 5 is adult or fully matured secondary sexual characteristics. See Table 13-4 for details.

TABLE 13-4 TANNER STAGES

Stage 1: Prepubertal
Stage 2: Sparse growth of downy hair at base of penis or along labia
• Girls: Breast bud development
• Boys: Enlargement of scrotum and testes with reddening and thickening of scrotal skin
Stage 3: Darkening, coarse hair sparsely in pubic area
• Girls: Enlargement of breasts (primary mound)
• Boys: Elongation of penis and increased size of testes
Stage 4: Adult pubic hair distribution (triangle) but smaller area covered with no extension to medial thighs
• Girls: Areola and papilla begin to mound above the level of the breast (secondary mound)
• Boys: Increase in breadth and development of penis, darkening of scrotal skin, enlargement of testes
Stage 5: Adult breasts, genitals, and hair distribution

The mom has a lot of questions about puberty. She is nervous about beginning to discuss sexual development with her daughter.

Question 13.3.7 What is a developmental fact that you can provide the mom for discussion with her daughter?

- A) Typically, in females, the first sign of puberty is pubic hair
- B) At 10 years old, the patient is experiencing premature puberty
- C) The height spurt occurs early during puberty and is almost complete at menarche
- D) Menarche occurs approximately 1 year after breast budding
- E) Schools discuss puberty and relieve mom or dad of that duty (whew!)

Answer 13.3.7 The correct answer is “C.” In girls, the growth spurt occurs early and is almost complete at menarche. Females begin puberty about 1 to 2 years before males. “A” is incorrect as thelarche, or breast budding, marks female onset of puberty. “B” is incorrect. The average age of breast budding is 10.9 years. Thus, the child is appropriate in her pubertal timing. “D” is incorrect. Menarche typically begins 2 years after breast budding. “E” is incorrect. Sex education in schools is highly variable, and these discussions are often limited in the time and content. It is important for the child to hear her mother’s opinions on puberty and sex.

HELPFUL TIP:

Precocious or early puberty is defined as the onset of secondary sexual characteristics before age 8 for girls and age 9 for boys. Delayed puberty is the lack of such changes by age 14.

► Objectives: Did you learn to ...

- Define failure to thrive in a child?
- Evaluate a child with failure to thrive?
- Evaluate a dehydrated child and determine severity of dehydration?
- Manage dehydration in the ED?
- Calculate rehydration fluids for a dehydrated child?
- Generate a differential diagnosis for pharyngitis with blisters?
- Describe changes of puberty and Tanner staging in a female?

QUICK QUIZ: FEEDING INFANTS

Which is *not* an indication for use of soy formula in an infant?

- A) Galactosemia
- B) Congenital lactase deficiency
- C) Cow milk protein intolerance
- D) Parental desire for a vegan diet

The correct answer is “C.” Few indications exist for use of soy-based formula over cow milk–based formula. Soy formula is lactose free and therefore should be used in conditions “A,” “B,” and “D.” Galactosemia is a metabolic disorder characterized by the inability to break down galactose. Dietary galactose comes from lactose found in human and cow milk. Remember, lactose is a disaccharide composed of galactose and glucose. An extensively hydrolyzed or amino acid formula should be used for cow milk protein intolerance. Infants who are sensitive to cow milk protein have an approximately 10% to 15% chance of also being sensitive to soy proteins. Reflux deserves special note. There is no data supporting the use of soy formula for reflux.

▶ CASE 13.4

A 2-year-old male presents to your office with his father complaining that the patient has had intermittent crying followed by episodes of profound lethargy during which he is difficult to arouse. The father relates that the patient will sometimes clutch at his abdomen and roll into the fetal position during episodes. These episodes have been going on for about 4 hours. He has had no fever, no vomiting, and no diarrhea. Nobody else at home has been sick. He is developmentally normal and has no significant past medical history. His examination reveals that he is afebrile and sleepy but can be aroused. *His abdominal examination is benign.* The rest of the examination is unremarkable.

Question 13.4.1 Given his presentation, your clinical suspicion is for:

- A) Meningitis
- B) Renal colic
- C) Intussusception
- D) Gastric outlet obstruction
- E) Appendicitis

Answer 13.4.1 The correct answer is “C.” The patient may have intussusception. The combination of abdominal colic plus mental status changes should suggest intussusception. The etiology of the mental status changes is not clear, but mental status changes are one of the classical findings of intussusception. “A,” meningitis, should still be a consideration in a patient with mental status changes, but he is afebrile and his symptoms are intermittent, making meningitis less likely. “B” is not associated with mental status changes. “D” and “E” usually present with some abnormal findings on abdominal examination.

HELPFUL TIP:

Fewer than 15% of patients with intussusception present with the classic triad of colicky abdominal pain, palpable sausage-shaped abdominal mass, and currant jelly stool.

Question 13.4.2 Which laboratory finding will help you to confirm the diagnosis of intussusception?

- A) CBC
- B) Urinalysis
- C) Glucose
- D) Serum lactate
- E) None of the above

Answer 13.4.2 The correct answer is “E.” None of the above will help to make the diagnosis of intussusception. Early in the course, the CBC may be normal and only 75% will have heme-positive stools.

HELPFUL TIP:

“Currant jelly stools” are a late finding in intussusception and are a reflection of mucosal ischemia. You really want to make the diagnosis before you see “currant jelly” per rectum. (Hey, have you ever actually seen currant jelly? It is bright red and gloopy, kind of like grandma’s cranberry sauce.)

Question 13.4.3 You decide that this patient probably has intussusception based on your history and physical examination. The next step in diagnosing this patient is:

- A) Upper GI with barium
- B) A plain film of the abdomen
- C) An air enema
- D) An abdominal ultrasound
- E) Administration of IV antibiotics

Answer 13.4.3 The correct answer is “D.” In general, an ultrasound is the diagnostic modality of choice. An ultrasound may show a typical “bull’s eye” lesion helping to make the diagnosis. “C,” an air enema, is a diagnostic and therapeutic intervention. An air enema can be used to reduce the intussusception obviating the need for surgery. In general, however, a diagnosis is first made by ultrasound. An upper GI, “A,” will be of no use since intussusception is a distal process. A plain film of the abdomen, “B,” will most likely be nondiagnostic as is the case in most abdominal processes (except perhaps bowel obstruction or free air).

HELPFUL TIP:

For intussusception, an air or water-soluble contrast enema is preferred over traditional barium enema. Bowel perforation is the main risk of nonoperative reduction. Air and water-soluble contrast enemas are much less harmful than barium if leaked into the peritoneum. Air enemas have also been noted to have a higher success rate compared to hydrostatic enemas, with rates of successful reduction around 83% and 70%, respectively (*Am J Roentgenol.* 2015;205(5):W542–549).

Well, the ultrasound tech is in the Cayman Islands, so you opt for an air enema, which simultaneously diagnoses and reduces the intussusception. The patient appears well

with no signs of perforation. He is eating goldfish crackers by the fistful in the ED and generally making a mess of the examination room. Recommendations vary as to the patient's disposition. Recurrence rate is less than 5% in the first 24 hours and about 10% in the first 48 hours after reduction. Some authors recommend admission for 24 hours post-reduction, but this does not change the recurrence risk. The child's clinical picture, access to care, and reliability of caregiver should be taken into account (*Pediatrics*. 2014;134(1):110). We suspect admission will be the right answer for the test.

HELPFUL TIP:

Most cases of intussusception are idiopathic. Less than 10% of patients have a pathologic lead point such as a Meckel diverticulum, intestinal polyp, or lymphoma. Increased age of child increases the risk of a lead point.

HELPFUL TIP:

Different types of intestinal obstructions occur at different ages. Obstruction at birth is typically an anatomic atresia, meconium ileus, or Hirschsprung disease. Volvulus due to malrotation can occur at any age, but most commonly appears in infancy (even within the first month of life ... watch for bilious vomiting, a sign of volvulus). Between birth and 5 weeks of age, hypertrophic pyloric stenosis appears. Intussusception is the most common cause of GI obstruction between 3 months and 6 years of age.

► Objectives: Did you learn to ...

- Recognize the clinical presentation of intussusception?
- Evaluate and treat a child with intussusception?

► CASE 13.5

Benjamin, a 4-month-old male, comes to your office for a well-baby examination. His parents have no concerns. Development and feeding are progressing as expected. Looking at him, you think to yourself, "My gosh. Infants have such big heads relative to their bodies." On your examination, his head is >95th percentile, but his weight and height are still at the 50th percentile. His previous head circumferences have all been at the 50th percentile. He is a social infant but is having difficulty supporting his large head.

Question 13.5.1 What is the imaging study LEAST likely to assist in the diagnosis of the macrocephaly?

- A) X-ray
- B) CT scan
- C) MRI scan
- D) Ultrasound

Answer 13.5.1 The correct answer is "A." Because the relative head size is so dramatic, an imaging study is needed, but skull radiographs are not likely to assist you in arriving at a diagnosis. The other modalities are used in this setting, and each has its benefits and detractors. Ultrasound is often used in infants when the anterior fontanelle is still patent and offers the advantage of no radiation exposure. Ultrasound is primarily used to assess fluid-filled spaces (ventricles in hydrocephalus, subdural hematoma, etc.). CT scan is a rapid and readily available test that can detect hemorrhages, intracranial calcifications, skull fractures, Chiari malformations, and more, but given the concern for radiation exposure and the risk of future malignancy, it is not the first-line imaging technique. CT is also limited in its ability to delineate soft-tissue problems, which is where MRI becomes important.

HELPFUL TIP:

The differential diagnosis of macrocephaly is long and includes hydrocephalus, brain tumor, benign familial macrocephaly, benign enlargement of the subarachnoid space (BESS), neurocutaneous disorder (e.g., neurofibromatosis, tuberous sclerosis), hemorrhage, and metabolic disorders (e.g., Tay-Sachs disease, mucopolysaccharidoses).

Question 13.5.2 The ultrasound tech is still on vacation (why can't we have his job?) and your MRI is undergoing scheduled maintenance, so you order a CT scan, which shows subdural hematomas. What is your next step in managing this patient?

- A) Admit to the hospital
- B) Examination of eyes in an ophthalmologist's office
- C) "Babygram" to view entire skeleton of infant for fractures
- D) Alert the department of human services within the next week
- E) Send the patient to a neurosurgeon's office for the next available appointment

Answer 13.5.2 The correct answer is "A." Subdural hematomas in an infant are highly suspicious of abusive head trauma. Your priority is to protect the child by admission to the hospital. A retinal examination and skeletal survey are important in the evaluation but are secondary to protection of the child. A "babygram" should never be done to evaluate for skeletal trauma. There is a specific procedure for performing a formal skeletal survey for abuse, which should be completed in cases of suspected abusive head trauma. Your state agency responsible for investigating child abuse must be notified within 24 hours (although clinicians are encouraged to know their legal responsibilities in the state in which they practice). Protection of the child is most important; if the family flees, calling the police or the appropriate state agency would be the first step. Suspicion of abuse, especially abusive head trauma, is an emergency, and it should not wait for a neurosurgeon's next available appointment.

**HELPFUL TIP:**

Retinal hemorrhages generally require a significant acceleration–deceleration mechanism to occur (e.g., shaking) and are *highly* suspicious for abuse. Nonabusive causes of retinal hemorrhages are very rare. Vaccinations, mild head trauma (such as falling off a sofa), CPR, seizures, and routine play do **not** cause retinal hemorrhages.

As you have done in this case, radiological studies should always be obtained in the evaluation of suspected child abuse. However, the cause of fractures has a broader differential than abuse.

Question 13.5.3 Which patient's injuries and/or radiological studies would be pathognomonic of abuse?

- A) A 9-month-old male with widened distal radius and ulna with fraying and cupping evident on radiograph
- B) A 21-month-old female with multiple fractures at different ages on radiograph. She has delayed tooth eruption and sparse hair
- C) A colicky 1-month-old male infant with callus on the left clavicle radiograph
- D) A 2-year-old female with a spiral fracture of the distal right tibia
- E) None of the above

Answer 13.5.3 The correct answer is “E.” None of these injuries is diagnostic of abuse. Although each of these children would make you think of possible abuse, none of them have been abused. “A” is a child with rickets. “B” is a child with osteogenesis imperfecta. “C” is a child who sustained a clavicle fracture at birth. “D” is a child with a “toddler’s fracture.” A toddler’s fracture is a spiral tibial fracture found in children age 9 to 36 months (see Chapter 12). These fractures are found in the distal one-third of the tibia. Long bone fractures in nonambulatory children, distal metaphyseal “wedge” fractures (often called “bucket-handle fractures”), and posterior-rib fractures (from squeezing) are among injuries that are VERY concerning for abuse.

Benjamin’s evaluation shows bilateral subdural hemorrhages and retinal hemorrhages. His skeletal survey is negative. The state agency removes him from the home and places him in foster care. Benjamin then returns for his 6-month well-child examination. He has been in foster care since you last saw him. His vision is being followed by an ophthalmologist. He smiles and squeals. His foster mother says, “Looks like he’s right-handed. Does that mean that he’s advanced for his age?” He rolls both ways. He has started on rice cereal and bananas. He sleeps well. On your examination, he continues to have macrocephaly but a soft fontanelle. His left hand is fisted. The rest of the examination is unremarkable.

Question 13.5.4 What is your assessment and plan for Benjamin?

- A) Normal 6-month-old: Routine anticipatory guidance and immunizations
- B) Infant with history of head trauma: Delay pertussis vaccination because of the autism risk
- C) Infant with history of head trauma: Perform Denver Developmental Screening Test and document findings; repeat in 3 months
- D) Hypertonic left upper extremity: Monitor progress at next well-child examination
- E) Hypertonic left upper extremity: Refer for further evaluation and treatment of his delay

Answer 13.5.4 The correct answer is “E.” Benjamin is at risk of developmental delays due to his abusive head injury. He should be monitored closely for delays. One way to monitor for delays is by performing a screening test, such as the Denver Developmental Screening Test. However, Benjamin has concerns that go beyond screening. His tightly fisted left hand with corresponding favoring of his right hand suggests spastic hemiplegia. Early hand preference is a worrisome sign. Typically hand preference is not definite before 18 to 24 months. Hand preference should prompt the physician to examine the other extremity. In this case, there is hypertonicity resulting from his trauma. Any child with concern of developmental delay should be referred for further evaluation. Some local and state agencies offer a free service to families to evaluate development and offer therapy. Do NOT watch and wait with a suspected delay. The earlier intervention begins, the better the outcome.

► Objectives: Did you learn to ...

- Recognize and evaluate macrocephaly in an infant?
- Generate a differential diagnosis of macrocephaly in an infant?
- Determine when child abuse should be included in the differential diagnosis?
- Describe some aspects of developmental delay and its management?

**QUICK QUIZ: DEVELOPMENTAL DELAY**

A mother brings her 18-month-old son in for a routine visit, but is concerned that he is not as verbal as he was 3 months ago. She reports that he eats well. He just started walking. You wish to screen him for a pervasive developmental disorder (which includes autism spectrum disorder, Rett syndrome, childhood disintegrative disorder, and others).

What is the most appropriate office tool to use with this patient given his age and presenting symptoms?

- A) Ages and Stages Questionnaire (ASQ)
- B) Conner’s Rating Scale—Revised Short Form
- C) Denver Developmental Screening Test
- D) Modified Checklist for Autism in Toddlers (M-CHAT)
- E) Parents Evaluation of Developmental Status (PEDS)

The correct answer is “D.” The Modified Checklist for Autism in Toddlers (M-CHAT for short) is a validated office screening tool for autism spectrum disorders. It would be the most appropriate tool of the options given. Of note, the AAP recommends screening all children for autism spectrum disorders using a standard screening tool such as the M-CHAT at ages 18 and 24 months. “A” is incorrect as the Ages and Stages Questionnaire is a broad-based developmental screening tool, as is “D,” the Denver Developmental Screening Test. “B” is incorrect because this test is used to detect ADHD. Note that the USPSTF does not recommend for or against autism screening between 18 and 30 months noting that there is insufficient evidence to take a position on such screening. However, most practitioners follow the AAP recommendations.

► CASE 13.6

A 7-year-old male presents to your clinic with his mother with a complaint of enuresis. Evidently, this child has never been completely continent at night, wetting his bed several times per week. This has become somewhat of a problem for him now that his friends are having sleepover birthday parties. Plus, his mother confides that she’s tired of paying for pull-ups and cleaning sheets. His incontinence is mono-symptomatic (meaning no overactive bladder symptoms or daytime wetting).

Question 13.6.1 What percentage of 7-year-olds continue to have enuresis?

- A) 1%
- B) 10%
- C) 20%
- D) 40%
- E) 75%

Answer 13.6.1 The correct answer is “B.” About 10% continue to have enuresis at age 7 years which tapers to 1% to 2% at age 15 years or greater. Even though this would suggest that it is a variant of normal, there is extreme social pressure on children by age 7 to remain dry at night. Parental expectations may depend on their experience with other children. For example, if an older sibling was dry at night at age 3 or if a younger sibling is dry while an older child has enuresis, parents may not accept the bed wetting as normal. Age 7 is considered the cutoff for “normal” enuresis; therefore, beyond age 7 years, it is considered a problem.

HELPFUL TIP:

Note that the child in this case is male. Enuresis affects twice as many males as females.

Because he has had no period of nocturnal dryness, this patient has primary enuresis.

Question 13.6.2 Which of the following is likely to be part of this child’s history?

- A) A family history of enuresis
- B) A stressful event in the family such as the birth of a new child or parental divorce
- C) Increased fluid intake over the past 2 months
- D) History of urinary tract infections

Answer 13.6.2 The correct answer is “A.” Enuresis is divided into primary and secondary enuresis. Primary enuresis occurs in cases where there is **never** a consistent period of dryness at night. Secondary enuresis occurs when there is a period of dryness (by convention, 6 months) before the patient develops enuresis. “B,” “C,” and “D” would more likely be seen in children with **secondary** enuresis. Primary enuresis tends to be a familial trait. Secondary enuresis requires some investigation.

HELPFUL TIP:

About 15% of patients have primary enuresis at age 5. About 15% of patients with enuresis become dry each year thereafter. The longer enuresis persists, the less likely it is to resolve.

This patient’s examination is essentially normal including neurologic evaluation.

Question 13.6.3 Further evaluation of this patient should include all of the following EXCEPT:

- A) Asking about a history of bowel problems
- B) Assessment of growth and development
- C) Investigation into family history of nocturnal enuresis
- D) Spine MRI to rule out pathologic lesion
- E) Urinalysis

Answer 13.6.3 The correct answer is “D.” Patients with enuresis who have an otherwise normal neurologic examination need not have an MRI done. If on examination this child had neurologic findings, an MRI would be indicated. All of the remaining options are part of a thorough evaluation of nocturnal enuresis. The assessment of growth and development is important to determine if the child is neurologically delayed, which could be contributing to enuresis. Attention to bowel problems is also important. Bowel and bladder dysfunction are common causes of enuresis. Fecal impaction can lead to incontinence. Asking about snoring can help to identify obstructive sleep apnea, which can be associated with enuresis.

You find no indication of a pathologic cause, and you decide that this is primary enuresis. The parents are desperate for some sort of intervention to fix the problem, since it is becoming a major source of anxiety in the home and of teasing at school (of course *anything* can be a source of teasing at school).

Question 13.6.4 Which of the following should constitute the initial treatment of this patient's primary enuresis?

- A) Patient education and motivational training (e.g., rewards for staying dry)
- B) Over-learning
- C) Enuresis alarm
- D) Nasal desmopressin (DDAVP)
- E) Oral desipramine

Answer 13.6.4 The correct answer is "A." All of the above have been found to be useful in the treatment of enuresis; however, the best initial approach includes education. Patients and parents should be informed of how common this condition is, how to reduce fluid intake in the evening without getting dehydrated, and how to schedule voiding. Motivational training plays a role as well. The other interventions are secondary. It is important to make sure the child knows that enuresis is not their fault! A child should never be punished for enuresis, as it is outside of their control. "B," over-learning, is thought to help prevent relapses in patients *who have been successful with an enuresis alarm*. Once continence is achieved with the alarm, the child drinks a set amount of fluid before bedtime. The amount is successively increased once dryness is achieved until a maximum is reached. The idea is that the patient is conditioned to respond to his increasing bladder capacity. "C," an enuresis alarm, is an effective treatment but relatively expensive and requires significant motivation on the part of the family. The enuresis alarm increases success of the other options, and when used in combination with other modalities, it has shown the best long-term results. "D" and "E" are incorrect in this scenario although they are used to treat enuresis. Relapse is more common when pharmacologic therapy is discontinued than with the other modalities. However, medications are effective as a short-term treatment option, but are felt to be second tier and used when the urine alarm fails or is impractical (think sleepover or summer camp). Of note, "D" is wrong for another reason: **nasal** DDAVP is no longer approved for nocturnal enuresis due to problems with hyponatremia. Oral DDAVP still carries the enuresis indication, but it can cause hyponatremia as well—it just occurs less often. Oral DDAVP may be used on an "as needed" basis for special events. Trying it at home on a "normal" night before the special event will help determine efficacy. Sometimes dose adjustment is required.

HELPFUL TIP:

Retention control training is no longer recommended as it was not found to significantly decrease wetting. Retention-control training was based on the (faulty) premise that enuretic children had smaller bladder capacities. The child would hold urine in an attempt to stretch the bladder and increase capacity. Retention control training can increase bladder capacity but does not improve enuresis. But maybe if you are a truck driver or a surgeon ...

► **Objectives: Did you learn to ...**

- Define primary and secondary enuresis?
- Describe some of the epidemiologic characteristics of enuresis?
- Evaluate a patient with enuresis?
- Develop a management strategy for enuresis?

QUICK QUIZ: MECONIUM

Delayed meconium passage occurs in which of the following conditions?

- A) Encopresis
- B) Hirschsprung disease
- C) Cystic fibrosis
- D) Hyperthyroidism
- E) B and C

The correct answer is "E." Seventy percent of newborns will pass meconium within the first 12 hours of life. More than 90% of newborns pass meconium within the first 24 hours. In those with delayed passage of meconium (generally defined as >24 hours of life), consider Hirschsprung disease, cystic fibrosis, hypothyroidism, sepsis, intrauterine narcotic exposure, or imperforate anus.

QUICK QUIZ: RASH

Your next patient is a 3-year-old female with a rash. After playing outside (could playing outside be a red herring? The editors think so ...), her father found spots on her legs, and she did not want to walk because her knees hurt. On examination, she is afebrile with normal vitals, slightly irritable, but otherwise interactive. She has slight nasal drainage, which her father says is residual from a cold last week. Her legs and buttocks have palpable purpura. Her knees are mildly swollen and are painful with range of motion. Her CBC (including platelets) and coagulation studies are normal, and her urinalysis is significant for 2+ hematuria.

The most likely diagnosis in this patient is:

- A) Acute exposure to lawn chemicals
- B) Henoch-Schönlein purpura (HSP)
- C) Juvenile idiopathic arthritis (JIA)
- D) Meningococemia
- E) Rocky Mountain spotted fever

The correct answer is "B." This is classic HSP (also known as "immunoglobulin A vasculitis"), an IgA-mediated, generally self-limited, leukocytoclastic vasculitis. The symptoms and signs of HSP are a rash (typically nonthrombocytopenic purpura), abdominal pain (from submucosal hemorrhage and edema), arthritis/arthralgia, and renal disease. Typically, the vasculitis follows an upper respiratory infection, as in this case, or streptococcal pharyngitis. Treatment for HSP is supportive, and

NSAIDs are first line. Monitoring for renal disease with serial UAs and blood pressure measurements after HSP is important.

“A,” lawn chemical exposure, usually results in nothing acute but may cause acute cholinergic symptoms if organophosphates are used. “C,” JIA, is not likely because the rash of systemic onset JIA is evanescent salmon-pink rash on the trunk and axilla that classically occurs when the patient spikes a fever. “D,” meningococcemia, is incorrect because the patient is afebrile, alert, and nontoxic appearing without laboratory evidence of disseminated intravascular coagulopathy. “E” is unlikely because Rocky Mountain spotted fever presents with headache, high fever, petechial rash involving the palms and soles, and the patients will appear toxic. In addition, patients with Rocky Mountain spotted fever have thrombocytopenia when their petechiae appear.

HELPFUL TIP:

The rash of HSP is frequently initially urticaria with surrounding edema. The rash tends to be symmetric and occur in dependent areas developing first on the legs or on pressure points (buttocks). A discussion of treatment is beyond the scope of this book. However, common involvements include renal failure, GI bleeding, and more rarely CNS involvement such as seizures, CNS hemorrhage, etc.

► CASE 13.7

A 7-month-old fully immunized female presents to the office with fever. Mom reports she has “not been herself” and felt “a bit warm on the forehead.” Vitals reveal a temperature of 39.2°C. Physical examination reveals an ill-appearing, nontoxic, and well-hydrated infant. You perform a complete history and physical but are unable to identify a source of the fever.

Question 13.7.1 After ensuring appropriate hemodynamics, what is the first step in your approach to this child?

- A) Obtain a urinalysis and urine culture
- B) Admit for observation and perform blood, urine, and CSF for culture
- C) Give an intramuscular dose of ceftriaxone
- D) Order acetaminophen 30 mg/kg and discharge the patient if the temperature comes down
- E) Admit for IV fluids overnight

Answer 13.7.1 The correct answer is “A.” At this age, occult serious bacterial infection is less likely than during the neonatal period especially when vaccinated against *Haemophilus influenzae* type b and *Streptococcus pneumoniae*. In a well-appearing child older than 90 days with a fever without a focal source, most experts recommend a screening urinalysis and urine culture as the initial diagnostic test. “B” is overly aggressive in a nontoxic patient, and “C” is not indicated and can make cultures more difficult to interpret should this child become

sicker. Use of antipyretics is reasonable, but in “D” the dose of acetaminophen is wrong (it should be 15 mg/kg/dose by mouth every 4–6 hours). Antipyretics may decrease fever of any cause, and “response” to acetaminophen would not negate the need for further evaluation. Since you are not seeing signs of dehydration, “E” is inappropriate.

HELPFUL TIP:

Studies have shown that the incidence of occult bacteremia is less than 1% in well-appearing **fully immunized** infants 3 to 36 months of age presenting with fever without localizing signs. Sometimes, a positive blood culture is due to contamination, which results in unnecessary additional testing, treatment, and cost. Some of you may be thinking, “What about a CBC?” In this patient, the WBC count can be equally misleading. The most important factors in decision-making are the patient’s age, immunization status, and clinical appearance. Procalcitonin and/or CRP have not been found to be particularly predictive in outpatients and are *not* part of the routine evaluation of febrile pediatric outpatients.

Question 13.7.2 What is the most appropriate method of obtaining a urine specimen in this child?

- A) Midstream “clean-catch”
- B) Bag specimen from sterile plastic bag taped to the perineal region
- C) Bladder catheterization
- D) Suprapubic aspiration
- E) C or D

Answer 13.7.2 The correct answer is “C.” The gold standard test for the diagnosis of urinary tract infection is a quantitative urine culture. While the urinalysis and microscopy may suggest UTI, no component, or combination of components, is as sensitive or specific as an appropriately collected culture. Therefore, if a child is likely to require antimicrobial therapy, one should attempt to obtain urine for culture in a manner not likely to cause contamination. The midstream “clean-catch” may be obtained in older children who are toilet trained, making certain that the perineum is cleansed first. Bag specimens are prone to contamination and should NEVER be used for culture. If UTI is suspected or the source of fever is unknown, diapered children should ALWAYS have a catheterized urine sample obtained BEFORE starting antibiotics. Suprapubic aspiration is the gold standard, but it is typically more uncomfortable for the child and should only be performed by experienced providers.

HELPFUL TIP(S):

A negative bag-collected urinalysis and microscopy in a nontoxic infant may be helpful. If this is positive (not completely normal), it must be followed up with urine obtained by catheterization or suprapubic aspirate for urinalysis, microscopy, and culture. Any

nontoilet-trained child who will need antibiotics on a relatively emergent basis for a UTI should have urine obtained by catheterization or suprapubic aspiration sent for culture.

How many WBC/HPF are necessary to call it a UTI you might wonder? The answer is “zero.” Thirteen percent of children with culture-proven UTI have no white cells in the urine (*Pediatrics*. 2016;138:e20160087). So, if you clinically think it is a complicated UTI, treat while awaiting the culture. Any delay in treating a febrile UTI in children leads to additional renal scarring (*JAMA Pediatr*. 2016 Jul 25).

Question 13.7.3 The patient has positive leukocyte esterase and nitrates on UA as well as 20 WBC/hpf on urine microscopy. Without knowing the culture and susceptibility results, which antibiotic would be the MOST appropriate choice for the treatment of a UTI in this child?

- A) Trimethoprim/sulfamethoxazole (TMP/SMX)
- B) Amoxicillin
- C) Amoxicillin/clavulanate
- D) Cefdinir
- E) Ciprofloxacin

Answer 13.7.3 The correct answer is “D.” The majority of urinary tract infections are due to Gram-negative organisms such as *Escherichia coli* in children and the resistance rate to amoxicillin is high (up to 40%). Thus, amoxicillin is not a good choice for empirically treating a UTI in children—or anybody, for that matter. The usual choice for empiric oral antibiotic treatment of UTI in children is a third-generation cephalosporin, such as cefdinir (“D”), cefixime, or cefpodoxime. Caution should be used with empiric use of first-generation cephalosporins, TMP/SMX (“A”), and amoxicillin/clavulanate (“C”) due to increasing resistance of *E. coli* to these agents, though these agents may be appropriate if local resistance is low. Fluoroquinolones, such as “E,” may be considered in adolescents or children with a complicated UTI. **No fluoroquinolones for cystitis:** The benefit is outweighed by the risk (persistent neurologic problems, hypoglycemia, etc.). Fluoroquinolones do seem to be as safe in children as in other patients but should be saved for situations where other drugs are suboptimal or ineffective, such as UTI caused by *Pseudomonas*. The duration of treatment should be 7 to 10 days for uncomplicated UTI. If the child appears clinically ill, has vomiting, or is less than 2 months old, initial parenteral treatment with ceftriaxone would be an appropriate first-line agent. After urine cultures return, coverage may be changed to a narrower-spectrum antibiotic, if possible. Note that nitrofurantoin is an acceptable alternative for cystitis (but not pyelonephritis) but is QID in children and expensive as a suspension.

Her urine culture reveals *Escherichia coli* susceptible to third-generation cephalosporins and resistant to narrower-spectrum drugs. You treat her appropriately.

Question 13.7.4 Following her initial treatment, what diagnostic study should be performed next?

- A) Abdominal supine and upright radiographs
- B) Renal ultrasound
- C) Voiding cystourethrogram (VCUG)
- D) Urology consultation for urodynamic studies
- E) Both B and C

Answer 13.7.4 The correct answer is “B.” In febrile infants with UTI, it is important to look for anatomic abnormalities of the urinary tract. Ultrasound imaging (not VCUG) is recommended following a first febrile UTI to identify those at risk for recurrence and subsequent damage to renal parenchyma (male or female). Urinary tract ultrasonography should be performed at the earliest convenient time. Ultrasound is useful in the evaluation for kidney size and hydronephrosis, but it is limited in the evaluation of vesicoureteral reflux (VUR), a common abnormality associated with recurrent UTI. VUR is evaluated with a VCUG or radionuclide cystogram (RNC). VCUG should be done after a first febrile UTI only when there is evidence of renal abnormality on the ultrasound, including scarring, hydronephrosis, abnormal anatomy, etc. Routine VCUG is NOT recommended. Thus, choices “B” and “E” are incorrect.

Right hydronephrosis was noted on ultrasound, and a VCUG is done. Your patient is found to have right-sided grade II reflux (see Table 13-5).

Question 13.7.5 Which of the following would be the most appropriate initial management of her grade II reflux?

- A) Prescribe prophylactic antibiotics
- B) Refer for surgical intervention
- C) Perform renal scintigraphy to assess renal scarring
- D) Observe for now with repeat ultrasound in 6 months
- E) None of the above

Answer 13.7.5 The correct answer is “E.” This remains a controversial topic. It seems (most) everyone agrees that children with grade I–II reflux with bladder and bowel dysfunction (BBD) benefit from prophylactic therapy in addition to treatment for the BBD. In those with grade I–II reflux and no bladder or bowel dysfunction, the benefit is less clear. Grade I and II reflux tends to resolve with maturity. It gets a bit trickier with grade III–IV. Overall, children with III–IV reflux seem to have

TABLE 13-5 INTERNATIONAL REFLUX STUDY COMMITTEE GRADING OF VESICoureTERAL REFLUX

Grade I: Involves the ureter only
Grade II: Involves the ureter, pelvis, and calyces without dilatation
Grade III: Involves the ureter, pelvis, and calyces with mild ureter and pelvis dilatation
Grade IV: Involves the ureter, pelvis, and calyces with significant dilatation and blunting of the calyceal fornices
Grade V: Demonstrates dilatation and tortuosity of the ureter as well as loss of the calyceal fornices

about half the number of infections with prophylactic therapy (typically with TMP/SMX); the benefit is most pronounced in those with a febrile first episode and bowel or bladder dysfunction. However, there is no difference in renal scarring and 63% develop resistant organisms vs. 19% in the placebo group (*N Engl J Med.* 2014;370;2367–2376; 2440–2441). The bottom line is to have a discussion with the parents and to promptly treat any UTIs to prevent renal scarring (particularly a risk in those with a temperature of $>39^{\circ}\text{C}$ or a non-*E. coli* organism). Renal scarring is best detected by radioisotope scanning with 99 m-technetium dimercaptosuccinate, but it is not indicated at this time. Therefore, “C” is incorrect. “D” is incorrect, as ultrasound would not be used to assess for resolution of VUR. Follow-up VCUGs are recommended only in presence of reflux, and generally are performed in 12- to 24-month intervals, though this is also (not surprisingly) variable.

HELPFUL (OR CONFUSING) TIP:

We don't know what the board examination will want as an answer. Historically, ultrasound **and** VCUG have been done after a first UTI in a male infant and a second UTI in a female infant. This gender differentiation no longer exists; do an US on every child with a first febrile UTI. Even though the AAP guidelines do not support doing a VCUG, the Section on Urology of the American Academy of Pediatrics published a statement in April 2012 disagreeing with the recommendation to not obtain a VCUG in children aged 2 months to 2 years after the first febrile UTI. Surgical intervention is generally reserved for those with severe reflux (grades IV and V) or recurrent UTI despite prophylactic antibiotics. See AAP guidelines in *Pediatrics*. 2011;128(3):595–610 (reaffirmed in 2016) for more information.

► Objectives: Did you learn to ...

- Evaluate an older (>3 months old) infant with fever?
- Diagnose and treat a child with an initial urinary tract infection?
- Recognize that urinary tract infection is often a marker for urinary tract abnormalities in children?
- Manage a patient with VUR?

► CASE 13.8

Anthony is a 2,300-g male infant born at 35 weeks gestation to a 23-year-old G2P2 mother. The mother did not seek prenatal care and routine screening labs were not available. She presented to the ED in active labor shortly following spontaneous rupture of membranes at home. Upon transfer to the obstetric ward, she was noted to be febrile (38.8°C) and tachycardic. She was diagnosed with chorioamnionitis and received intravenous antibiotics. Five hours later, Anthony was delivered via spontaneous vaginal delivery.

Question 13.8.1 Management of this newborn infant whose mother was diagnosed with chorioamnionitis should include which of the following?

- A) Empiric therapy with ampicillin and gentamicin
- B) Empiric therapy with ampicillin
- C) Empiric therapy with vancomycin
- D) Empiric therapy with ceftriaxone
- E) Empiric therapy with ampicillin and erythromycin

Answer 13.8.1 The correct answer is “A.” Maternal chorioamnionitis is an important risk factor for early onset sepsis in the newborn. Based on the 2010 CDC guideline on the prevention of perinatal group B streptococcal disease (which remains current at the time of this edition), all infants born to mothers with chorioamnionitis should have screening labs and blood cultures at birth followed by minimum of 48 hours of antibiotic therapy. Antibiotic therapy may be extended and/or modified depending on the clinical course and culture results. Of note, there is significant institutional variation in this area, and some institutions utilize clinical prediction tools, such as the Kaiser Permanente Neonatal Sepsis Calculator, to guide decision-making and antibiotic treatment. Data suggests that a risk-based approach (compared to current CDC guidelines) may markedly reduce antibiotic use in infants without increasing the rate of early-onset sepsis (*JAMA Pediatr.* 2017;171(4):365–371). Updates to the CDC guidelines are in process, but for now we suspect that the test will follow current CDC guidelines. A lumbar puncture for CSF culture and analysis should be performed if the child is ill-appearing. Ampicillin and gentamicin (“A”) as empiric therapy covers the most likely organisms including Group B streptococcus (GBS) and Gram-negative pathogens, respectively. Ceftriaxone (“D”) should not be used in neonates, at it may displace bilirubin from albumin, leading to severe hyperbilirubinemia. Other third-generation cephalosporins, such as cefotaxime, can be used as an alternative to gentamicin in conjunction with ampicillin.

Anthony is started on appropriate antibiotics. Examination of this neonate reveals hepatosplenomegaly, lymphadenopathy, petechiae, and white mucocutaneous patches in the infant's mouth. His CBC reveals hemoglobin of 12 g/dL and a platelet count of $85,000/\text{mm}^3$ with evidence of hemolysis on the peripheral smear.

Question 13.8.2 The most likely pathogen infecting this infant is:

- A) Rubella
- B) Cytomegalovirus
- C) *Toxoplasma gondii*
- D) *Treponema pallidum*
- E) *Candida albicans*

Answer 13.8.2 The correct answer is “D.” Neonatal manifestations of congenital syphilis include hepatosplenomegaly, lymphadenopathy, jaundice, rash, hemolytic anemia, and thrombocytopenia. Unfortunately, these findings overlap considerably with many of the other congenital TORCH (toxoplasmosis, rubella, CMV, herpes) infections. Abnormalities more specific to congenital syphilis

include white, patchy mucocutaneous lesions (think “condylomata lata”), edema, rhinitis (snuffles), osteochondritis, and pseudoparalysis. Congenital syphilis is caused by transplacental transmission of the spirochete *T. pallidum* (“D”). Intrauterine infection can result in stillbirth, hydrops fetalis, or prematurity.

HELPFUL TIP:

Late sequelae of congenital syphilis involve the bones and joints, teeth, eyes, and CNS and include bowed shins (Saber shins), frontal bossing, saddle nose, pegged central incisors, interstitial keratitis, and sensorineural deafness. The Hutchinson triad includes interstitial keratitis, deafness, and notched, peg-shaped teeth.

In addition to the laboratory data obtained above, you order an ultrasound of the patient’s head, which appears normal.

Question 13.8.3 Intracerebral calcifications are CLASSICALLY associated with which congenital infection(s)?

- A) Cytomegalovirus
- B) Toxoplasmosis
- C) *Treponema pallidum*
- D) Rubella
- E) A and B

Answer 13.8.3 The correct answer is “E.” The clinical manifestations of congenital cytomegalovirus and toxoplasmosis are often similar. Infants are typically asymptomatic at birth, but a significant number ultimately develop visual impairment, learning disabilities, and developmental and intellectual delays months to years later. Those infants who are symptomatic at birth may demonstrate intrauterine growth retardation, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenia. Intracerebral calcifications also occur in both CMV and toxoplasmosis. The calcifications tend to be periventricular in CMV (remember this by the fact that the calcifications look like a “C” in CMV) and more dispersed throughout the cortex in toxoplasmosis (remember by noting the “X” in both cortex and toxoplasmosis). Additional central nervous system abnormalities include microcephaly, chorioretinitis, and sensorineural hearing loss.

► Objectives: Did you learn to ...

- Appropriately manage the neonate born to a mother who has evidence of chorioamnionitis?
- Recognize that many congenital TORCH infections may have overlapping signs and symptoms?
- Recognize that many infants with congenital TORCH infections are asymptomatic at birth?

QUICK QUIZ: CONGENITAL INFECTIONS

A small-for-gestational age newborn infant is found to have hepatosplenomegaly, jaundice, and thrombocytopenia. Cardiac examination reveals a grade II/VI continuous murmur heard

best at the left upper sternal border. An ophthalmologic examination demonstrates microphthalmia and cataracts.

The result of which maternal prenatal screening lab is likely to have been concerning in the above case?

- A) VDRL
- B) Rubella immunity status
- C) HIV status
- D) Varicella zoster immunity status
- E) Group B streptococcal (GBS) cultures

The correct answer is “B.” Cardiac, ophthalmologic, auditory, and neurologic findings predominate in the symptomatic infant with congenital rubella. Up to 85% of infants infected during the first 12 weeks of gestation will have some form of congenital defect. This decreases to 5% when the primary infection occurs after the third to fourth month of gestation. Ophthalmologic findings include microphthalmia, cataracts, glaucoma, and salt and pepper retinopathy. Infants are often microcephalic and develop sensorineural hearing deficits, meningoencephalitis, and developmental delay. **Deafness, cataracts, and cardiac anomalies are the classic findings with congenital rubella.** Additional findings of hepatosplenomegaly, thrombocytopenia, and osteitis may be present. A characteristic “blueberry muffin” appearance may be present due to the combination of jaundice and extramedullary (skin) hematopoiesis. Syphilis and GBS infections are described above and they do not typically cause the ophthalmologic findings described in this case. “C” is incorrect because congenital HIV infection is commonly asymptomatic. Evidence of immune deficiency may present later in the child’s life with failure to thrive, generalized lymphadenopathy, hepatosplenomegaly, and recurrent infections. “D” is incorrect because congenital herpes infections do not cause cardiac abnormalities.

HELPFUL TIP:

USPSTF recommends (Grade A) universal newborn screening for hemoglobinopathies and congenital hypothyroidism as well prophylactic ocular topical medication for gonorrhea in all newborns. The USPSTF had previously recommended universal hearing screening for all newborns (Grade B) but are now silent on the issue. The AAP and AAFP still support universal hearing screening in all newborns. An eye exam is now recommended at age 3 to 5 years for all patients (<https://www.uspreventiveservicestaskforce.org/>).

QUICK QUIZ: CONGENITAL RUBELLA

Which of the following cardiac lesions is most likely to be found in an infant with congenital rubella?

- A) Patent ductus arteriosus (PDA)
- B) Tetralogy of Fallot
- C) Transposition of great vessels
- D) Coarctation of aorta
- E) Bicuspid aortic valve

The correct answer is "A." The most common cardiac lesions associated with congenital rubella are PDA and peripheral pulmonary artery stenosis. PDA is characterized by a continuous "machine-like" murmur heard best over the left upper sternal border. *Tetralogy of Fallot and transposition of great vessels are classically cyanotic heart defects that have no known association with congenital infections.* Coarctation of the aorta and bicuspid aortic valve both cause harsh systolic murmurs. The murmur of coarctation radiates to the back. Both coarctation and bicuspid aortic valve are commonly found in females with Turner syndrome.

► CASE 13.9

A term newborn infant is noted to have a solitary, tense bulla located on the dorsum of his wrist. The underlying skin is nonerythematous. Pregnancy was uncomplicated; however, the infant was delivered via cesarean section for failure to progress. The infant appears to be a vigorous feeder and is noted to frequently suck on his hands and wrists while in the nursery. He is otherwise asymptomatic.

Question 13.9.1 Which of the following is MOST appropriate at this time?

- A) Start acyclovir
- B) Perform lumbar puncture and send a sample of the CSF for HSV PCR
- C) Perform a Tzanck smear of the bulla fluid
- D) Obtain CBC and blood cultures
- E) Observation with no intervention at this time

Answer 13.9.1 The correct answer is "E." Nothing needs to be done at this time. The appearance and location of the bulla is consistent with a sucking blister. A solitary bulla or blister on normal-appearing skin located on the upper limbs may be present at birth from in utero sucking. Often when presented with the affected extremity, the infant will demonstrate the sucking behavior in that location. Such blisters are often mistaken for herpes simplex, but the solitary nature and location help to establish the correct diagnosis—although there may be multiple blisters at times. Additional history of cesarean section makes HSV less likely in this scenario. Nonetheless, a sucking blister is a diagnosis of exclusion, and other more serious diagnoses should be ruled out by history and examination and further testing as indicated.

Question 13.9.2 The FALSE statement regarding neonatal herpes simplex virus infection is:

- A) The majority of infants with neonatal HSV are born to mothers with symptomatic herpetic lesions
- B) The incidence of neonatal transmission is higher when the pregnant woman experiences primary infection versus secondary reactivation
- C) Most neonatal HSV infections are caused by HSV 2
- D) Intrauterine exposure accounts for the minority of perinatal HSV infection
- E) Herpetic skin lesions are often present in infants with CNS or disseminated HSV

Answer 13.9.2 The correct answer is "A." Less than one-third of infants with neonatal HSV are born to mothers with active genital lesions. In fact, most cases of neonatal HSV are found in infants of *asymptomatic mothers who are shedding the virus*. Neonatal herpes simplex virus often results in serious morbidity and mortality. Infants with HSV present with one of the following three disease patterns with overlapping features: localized disease involving the skin, eyes, and mouth; CNS disease; or disseminated infection. Encephalitis may occur with or without skin involvement; therefore, HSV infection should be suspected in any infant from birth to approximately 4 weeks of age that presents with fever, seizure, or mental status abnormalities such as lethargy, irritability, or poor feeding.

The other options are correct. A woman who contracts a primary infection during the pregnancy has a greater than 30% chance of transmitting the virus to her infant ("B"). There is less than 2% transmission if she experiences a secondary reactivation intrapartum. The majority of neonatal HSV is due to infection with HSV 2 ("C"). Only 5% of congenital infections occur in utero ("D"), as the majority occurs via exposure to infected cervical secretions during birth. Skin lesions ("E") are present in 60% of CNS cases and about 75% of disseminated cases.

HELPFUL TIP:

Most neonates with HSV infection do not present with skin findings at birth. It is more typical for neonates to develop HSV skin lesions 5 to 14 days after delivery.

HELPFUL TIP:

Infants born vaginally or via cesarean delivery to moms with active genital HSV lesions need HSV cultures or PCR of the mouth, nasopharynx, conjunctiva, and rectum obtained at 12 to 24 hours of age. In infants born to moms with a **primary** outbreak at time of delivery, guidelines recommend empiric acyclovir therapy after obtaining surface cultures/PCRs, blood PCR, and CSF PCR. Asymptomatic infants of mothers with a recurrent outbreak do not require empiric acyclovir treatment but still should receive surface swabs and blood PCR and be monitored closely for signs of infection. Symptomatic infants additionally require CSF for HSV PCR and acyclovir treatment.

► Objectives: Did you learn to ...

- Differentiate between a herpes lesion and a sucking blister?
- Recognize rates and modes of transmission of herpes in neonates?
- Identify some of the clinical manifestations of neonatal herpes?

▶ CASE 13.10

A bunch of parents in your neighborhood decide to have a “chickenpox” party (prompting you to consider moving to a place where people believe in modern medicine). They want to synchronize their kids’ chickenpox outbreaks with their busy schedules (heaven forbid we should get immunized—after all, it isn’t natural!). One of the mothers, who has never had chickenpox herself, finds out that she is pregnant the day after being exposed to chickenpox. She is not yet symptomatic—from the pregnancy or the chickenpox

Question 13.10.1 The best advice for this potential mother about her pregnancy is:

- A) Consider termination since it is likely that the child will have congenital varicella
- B) Get treated within 96 hours of exposure with varicella immune globulin
- C) Get treated within 96 hours of exposure with varicella immune globulin plus varicella vaccine
- D) Get treated within 96 hours of exposure with IVIG plus varicella vaccine
- E) No further action is needed

Answer 13.10.1 The correct answer is “B.” Women who are varicella-susceptible (nonimmune), pregnant, and exposed to chickenpox should be treated with varicella immune globulin (VariZIG) within 96 hours of exposure, though some sources recommend administration up to 10 days post-exposure. If VariZIG is unavailable, IVIG may be given instead. The vaccine should be avoided during pregnancy (thus “C” and “D” are incorrect). It is a live, attenuated virus and still carries some risk to the fetus (although the degree of risk is unknown). It is safe to give the vaccine to mom in the *postpartum* period and is indicated if the mother is screened to be varicella nonimmune during her pregnancy. The risk of congenital varicella syndrome if the fetus is exposed in the first trimester is about 2%. The risk of neonatal infection is much higher if the mother is infected within 5 days of birth, and 30% of these cases result in severe neonatal varicella infection.

Question 13.10.2 You can let the mother know that:

- A) Varicella immune globulin has been shown to reduce the risk of congenital varicella
- B) Varicella immune globulin is aimed mostly at attenuating the case in the mother should she be infected
- C) Varicella immune globulin has been shown to prevent congenital varicella
- D) A and B
- E) B and C

Answer 13.10.2 The correct answer is “B.” Varicella immune globulin is aimed at reducing the symptoms in the mother and attenuating her case of varicella. Both “A” and “C” are false. There are no good data either way about how VariZIG will affect the child’s outcome vis-à-vis congenital varicella. The theoretical benefit outweighs the risk of administration of VariZIG.

Question 13.10.3 Manifestations of intrauterine infection with varicella zoster include all of the following defects EXCEPT:

- A) Optic atrophy
- B) Congenital cataracts
- C) Cardiac abnormalities
- D) CNS abnormalities
- E) Limb hypoplasia

Answer 13.10.3 The correct answer is “C.” Cardiac abnormalities are not seen with varicella zoster exposure in utero. In addition to the findings above, patients with congenital varicella zoster will have cutaneous scarring called cicatrix. Intrauterine growth restriction is also a common finding.

Glory! The chickenpox party worked! Now that all of these children have been infected with varicella zoster, the question arises about how long they should be kept out of school.

Question 13.10.4 These children are considered infectious until:

- A) 5 days after the first lesion appears
- B) 10 to 14 days after the first lesion appears
- C) New lesions are no longer forming
- D) All lesions are crusted over
- E) They are no longer febrile

Answer 13.10.4 The correct answer is “D.” Patients are considered infectious until all lesions are crusted over. Lesions need not have healed entirely, only crusted over.

Question 13.10.5 The mother of your next patient has 4 children, and she is interested in having them vaccinated for varicella (At last, VICTORY!). In which of the following children is varicella vaccination contraindicated?

- A) A 4-year-old with asthma on medium-dose inhaled corticosteroids
- B) A healthy 3-year-old whose father is on immunosuppression for rheumatoid arthritis
- C) A healthy 1-year old who has a newborn baby brother at home
- D) A 8-year-old child with HIV and a normal CD4+ T-cell count
- E) None of the above

Answer 13.10.5 The correct answer is “E.” All of the above children may receive the varicella vaccine. Children with asthma and other conditions requiring **systemic** corticosteroids should not receive the varicella vaccine (remember, it is a live-attenuated vaccine) if they are on 2 mg/kg/day or more (up to 20 mg) of prednisone-equivalent for 14 days or more. Thus, “A” is incorrect. Children exposed to immunocompromised individuals, such as “B” should get the varicella vaccine to decrease risk of bringing wild-type varicella into the home. They do not

need to be isolated from the immunosuppressed person, unless they develop skin lesions, at which time they should avoid direct contact until the lesions are resolved. Varicella-naïve siblings (“C”) and mothers (even if breastfeeding) of infants should receive varicella vaccine. If a woman of child-bearing age obtains varicella vaccination, she should avoid pregnancy for 1 month after immunization, since the effect of the attenuated virus on a fetus is not known. Children with HIV, such as “D,” may receive varicella vaccination if they have a normal CD4+ T-cell count (CD4+ T-cell percentage $\geq 15\%$ for children 1 through 13 years of age and CD4+ T-cell count $\geq 200/\text{mm}^3$ for adolescents ≥ 14 years of age). Children with immunodeficiencies affecting T-cell mediated immunity should **not** receive the vaccine.

► **Objectives: Did you learn to ...**

- Offer treatment for varicella exposure to a pregnant nonimmune female?
- Recognize the uses of varicella immune globulin?
- Identify symptoms of congenital varicella infection?
- Enumerate contraindications to varicella vaccination?

► CASE 13.11

A 3-year-old child presents to your office with a history of bright red cheeks. Over the past several days, she has had mild fever with mild muscle aches. Except for the rash, the child is now asymptomatic.

Question 13.11.1 The most likely cause of this patient’s illness is:

- A) Parvovirus B-19
- B) Herpes virus 6
- C) Rubella
- D) Rubella
- E) Influenza virus

Answer 13.11.1 The correct answer is “A.” A mild systemic illness followed by red, “slapped cheeks” is typical of erythema infectiosum or “fifth disease,” caused by parvovirus B-19. The red, slapped cheeks are generally followed by a lacy, reticular rash on the extremities and trunk. This is usually a self-limited illness in children.

Question 13.11.2 Which of the following is LEAST likely to be a complication of parvovirus B-19 infection—either congenital or acquired?

- A) Aplastic anemia
- B) Birth defects, including CNS and limb disease
- C) Hydrops fetalis
- D) Inflammatory arthritis
- E) Intrauterine fetal death

Answer 13.11.2 The correct answer is “B.” Parvovirus B-19 causes all of the above except for birth defects. Fetal death, anemia, or nonimmune-mediated hydrops fetalis are potential outcomes of intrauterine exposure (one-third of infected women will pass the virus to their fetus). Most infants infected in utero are born normally at term, including those with evidence of hydrops earlier in the pregnancy. A small subset will acquire chronic or prolonged postnatal infection of unknown significance. “A,” transient aplastic crisis, can occur in those with chronic hemolytic conditions such as sickle cell anemia. “D,” inflammatory arthritis, is common in adults and adolescents with females more commonly affected. Although a few reports describe congenital abnormalities with parvovirus infection, most parvovirus infections do not cause congenital anomalies.

The question of whether or not to exclude this child from preschool is raised. The patient still has the rash. There are a couple of pregnant teachers at the preschool.

Question 13.11.3 You can tell the child’s mother that:

- A) This child is infectious and should be excluded from preschool until the rash resolves
- B) Since almost all adult women are already immune, there is no need to worry about transmission to the teachers
- C) Since this virus is an enterovirus, careful hygiene in the school will prevent spread
- D) This child can be allowed back into preschool and is no longer infectious

Answer 13.11.3 The correct answer is “D.” Once the rash is present, this child is no longer infectious and can be allowed back into school. “B” is incorrect because only about 50% of adult women are immune. “C” is incorrect. First, this is not an enterovirus. Even though URI symptoms are often absent, transmission is mostly respiratory with vertical transmission of mother to fetus, and hematogenous spread (via transmissions) being much less common.

HELPFUL TIP:

Just try getting this child with a rash back in school and past the school nurse (we dare you); it can be difficult! On a related note, some schools are sure that there is a “magical effect” of topical antibiotics in preventing the spread of viral conjunctivitis. Don’t drink the Kool-Aid.

► **Objectives: Did you learn to ...**

- Recognize the clinical manifestations of parvovirus B-19 infection (“fifth disease”)?
- Identify complications of parvovirus B-19 infection?

**QUICK QUIZ: CHILDHOOD INFECTIONS**

Which of the following is characterized by a high fever, possibly over 40°C, a bulging fontanelle, a maculopapular rash that begins *after* the fever abates, conjunctivitis, and upper respiratory symptoms?

- A) Roseola infantum (erythema subitum)
- B) Rubeola (measles)
- C) Rubella (German measles)
- D) Varicella (chicken pox)
- E) Meningococcal meningitis

The correct answer is “A.” Such a clinical presentation is typical of roseola infantum. Roseola infantum, which is caused by the human herpes 6 (and rarely herpes 7) virus, is characterized by a high fever for 3 to 5 days (often over 40°C), generalized malaise, a bulging fontanelle in up to 26% of infants, conjunctivitis, perhaps oral mucosal ulcers, and a rash that appears as the child begins to defervesce. Children usually look amazingly well given the degree of fever that they experience.

**QUICK QUIZ: GASTROINTESTINAL SYMPTOMS**

A young couple brings in their 18-month-old female for a 12-hour history of vomiting and diarrhea. The patient has felt warm, and her oral intake has been depressed. However, she continues to make tears with crying and has wet diapers. Her medical history is unremarkable. On examination, you find a tired-looking toddler who perks up slightly when you open a bag of toys (who *are* you anyway ... Santa?). Her temperature is 38.5°C, and her capillary refill is less than 3 seconds. The remainder of the examination is unremarkable. You think that she has a viral gastroenteritis and give the parents some advice regarding rehydration.

Which of the following is the most appropriate advice for this patient?

- A) Avoid all solid food for the next 24 to 48 hours
- B) Use milk as the primary rehydration solution
- C) Use only watered-down tea for rehydration
- D) Use a commercially prepared oral rehydration solution and reintroduce foods as tolerated
- E) Use cola beverages (e.g., Coca-Cola or Pepsi) because they contain more sodium than commercially available oral rehydration solutions

The correct answer is “D.” Effective oral rehydration can be accomplished with any one of the rehydration solutions on the market (e.g., Pedialyte). “A” is incorrect. There is no need to limit the food intake of patients with vomiting or infectious diarrhea. They can have whatever they can tolerate *without vomiting*. The concept of “gut rest” is obsolete and leads to increased bowel permeability and prolonged diarrhea. So, early feeding is optimal and recommended. There is no need to avoid lactose-containing products. Transient lactase deficiency after gastroenteritis is

usually self-limited (and generally limited to those <2 months of age) and does not require treatment unless symptoms are prolonged or severe after dietary re-introduction. “C” and “E” are incorrect. There is no role for weak tea, flat soda, “Jello water,” sports drinks, juice, etc., in the management of gastroenteritis. The most common cause of hyponatremic seizures in the child is improper rehydration during gastroenteritis. Many commercial drinks, such as cola beverages and sports drinks, are not specifically designed for oral rehydration, and the sodium concentration is typically much lower than that in rehydration solutions, risking hyponatremia (in other words, the reverse of “E” is true). In addition, many of these have a high sugar content, which can worsen diarrhea due to osmotic effects.

**HELPFUL TIP:**

In the exclusively breastfed infant with vomiting and/or diarrhea, breastfeeding should be encouraged and not replaced with oral rehydration solutions. Similarly, use of formula or expressed breast milk in bottle-fed infants should be encouraged as long as it is tolerated.

**HELPFUL TIP:**

During a GI illness, advise parents to avoid nonabsorbable sugars, like those found in apple or grape juice. These can promote an osmotic diarrhea.

▶ CASE 13.12

A new mother and father bring their 2-month-old infant to your office with a complaint of inconsolable crying. This started at about 3 weeks of age and occurs about the same time every day. The crying will last for hours and is becoming quite disruptive. The child will draw up his knees and seem to be in quite a bit of pain. They have tried pretty much everything that they can think of, including car rides, swings, swaddling, various types of soothing music (such as death metal), etc., but to no avail. Shivers run up and down your spine as you recall your own early parenting experiences ... or as you remember why you don't have kids (please apply the appropriate phrase for your personal experience).

Question 13.12.1 The most likely diagnosis is:

- A) Colic
- B) Intussusception
- C) Hair around the penis or toes or corneal abrasion
- D) Constipation
- E) Cluster headache

Answer 13.12.1 The correct answer is “A.” Colic generally begins at 3 weeks of age, peaks at about 6 weeks of age, and abates by 3 months of age. It is defined by a rule of 3s: intense crying for 3 hours per day, for 3 days per week, for 3 weeks. However, most parents, grandparents, nosy aunts, and pediatricians will describe any particularly fussy baby as “colicky.” The

cause is unknown. “B” is incorrect. While intussusception can certainly present with colicky abdominal pain, it is not likely to be recurrent for several days or weeks without a more significant problem (e.g., bloody stools) developing. “C,” a hair or thread around a child’s toes or penis or corneal abrasion, should be considered in any child with inconsolable crying. Again, this is not likely to result in crying that is daily and episodic. “D” is incorrect as this history is not consistent with constipation. And “E,” a cluster headache, does not occur in this age group.

**HELPFUL TIP:**

While inconsolable crying has often been attributed to a corneal abrasion, recent data calls this into question. Just as many children who were NOT crying had corneal abrasions.

Question 13.12.2 You can advise the parents that:

- A) Phenobarbital is safe and effective for controlling infant colic (when given to the parents to help them “chill out”)
- B) Elimination of cruciferous vegetables from the diet of breastfeeding mothers has been shown to reduce infant colic
- C) Simethicone has been shown to be effective in infant colic
- D) Anticholinergic drugs may be effective in treating infant colic, but the risks are unacceptable
- E) Children who breastfeed are less likely to develop colic

Answer 13.12.2 The correct answer is “D.” Anticholinergic drugs have been shown to be effective in the treatment of colic. However, the risks associated with the use of these drugs are generally considered unacceptable; thus, they should NOT be used for colic. The rest of the answers are incorrect. It does not seem as though breastfed infants are any less likely to develop colic than are bottle-fed infants (“E”). The evidence for elimination of cruciferous vegetables is inconclusive. Simethicone (“C”) is NOT effective in treating infantile colic and can be expensive, but it is not harmful and gives the parents something to do.

**HELPFUL TIP:**

The cause of colic is unknown and likely multifactorial. Rarely is a medical explanation found. **It is important to identify alternative caregivers, since infant colic can be a major stress on parents and can possibly lead to abuse (particularly shaken baby syndrome).** Parent education is critical.

**HELPFUL TIP:**

There is evidence to support a trial of an extensively hydrolyzed infant formula (e.g., Nutramigen) for infant colic. Data isn’t the strongest, though. Use of partially hydrolyzed or lactose-free formulas is of no benefit. Changing to a soy formula does not work.

**HELPFUL TIP:**

Data suggest that probiotics are *NOT* effective in infant colic (*BMJ*. 2014;348:g2107). However, they are safe and give the parents something to do. In breastfeeding women, elimination of common allergens (milk, eggs, nuts, wheat) can be tried. Again, the data isn’t the greatest. Evidence for spinal manipulation in treating colic is inconclusive and may carry risk. As with most chiropractic studies, the data is poor. In a crossover study, 24% sucrose has been shown to be beneficial (Tootsweet and other brands ... or make it yourself), but is not routinely recommended. Finally, though the data is poor, acupuncture is standard in Sweden (of course they also eat lutefisk).

► **Objective: Did you learn to ...**

- Evaluate a patient with colic and offer management strategies to the parents?

**QUICK QUIZ: EPIGLOTTITIS 1**

You have an anxious child in the ED who is toxic appearing with a history of sudden onset of high fever, drooling, and stridor. He is leaning forward, with his neck hyperextended, and chin thrust forward (tripod position). You suspect epiglottitis.

What is the FIRST step in the treatment of this patient?

- A) Draw blood work including a CBC
- B) Place an IV for access and fluids
- C) Give a dose of IM steroids (e.g., dexamethasone 0.6 mg/kg) to help shrink the epiglottis
- D) Put a face mask on the child and administer albuterol
- E) Leave the child on the mother’s lap and don’t upset the child (you don’t want a temper tantrum in the ED)

The correct answer is “E.” Anything that upsets the child can lead to increased airway obstruction. Leave the child in the parent’s lap and do not upset him. “A” and “B” are incorrect because they may upset the child, leading to increased work of breathing and increased obstruction. “C,” dexamethasone, is indicated for croup and not for epiglottitis. “D” is also incorrect. However, it would **not** be wrong to give blow-by oxygen or blow-by nebulized epinephrine **if it did not agitate the child.**

**QUICK QUIZ: EPIGLOTTITIS 2****Which of the following is NOT needed in the optimal diagnosis and treatment of epiglottitis?**

- A) “Thumb sign” on radiograph
- B) Antibiotics to cover *H. influenzae*
- C) Antibiotics to cover *S. pneumoniae*
- D) An operating room
- E) Personnel able to emergently manage the airway

The correct answer is “A.” The use of radiographs in suspected epiglottitis is fraught with problems and delays potentially life-saving therapy. DON’T DO IT. Epiglottitis is a clinical diagnosis that requires visualization of the epiglottis. This is preferably done in the operating room with a setup for both intubation and tracheostomy should that become necessary. If the child is mildly ill, looking at the epiglottis in the ED is permissible. However, be prepared to manage the airway. “B” and “C” are both correct. Since the advent of *H. influenzae B* vaccine, there is no longer a single organism causing most cases of epiglottitis. Bacteria that can cause epiglottitis include *H. influenzae*, *S. pneumoniae*, *S. aureus*, and groups A, B, and C beta-hemolytic streptococci. Epiglottitis may also be of viral origin.

QUICK QUIZ: NEONATAL INFECTIONS

What is the most likely etiologic agent in this child: 2-week-old male with conjunctivitis, cough, rales, nasal congestion, infiltrate on radiograph, but no fever or wheezes?

- A) Influenza
- B) *Chlamydia*
- C) Respiratory syncytial virus (RSV)
- D) Parainfluenza
- E) *Gonorrhea*

The correct answer is “B.” This is a classic description of *Chlamydia trachomatis* infection in the newborn. Patients usually present between 5 and 14 days with exudative conjunctivitis and pneumonia. The gold standard for diagnosis of neonatal *Chlamydia* infection remains a culture obtained from conjunctival swabs of the everted eyelids; however, nucleic acid amplification tests of conjunctival scrapings have been found to have high sensitivity and specificity when compared with culture. Conjunctival cells must be present for an adequate specimen because *Chlamydia* is an intracellular pathogen. Exudates are not adequate for testing. Treatment is with systemic antibiotics **even if conjunctivitis is the only symptom present**. A macrolide is the appropriate treatment. Erythromycin (50 mg/kg/day divided four times daily for 14 days) or azithromycin (20 mg/kg/day for 3 days) may be used. Topical treatment may be used as an adjunct but alone is not sufficient for treatment of this patient. *Remember, the antibiotic eye ointment applied to the neonate at birth protects against ocular gonococcal infection but not Chlamydia.*

▶ CASE 13.13

A 12-month-old presents to your office in January with a 2-day history of runny nose and cough. The child now has wheezing with nasal flaring and retractions, and his oxygen saturation is 89%. There has been no fever, and several of the other children and adults in the family have had “a cold” over the past several weeks. On examination, you hear scattered wheezes and rales. You diagnose bronchiolitis.

Question 13.13.1 The MOST LIKELY virus involved in this child’s illness is:

- A) Rhinovirus
- B) Adenovirus
- C) Respiratory syncytial virus (RSV)
- D) Parainfluenza
- E) Human metapneumovirus

Answer 13.13.1 The correct answer is “C.” The most common cause of bronchiolitis in children is RSV. All of the others can also cause bronchiolitis, as can influenza virus, but less commonly than RSV.

Question 13.13.2 Which of the following treatments has been unequivocally shown to be effective in bronchiolitis?

- A) Nebulized albuterol
- B) Nebulized epinephrine
- C) Corticosteroids such as prednisone or dexamethasone
- D) All of the above
- E) None of the above

Answer 13.13.2 The correct answer is “E.” None of the above has been shown to be effective in bronchiolitis. The mainstay of treatment is supportive care. Albuterol may transiently worsen hypoxia due to induction of V/Q mismatch and is not recommended.

HELPFUL TIP:

Hypertonic saline was previously used in hospitalized infants and children as a treatment for bronchiolitis. It is no longer routinely recommended; it did not change duration of illness or hospitalization. Supportive care (maintenance of oxygenation and hydration) remains the mainstay of treatment.

Question 13.13.3 RSV is usually diagnosed by:

- A) Nasal wash using immunofluorescence, antigen detection, or PCR
- B) Baseline and convalescent antibody titers
- C) Blood culture for RSV
- D) Sputum Gram stain
- E) Induced sputum culture

Answer 13.13.3 The correct answer is “A.” A nasal wash for RSV immunofluorescence, antigen detection, or PCR is used to diagnose RSV. If a nasal wash cannot be obtained, a nasopharyngeal swab or throat swab offers the next best alternative. RT-PCR assays are becoming more cost-effective. Thus, they are being increasingly utilized as the first-line test at some institutions. Keep in mind that doing viral testing for children with bronchiolitis is **not** routinely recommended. In general, knowing which virus is causing the illness will not change management. Influenza testing may be useful at times of high prevalence in the community, as use of oseltamivir may be indicated. The other options are incorrect. Remember that “respiratory panels” can cost upwards of several hundred dollars.

**HELPFUL TIP:**

Bronchiolitis is a clinical diagnosis that does not require any diagnostic testing. Routine use of chest x-rays, CBCs, and viral testing is not recommended.

**HELPFUL TIP:**

Never give aerosolized ribavirin for the treatment of RSV. It doesn't work.

Question 13.13.4 Which of the following is indicated for the prevention of RSV in high-risk infants?

- A) Vaccination against RSV
- B) Oral ribavirin
- C) Rimantadine or oseltamivir
- D) Palivizumab (Synagis®)
- E) RSV-IVIG (RespiGam)

Answer 13.13.4 The correct answer is “D.” Palivizumab is a licensed prophylactic monoclonal antibody against RSV that is given via monthly intramuscular injection to high-risk patient populations during the RSV season. Administration of palivizumab is recommended before RSV season begins and then is given monthly for a maximum of five doses. RSV-IGIV, or RespiGam, is no longer used. There is no current RSV vaccine. None of the antiviral medications (“B” and “C”) works for prevention or treatment of RSV.

**HELPFUL TIP:**

The following are the criteria for palivizumab:

- First year of life if born before 29 weeks, 0 day gestation.
- First year of life for infants born before 32 weeks, 0 day gestation with chronic lung disease of prematurity requiring oxygen for at least 28 days after birth.
- First year of life if cyanotic or hemodynamically significant heart disease.
- Second year of life if still requiring at least 28 days of oxygen and needing interventions such as steroids, diuretics, etc.
- Consider for immunosuppressed infants <24 months of age who will be immunosuppressed during RSV season.
- Keep abreast of RSV in your state; each state has specific rules for when Medicaid will cover palivizumab.

► **Objectives: Did you learn to ...**

- Recognize the clinical presentation of a patient with RSV bronchiolitis?
- Diagnose and treat RSV bronchiolitis?
- Describe what patients may possibly benefit from RSV prophylaxis?

► **CASE 13.14**

A 4-week-old infant presents to your office with his parents. The parents note that he vomits every time he eats. His vomitus is mostly formula and is always nonbilious. He seems to be hungry and is demanding to be fed often. He does not have diarrhea. Examination reveals an afebrile and moderately dehydrated infant in no distress with tachycardia, a normal cardiopulmonary examination, and a relatively benign abdomen. His weight today is unchanged from a weight taken in your office 2 weeks ago. There is no “olive” palpable (really, have any of you actually felt the “olive”)?

Question 13.14.1 Your working diagnosis is:

- A) Midgut volvulus
- B) Gastroenteritis
- C) Pyloric stenosis
- D) CNS injury with increased intracranial pressure

Answer 13.14.1 The correct answer is “C.” This most likely represents idiopathic hypertrophic pyloric stenosis. The classic presentation of pyloric stenosis is nonbilious vomiting immediately after feeding, followed by a demand to feed again soon after (much the same as a teenager ... the demand of feeding, not the vomiting). The symptoms are progressive. Initially, the vomiting may or may not be projectile and may occur after every feed or intermittently. Classically, pyloric stenosis occurs in infants 2 weeks to 2 months of age. Patients with prolonged symptoms are likely to have a hypokalemic hypochloremic metabolic alkalosis. “A,” midgut volvulus, a surgical emergency, is unlikely because these patients have *bilious* vomiting. Our patient has nonbilious vomiting. “B,” gastroenteritis, is not likely because there is no diarrhea, fever, or appetite loss. “D” is unlikely. While CNS injury with increased intracranial pressure and vomiting is a possibility, you would expect to see other evidence of CNS injury such as lethargy, possibly signs of head injury, etc. Note that this patient’s weight is unchanged from 2 weeks ago, but it should be higher than 2 weeks ago.

Question 13.14.2 Which of the following patients is most likely to present with pyloric stenosis?

- A) A first-born male
- B) A first-born female
- C) A second-born male
- D) A second-born female
- E) The rate of pyloric stenosis is equal in all of these groups

Answer 13.14.2 The correct answer is “A.” There is a 4:1 male:female preponderance, and about 30% of all cases occur in a first-born child. Family history is important as infants born to a mother or father who had pyloric stenosis are at increased risk.

You give the patient a bolus of IV normal saline and decide to proceed with imaging to confirm the diagnosis.

Question 13.14.3 Of the following, which is the MOST appropriate initial study to assess for pyloric stenosis?

- A) Plain abdominal x-ray
- B) Upper endoscopy
- C) Abdominal ultrasound
- D) Upper gastrointestinal (UGI) contrast study
- E) Abdominal CT
